   c. Vegetable matter

   d. **Disk batteries**

2. Which of the following is not a safe technique for removing a disk battery?

   a. Using suction in a dry ear to create a seal between the tip of the suction and the battery

   b. **Applying hydrogen peroxide in an attempt to get the battery to dislodge**

   c. Gently passing a right-angled hook behind the battery in an attempt to lateralize it

   d. Passing a strong magnet in the meatus of the external auditory canal

3. Which of the following is true?

   a. A living insect within the external auditory canal can be extracted the following day.

   b. One should never use irrigation in extracting vegetable matter.

   c. If a foreign body easily enters the external auditory canal, it will typically fall out on its own.

d. **Beads are the most common type of jewelry item to enter the external auditory canal in a child.**

Osteomas and Exostoses of the External Auditory Canal

Michele Hargreaves

Introduction

Osteomas and exostoses are benign bone growths found in the temporal bone, most commonly in the bony external auditory canal (EAC). The structure of the EAC takes a tortuous route from the external auditory meatus to the tympanic membrane (TM), through the cartilaginous lateral third to the medial bony two-thirds.

The S-shaped structure of the canal provides a protective mechanism to the TM. The function of the EAC serves not only to protect the TM, but it also conducts sound to the TM and middle ear. In conjunction with the concha, the EAC amplifies sound from 5 to 20 dB from the free field to the TM due to the resonance of both structures. Occlusion of the EAC, whether congenital or acquired, causes conductive hearing loss.

The EAC is normally self-cleansing due to the epithelial migration from the surface of the TM to the EAC. Unimpeded epithelial migration acts similar to a conveyor belt to carry cerumen and desquamated epithelial cells out to the lateral aspect of the canal, where this debris can easily be removed. Lesions that cause partial or complete occlusion of the EAC can impede epithelial migration, leading to an accumulation of cerumen and/or epithelial debris medial to the lesion. This can trigger recurrent episodes of acute otitis externa (OE) as the skin of the EAC becomes inflamed. Conductive hearing loss can also develop due to of impaction of debris if the debris is made inaccessible for cleaning by the presence of these bony growths.

Exostoses are bilateral, lamellar outgrowths of the bone of the medial EAC, typically triggered by reactive hyperemia of the EAC skin

following exposure to cold water (Fig. 127.1). Reactive hyperemia is seen following the initial vasoconstriction that occurs with cold exposure and is a hallmark of first-degree frostbite injury. The hyperemia reflects the attempt of the tissue to protect from further thermal injury due to recurrent exposure to cold water. The condition was originally described as "surfer's ear" and is commonly seen in cold water surfers, kayakers, divers, and swimmers. There is a male predilection. Formation of the exostoses occurs in a time-dependent fashion, with a greater degree of EAC occlusion seen with longer durations of exposure and increasing age. Exostoses can develop along the anterior, posterior, and superior bony EAC, with anterior and posterior exostoses commonly exhibiting a sessile structure.[1]

Osteomas are relatively rare when compared with exostoses. These are solitary, unilateral bone lesions located more laterally in the bony EAC, often pedicled to the tympanosquamous or tympanomastoid suture line. Osteomas are considered true neoplasms of bone (Fig. 127.2).[1]

Treatment of osteomas and exostoses is symptom dependent. Most patients with osteomas or exostoses are diagnosed incidentally on routine examination of the ear. If the degree of EAC occlusion is less than 80%, most patients require either no treatment or conservative management with periodic débridement of the EAC to prevent cerumen impaction, OE, or conductive hearing loss.[2] Use of earplugs when exposed to cold water may slow progression of the disease in the case of exostoses.

Surgical treatment should be reserved for symptomatic patients, including patients who develop frequent OE and/or frequent cerumen impactions causing hearing loss, patients who desire a more permanent treatment to avoid the need for repeated débridement, and patients in whom the EAC has become completely occluded.[3] The latter condition requires surgical treatment due not only to the resulting conductive hearing loss, but these patients are also at risk for cholesteatoma formation and its complications in the medial EAC due to trapped epithelial debris.

Key Operative Learning Points

1. Reserve surgical treatment for symptomatic patients.

2. Structures at risk for injury include the tympanic membrane, ossicular chain, temporomandibular joint (TMJ) anteriorly, and the facial nerve posteroinferiorly.

3. Surgery is most commonly performed with a high-speed otologic drill, but the use of osteotomes can be considered as an alternative.

4. Preservation of medially based skin flaps provides more rapid healing and a reduced risk of soft tissue stenosis postoperatively.

Preoperative Period

History

1. History of present illness

   a. Question the patient regarding the presence of frequent cerumen impactions, OE, or persistent hearing loss.

   b. A careful history should be taken to elicit symptoms related to obstruction of the EAC, such as the need for frequent débridement of the impactions, frequent pain or otorrhea suggesting recurrent OE, and frequent or persistent hearing loss. An attempt should be made to determine the frequency and severity of symptoms and how bothersome they are to the patient.

   c. Question the patient regarding prior treatment and willingness to return for periodic ear cleaning.

   d. Determine how frequently the patient has required treatment for OE or removal of impacted cerumen, if at all. Patients in whom OE and/or cerumen impactions are occurring very often should be offered surgical treatment as an option. Also, if it is highly impractical for a patient to return for periodic ear cleaning as a form of conservative management, this is also an indication for surgical therapy.

   e. The patient should be questioned regarding participation in water sports.

   f. If the patient is an active participant in cold water sports, the patient should be counseled regarding the use of ear plugs to help slow the

progression of existing exostoses and to help prevent recurrence postoperatively.

2. Past medical history

   a. Need for prior treatment with débridement of cerumen and/or ototopical drops for OE

   b. Medical illness, including any contraindications to general anesthesia

   c. Prior surgical history, with attention to any prior ear surgery

   d. Family history, including any reactions to anesthesia

   e. Medications, including anticoagulants or antiplatelet drugs

FIG. 127.1 View of the right external auditory canal revealing multiple broad-based exostoses located medially near the tympanic membrane.

FIG. 127.2 Excised osteoma of the external auditory canal with its narrow pedicle located on the right side of the bony tumor.

Physical Examination

1. Binocular microscopic examination of the ears

Binocular microscopy should be performed to determine the location and extent of any exostoses or osteoma present. Attention should be paid to the percentage of obstruction of a cross section of the EAC caused by the lesions. Additionally, binocular microscopy enables the surgeon to determine whether the ear may be adequately cleaned in its present state or whether there are locations medially, anteriorly, or posteriorly that are inaccessible and therefore at risk for cholesteatoma formation or persistent trapped debris.

2. Otologic endoscopy

This can be performed as an adjunct to binocular microscopy to assess the medial EAC for trapped debris and to determine the medial extent of exostoses or osteoma, if not visible due to severe stenosis.

3. Audiometry and tuning fork testing

Tuning fork testing should be performed on all patients to screen for a

conductive hearing loss. A full audiogram with tympanometry and acoustic reflex testing should be performed preoperatively on all surgical candidates to assess the type and degree of any pre-existing hearing loss and to counsel the patient on expected improvement following surgery. Audiometry may also document a pre-existing high frequency sensorineural hearing loss (SNHL). As high frequency SNHL can be a surgical complication due to noise exposure from the high-speed drill and/or contact with the ossicular chain, any pre-existing SNHL must be documented for patient counseling and medicolegal purposes.

4. Head and neck examination

A full otolaryngologic examination should be performed to ensure there are no other factors that could potentially impact the decision for surgery, including the presence of a difficult airway or craniofacial anomalies that could portend an aberrant anterior course of the facial nerve.

Imaging

Computed Tomography

A high-resolution temporal bone computed tomography (CT) should be obtained preoperatively in cases of osteoma extensive enough to prevent visualization of the medial EAC (Fig. 127.3). The CT confirms the diagnosis, evaluates for possible medial cholesteatoma, and determines the location and width of the pedicle. Osteomas have the appearance of a well-circumscribed bony lesion pedicled at the tympanosquamous or tympanomastoid suture line, slightly hypodense compared to cortical bone of the mastoid. The location of the pedicle is usually readily identified to allow for surgical planning (Fig. 127.4).

In cases of severe exostoses with near complete or complete closure of the EAC, temporal bone CT should also be performed to evaluate for the presence of a cholesteatoma medially that would need to be addressed surgically. The preoperative CT can also indicate the medial extent of the exostoses, as the growths can abut the TM, requiring special care during removal to avoid trauma to the TM.

Indications

1. Complete or near complete occlusion of the EAC, causing accumulation of epithelium that cannot be débrided in the office

2. Persistent conductive hearing loss caused by occlusion of the EAC or by persistent entrapment of cerumen or epithelial debris

3. Recurrent acute OE poorly controlled with medical management, particularly if reactive soft tissue stenosis is noted

4. Frequent cerumen impactions requiring an unacceptably high number of office visits for treatment

Contraindications

1. Medical comorbidities that put the patient at an unacceptably high risk of general anesthesia

Surgery for exostoses frequently requires a postauricular approach and is typically performed under general anesthesia, which may be contraindicated in the case of severe cardiopulmonary disease. Surgical removal of a single osteoma, particularly if on a narrow pedicle, is often possible under local anesthesia.

FIG. 127.3 Right external auditory canal with a posteriorly based osteoma *(O)* obstructing complete examination of

the medial canal and tympanic membrane. *P*, Posterior.

2. Active OE

Attempts should be undertaken prior to surgery to eradicate or maximize control of any OE present in the operated ear. Active OE at the time of surgery can increase the risk for cellulitis and exuberant granulation tissue during the healing process, which can lead to soft tissue stenosis of the EAC.

Preoperative Preparation

1. Discontinue any anticoagulants/antiplatelet medications for at least 7 days preoperatively if possible or as directed by the prescribing physician.

2. Treat any active or ongoing OE with ototopical antibiotics until the time of surgery.

3. Evaluate preoperative imaging, if obtained, to help determine the surgical approach and type of anesthesia to be used.

Operative Period

Anesthesia

General

For removal of exostoses, a postauricular approach is frequently required. In this case, general anesthesia is recommended to prevent pain and to avoid patient discomfort due to the noise of the otologic drill.

Local With/Without Sedation

For select osteomas that are laterally based with a very narrow pedicle, removal can be accomplished under local anesthesia via a transcanal approach. Sedation can be added based on patient preference.

Positioning

Supine

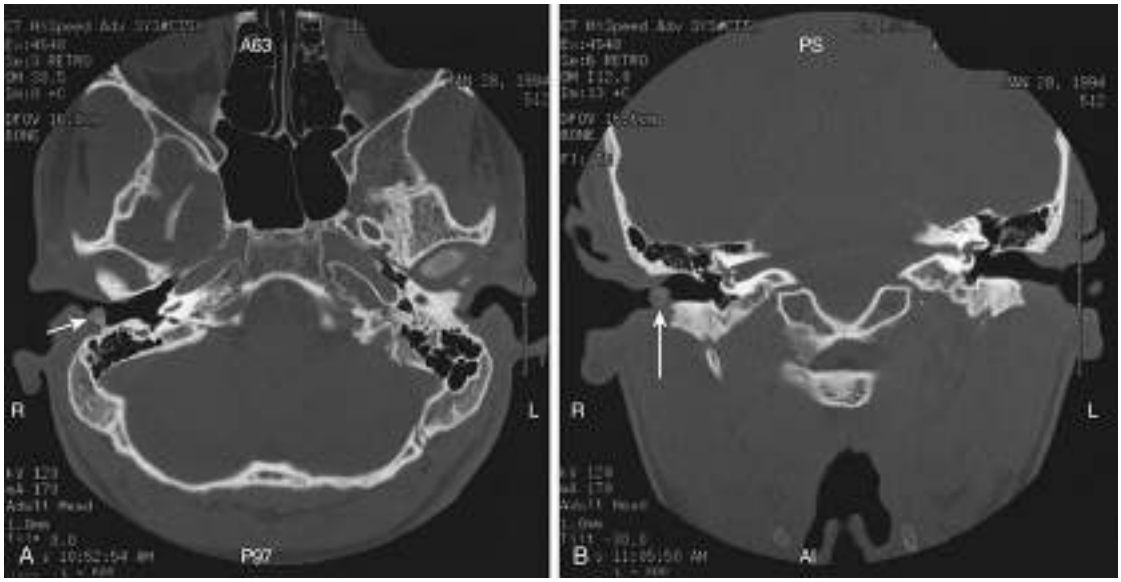

FIG. 127.4 Axial, **A,** and coronal, **B,** bone-windowed computed tomography images demonstrating a pedunculated attachment to the lateral posterior canal wall *(arrows)*. The remaining external auditory canal and middle and inner ear are normal.

The patient's head should be positioned on a foam "doughnut," turned partially toward the nonoperative ear. Ensure that the contralateral pinna is not compressed during positioning.

Perioperative Antibiotic Prophylaxis

None necessary

Perioperative antibiotic prophylaxis is not necessary unless the ear is actively infected at the time of surgery. If this is the case, then a preoperative intravenous dose of an anti-pseudomonal penicillin or cephalosporin is recommended.

Monitoring

Electromyography (EMG)

Using a facial nerve monitor should be strongly considered during surgery for exostoses or osteoma. The facial nerve frequently courses lateral to the tympanic annulus in the postero-inferior bony EAC and can be injured during surgery.[4]

Instruments and Equipment to Have Available

1. Operating microscope

2. Standard middle ear/mastoid instrument

3. High-speed otologic drill, with 3, 2, and 1 mm extended length fluted ball or coarse diamond burs for bone removal and fine diamond burs for polishing

4. Suction irrigation system

5. Facial nerve monitor

6. Silastic sheeting and/or sterile foil suture packs to protect critical structures during drilling

7. #10 blade and scalpel in case a split-thickness skin graft is needed

8. Optional: 1–3 mm straight and curved osteotomes and mallet

9. Optional: otologic endoscope

Key Anatomic Landmarks

1. Tympanic annulus: demarcates the medial extent of dissection if exostoses extend up to the TM

2. TMJ: The TMJ is located just anterior to the bony EAC, approximately halfway between the bony-cartilaginous junction and the anterior annulus. Care must be taken to avoid entry into the soft tissues of the TMJ when drilling along the anterior wall of the EAC.

3. Facial nerve: The facial nerve courses lateral to the tympanic annulus

in the posterior-inferior bony EAC in approximately 70% of patients. The distance between the annulus and the vertical segment of the nerve ranges from 2 to 5 mm. In some patients, the facial nerve is located anterior to the most posterior point of the annulus as well. There are no external landmarks within the EAC to identify the course of the facial nerve, so care must be taken during bone removal in the posteroinferior EAC.

4. Short process of the malleus: Avoid contacting the malleus with the otologic drill to prevent conductive or sensorineural hearing loss.

5. Posterior wall of the EAC: Care must be taken not to extend the dissection too deeply along the posterior wall of the EAC, lest entry to the mastoid air cells occurs.

Prerequisite Skills

1. Proficiency in otologic surgery

2. Proficiency with the high-speed otologic drill

3. Familiarity with the structure and landmarks of the EAC

4. Familiarity with the postauricular, transcanal, and endaural approaches

Operative Risks

1. Inadequate bone removal

2. Soft tissue stenosis of the EAC

3. Injury to the TM

4. Conductive hearing loss

5. Sensorineural hearing loss

6. Mastoid fistula

7. TMJ violation and dysfunction

8. Facial nerve injury

Surgical Technique

1. Place facial nerve monitor electrodes prior to sterile preparation. Prep and drape the patient as for routine otologic surgery.

2. Perform four quadrant canal injections with xylocaine with epinephrine for vasoconstriction.

3. Determine the surgical approach to be used: Endaural or transcanal approaches are appropriate for a single, laterally based osteoma, whereas a postauricular approach is more appropriate for extensive medial exostoses.

4. Perform the postauricular approach in the standard fashion, creating a laterally based Koerner's flap via a posterior vertical incision in the lateral bony EAC with lateral releasing incisions at 6 and 12 o'clock (Fig. 127.5). As the individual anatomy of each patient, as well as surgeons' individual preferences, impact the exact location of the Koerner's flap incisions and postauricular incisions, more exact details would not be appropriate as exact positioning of the incisions is best left to the surgeon's discretion at the time of surgery. This provides a general outline of appropriate incisions. Back elevate the Koerner's flap and then create a postauricular incision, and connect the two incisions. Retract the auricle anteriorly using a Penrose drain or twill (tracheotomy) tape and place self-retaining retractors (Fig. 127.6).

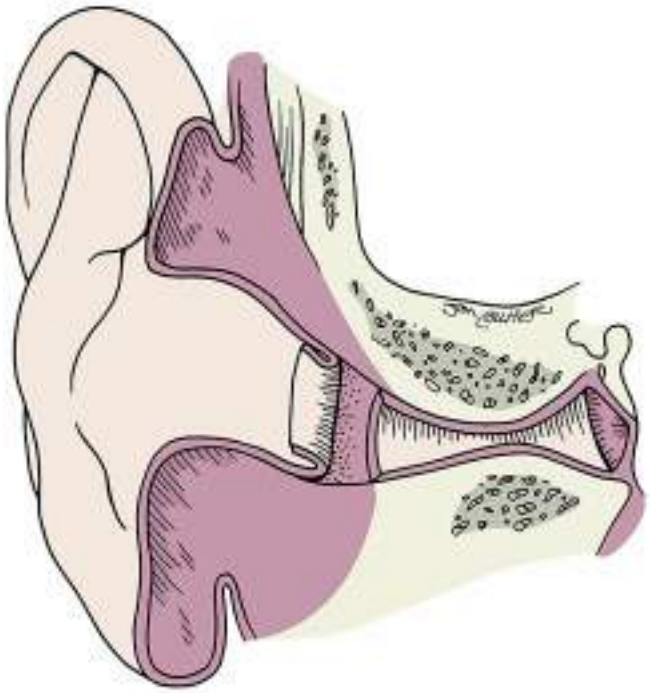

FIG. 127.5 Through the external auditory meatus, a Koerner's (conchal) flap is incised and back elevated. Note the narrowed bony canal medially.

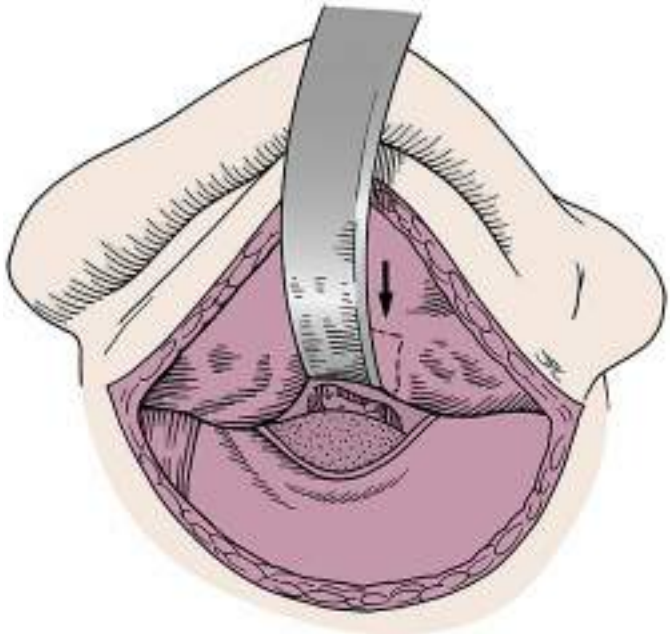

FIG. 127.6 A postauricular incision has been made, and a tracheostomy tape is placed to evert the Koerner's flap within the canal *(arrow).* A self-retaining retractor (not

shown) provides the necessary exposure.

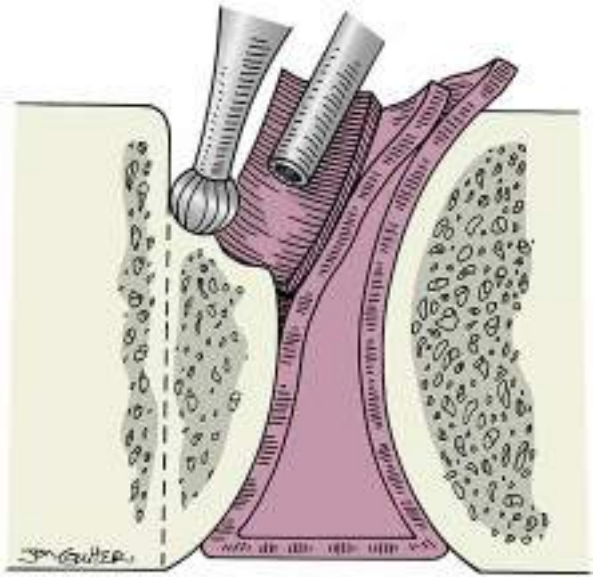

FIG. 127.7 Beginning laterally, the posterior canal wall skin is elevated and protected with a sheet of suture pack foil or Silastic. The suction tip is used to retract the skin and maintain a clean surgical field. The bony exostosis is drilled to contour the canal.

5. For exostoses: Create medially based skin flaps around each exostosis to be removed. For the posterior exostosis, the same circumferential incision should be used as for the Koerner's flap. Separate circumferential incisions should be made for anterior exostoses. Vertical releasing incisions are then made, and the skin is elevated medially. Skin flaps should be folded over the TM and protected with Silastic sheeting or foil cut from a sterile suture pack (Fig. 127.7).

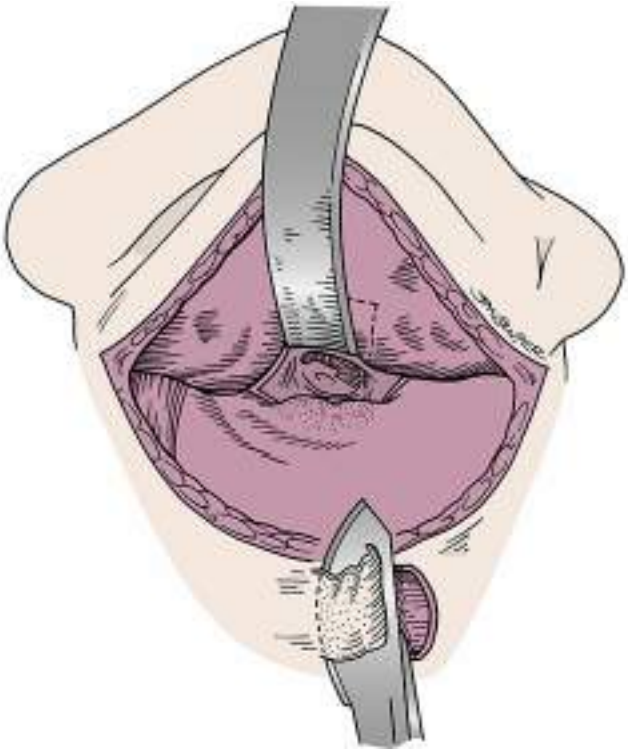

FIG. 127.8 Excessive loss of canal skin should be replaced. A freehand split-thickness Thiersch graft is harvested from the postauricular skin overlying the mastoid.

6. For exostoses: Remove the exostoses in a lateral to medial fashion using a high-speed otologic drill with 3, 2, and 1 mm coarse and fine diamond burs and copious irrigation. Care must be taken when drilling along the scutum to avoid entry into the attic and trauma to the ossicular chain. Avoid contact with the short (lateral) process of the malleus as well. Avoid entry into the TMJ anteriorly; if the periosteum of the glenoid fossa is seen, avoid further dissection in this area. Use caution when drilling in the posterior inferior bony EAC, as the vertical segment of the facial nerve is often lateral to the annulus in this location. It may be necessary to use a 1-mm chisel and osteotome to remove exostoses that extend to the annulus or excavate under a thin lip of bone and then gently fracture it away from its connection near the annulus.

7. Take care to preserve the skin flaps. If the skin flaps are intact, they may be laid back in anatomic position without the need for free skin grafts. If the skin flaps have been damaged, a free Thiersch skin graft may be harvested from the postauricular region using a #10 blade,

trimmed, and placed in denuded regions of the EAC (Fig. 127.8).

8. If no free skin grafts were required, the EAC may be packed with Gelfoam soaked in ototopical antibiotic solution. If free skin grafts were required, lateral and medial rosebud packing should be placed in the EAC to avoid soft tissue stenosis during the healing process (Fig. 127.9).

9. For osteomas: Many osteomas that are based on a narrow pedicle can be removed with a bone curette via a transcanal or endaural approach (Fig. 127.10). For a broad-based osteoma, a skin flap should be elevated and preserved as for removal of exostoses (Fig. 127.11A and B). The bone pedicle can then be smoothed with a high-speed drill and coarse diamond burs so it is level with surrounding bone. If only a small area of skin is denuded, it can be left to heal by secondary intention. Skin flaps are replaced and held in position with Gelfoam or a silk strip (see Fig. 127.11C).

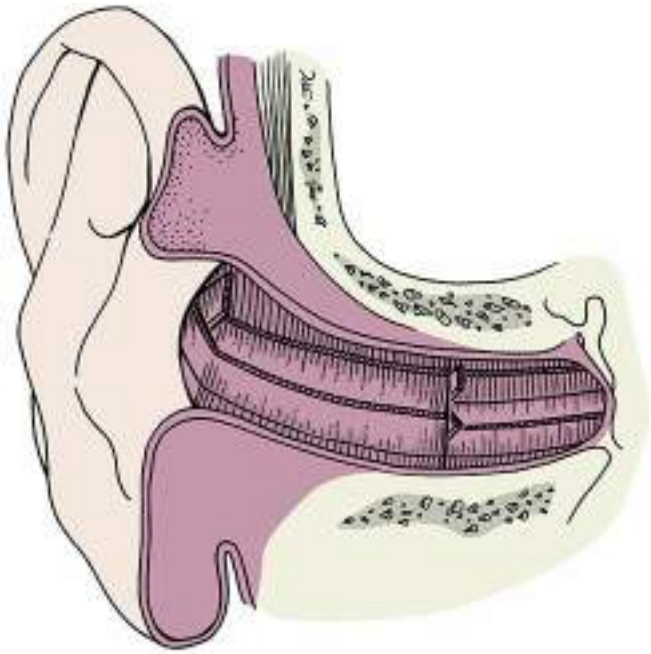

FIG. 127.9 Double-rosebud packing is used to secure skin that was replaced in sections.

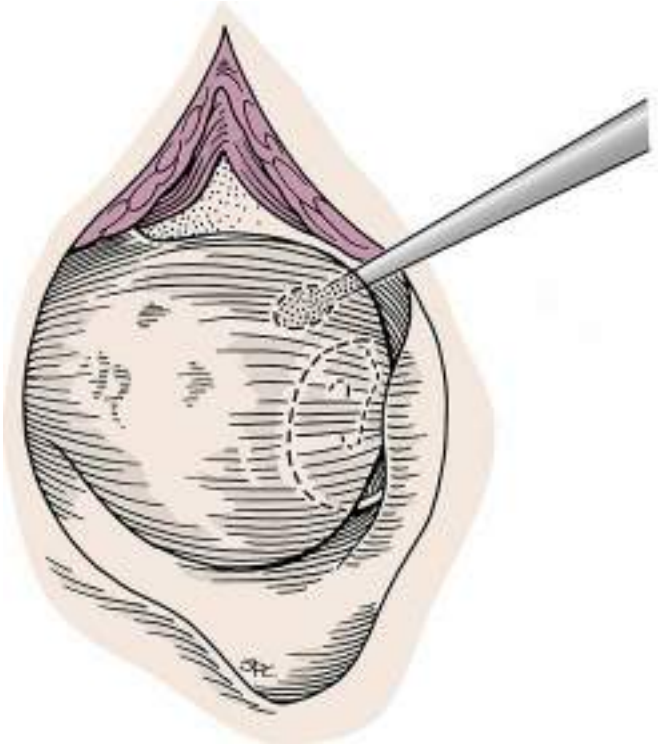

FIG. 127.10 An incision made in the incisura widens the aperture to the external auditory meatus. A curette is positioned medial to the osteoma in preparation for removal. The tympanic membrane is ghosted in.

Common Errors in Technique

1. Failure to preserve adequate skin flaps during drilling, leaving large areas of the bony EAC denuded

2. Failure to protect medially based skin flaps and the TM using Silastic sheeting or foil trimmed from a suture pack

3. Attempting a transcanal approach for extensive exostoses, limiting visualization during drilling

4. Overly aggressive drilling along the anterior, posterior, or superior EAC, resulting in complications described above

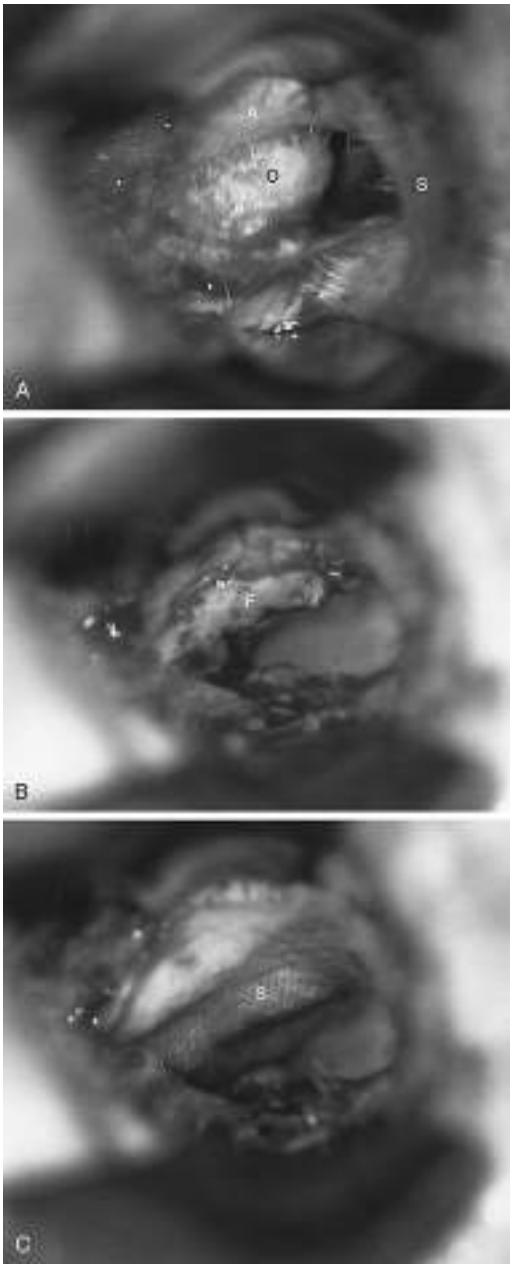

FIG. 127.11 **A,** Broad-based osteoma *(O)* of the left ear located on the anterior external auditory canal wall. *A,* Anterior; *S,* superior. **B,** A skin flap *(F)* based medially was created and returned to cover the exposed bone. **C,** A strip of silk *(S)* is positioned on the anterior canal wall to secure the skin flap.

5. Inadequate irrigation, causing thermal injury to the underlying bone

Postoperative Period

Postoperative Management

1. Initiate antibiotic ototopical drops twice a day (BID), beginning on the day of surgery.

2. Provide adequate postoperative pain control with oral narcotic analgesics if necessary.

3. If a postauricular incision was made, it should be kept dry for 1 week. Thereafter, the patient may shower/bath as usual, keeping the EAC dry by placing a cotton ball covered in Vaseline in the conchal bowl.

4. The first postoperative visit should occur at 7 to 10 days, at which time, packing may be removed if free skin grafts were not placed. Packing should remain in place for 14 days if free skin grafts were used to supplement pedicled skin flaps.

5. Observe for granulation tissue or hypertrophic scar formation. Granulation tissue can be treated with topical silver nitrate, and hypertrophic scarring in the EAC can be treated with corticosteroid injections. Vigilance is necessary to prevent soft tissue stenosis if these conditions arise. The patient should be seen weekly, and a Merocel stent should be kept in the ear canal until full epithelialization has occurred.

6. Once full healing of the EAC has occurred, the patient may discontinue dry ear precautions and resume water sports activities. Use of earplugs may prevent recurrence of exostoses.

7. After full healing has occurred, a postoperative audiogram should be performed to document any improvement in conductive hearing loss and assess for any new sensorineural hearing loss.

Complications

1. Inadequate bone removal

Failure to fully remove exostoses can lead to early recurrence. In addition, if a bony lip remains medially, the patient may experience a recurrence of symptoms due to persistent trapped debris or conductive hearing loss from contact between the bone and TM.

2. Soft tissue stenosis of the EAC

If a significant surface area of the EAC is denuded or if extensive free split-thickness skin grafts are required, soft tissue stenosis of the EAC can develop during the healing process. This can be managed as described above using silver nitrate cautery, corticosteroid injections, and/or stenting of the EAC during the healing process. Late soft tissue stenosis may require revision surgery.

3. Injury to the TM

The annulus can be avulsed during medial drilling. The TM can also be torn by the drill directly or by rotating and removing segments of bone detached by fracturing with an osteotome. Risk can be minimized with awareness of surgical landmarks and by protecting the TM with a layer of Silastic sheeting or foil trimmed from a sterile suture pack. Small tears in the TM can be medially supported with Gelfoam and usually heal spontaneously. Large tears should be repaired at the time of surgery.

4. Conductive hearing loss

Disruption of the ossicular chain due to overly aggressive drilling along the scutum and entry into the attic may occur. Care must be taken when drilling along the postero-superior EAC not to enter the attic or contact the short process of the malleus.

5. Sensorineural hearing loss

Noise-induced hearing loss from the high-speed otologic drill may occur. This can be due to sound transmission through contact with the short process of the malleus but can occur in the absence of contact with the ossicular chain. Short breaks from drilling will likely reduce the incidence of noise-induced hearing loss. New SNHL in the immediate postoperative period can be treated with high-dose corticosteroids.

6. Mastoid fistula

Overly aggressive drilling along the posterior bony EAC can cause entry into the mastoid air cell system. If not recognized and repaired, this can eventually lead to cholesteatoma formation if epithelium migrates into the mastoid.

7. TMJ dysfunction

Drilling along the anterior EAC can cause disruption of the soft tissues of the TMJ if the inner periosteum of the glenoid fossa is violated. This

can cause prolapse of the soft tissues of the TMJ into the EAC, TMJ pain, TMJ dysfunction, and/or popping or clicking sounds in the ear with jaw movement.

8. Facial nerve injury

Drilling along the posterior inferior EAC can cause inadvertent injury to the vertical segment of the facial nerve while it occasionally courses lateral to the annulus. Caution must be taken when using the drill or osteotome in this location. Copious irrigation should be used to avoid thermal injury to the nerve. If facial stimulation occurs on EMG monitoring, dissection should cease immediately. Management of facial nerve paresis or paralysis should follow the same principles as for iatrogenic injury during any otologic procedure.

Alternative Management Plans

1. Nonsurgical management: appropriate for osteomas or exostoses that are not fully occluding the EAC and that allow for full débridement of the EAC in the office with the use of a binocular microscope. The patient may be seen periodically for débridement to prevent medial entrapment of cerumen or epithelial cells causing conductive hearing loss and to prevent OE due to resulting irritation of the EAC skin.

2. Alternative surgical techniques have been espoused, such as limiting bone removal to the anterior wall of the EAC in the case of exostoses or use of osteotomes for exostosis removal.[5] Rationale for limiting drilling to the posterior inferior wall of the EAC includes a significantly lower risk of facial nerve injury, and some authors note that the goals of a patent EAC, resolution of conductive hearing loss, and access for débridement in office can be met by removing anterior exostoses only. Rationale for use of osteotomes instead of the otologic drill includes lower risk of sensorineural hearing loss, less damage to pedicled skin flaps, and potentially lower risk to the facial nerve. An endoscopic approach may also be undertaken to visualize the medial limits of exostoses and help guide osteotome placement.

Discussion

Evidence-Based Medicine Question

Does removal of EAC exostoses and osteomas improve patient quality of life?

A recent retrospective study sought to assess patients' health related quality of life following surgery for exostoses and osteoma.[6] The motivation for this review was the relatively high complication rates cited in the medical literature coupled with relatively low reported rates of symptom relief. Thirty-nine patients undergoing surgery for exostoses or osteomas were retrospectively reviewed using the Glasgow Benefit Inventory. The majority of the patients were male, with an average age of 50. The majority suffered from exostoses, and preoperative complaints included hearing loss, cerumen impactions, and recurrent OE.

In addition, 76.9% of the patients returned the survey, and 83.3% of the patients surveyed received quality of life benefit from the surgery. Ninety percent of the patients were satisfied with their postoperative outcome. Also, 70% of patients were asymptomatic following surgery. Only three patients indicated dissatisfaction with the surgical outcome; in all three cases, the patients had suffered complications. Two of the three complications involved damage to the inner ear with or without tinnitus. The authors concluded that surgery for exostoses and osteomas improves patients' quality of life in most cases with the caveat that only symptomatic patients should be surgical candidates. The authors also cautioned that surgical complications are the most significant contributing factor to patients' dissatisfaction with postoperative outcomes.

Editorial Comment

Bony obstruction of the external ear canal can result in cerumen impaction which may lead to recurrent OE, conductive hearing loss, and medial entrapment of cholesteatoma. Asymptomatic subtotal occlusion does not require surgical intervention. Physical examination of the ear canal, with an operating microscope, provides a preliminary assessment or the status of the EAC. Bone lesions located laterally giving the impression of having a narrowed pedicle are suggestive of osteoma. These are typically amenable to transcanal removal with a curette or

osteotome. CT imaging should still be obtained to confirm the location and origin of the lesion and to determine whether additional disease is present in the medial canal. The CT scan also provides information as to the relationship of the glenoid fossa anteriorly and the course of the vertical portion of the facial nerve and aeration of the mastoid near the ear canal posteriorly.

It is also common to see partial bone obstruction of the EAC in patients having concomitant pathology such as chronic otitis media, TM perforation, or conductive hearing loss. If access to the TM is limited, a staged approach to the TM or middle ear may be warranted. Correction of the obstruction of the EAC is undertaken as the principle procedure before addressing problems such as otosclerosis.

Meticulous attention to preserving the native skin of the EAC reduces the likelihood of healing problems such as the development of granulation tissue in the canal and subsequent stenosis. The surgeon must decide if exposed bone can be covered with a temporalis fascia graft or needs a split-thickness (Thiersch) graft.

The surgeon must also be vigilant in the postoperative period in looking for problems of healing. Small area of granulation tissue can be cauterized with silver nitrate. Larger areas should be stented with a wick and monitored on a weekly basis. On occasion, the patient may need to return to the operation room for débridement, skin grafting, or replacement of conforming packing.

The author has nicely summarized the process of assessment, diagnosis, planning, execution, and postoperative management. All are important steps in achieving success in correcting this pathology.

Review Questions

1. What surgical techniques can safely be used to remove osteomas and/or exostoses?

   a. High-speed otologic drill

   b. 1- to 3-mm osteotomes

c. Bone curette

d. **All of the above**

2. Where is the facial nerve most at risk when removing bone from the EAC?

a. Anterior superior

b. Anterior inferior

c. Posterior superior

d. **Posterior inferior**

3. What structure lies immediately anterior to the anterior bony EAC at its midpoint and can be injured during bone removal?

a. Facial nerve

b. Temporomandibular joint

c. Parotid gland

d. **Tympanic annulus**

4. Which of the following is not a surgical indication for removal of exostoses/osteoma?

a. Persistent conductive hearing loss

b. Medial canal cholesteatoma

c. Recurrent OE

d. **Cerumen impaction once a year**

Keratosis Obturans and Canal Cholesteatoma

Yu-Lan Mary Ying

Introduction

Keratosis obturans (KO) and external auditory canal cholesteatomas (CC) are uncommon diseases of the external auditory canal that share the common characteristic of a buildup of desquamated keratin in the ear canal. Since the 19th century, KO and CC have been considered variants of the same disease until 1980, when Piepergerdes et al. classified these diseases as separate entities, often requiring distinct management plans.[1,2] Distinguishing between these two disease entities remains clinically challenging because of the overlap in disease presentation with involvement of the wall of the ear canal, which is commonly observed in both KO and CC.

CC may appear as a keratin "pearl" often on the floor of the ear canal. More extensive involvement causes deeper irregular erosion of the bony ear canal, which is usually restricted in the area lateral to the annulus. There is often thinning of the skin that exposes bone within the canal. KO is also lateral to the annulus but encompasses the circumference of the canal skin. There is diffuse failure of epithelial desquamation and migration creating a laminar keratin plug that widens the diameter of the ear canal. It can cause occlusion of the ear canal resulting in a conductive hearing loss.

Key Operative Learning Points

1. High-resolution computed tomography (CT) scan can help to differentiate the two conditions by the presence of focal bony erosion, seen only in CC, versus a widened bony canal, seen typically in KO.

2. External auditory CC should be distinguished from squamous cell carcinoma by histologic examination of the ulcerated skin edges.

3. When performing canaloplasty for either disease condition, drilling of the medial posteroinferior canal wall may expose the mastoid segment of the facial nerve.

4. Complete removal of unhealthy canal skin and devitalized bone, with the smooth contouring of the bony canal defect and relining the denuded bone with fascia or skin graft, is the definitive surgical management of external auditory CC.

5. Exposed mastoid air cells need to be obliterated with fascia or adipose tissue to avoid persistent otorrhea or fistula formation resulting in recurrent cholesteatoma formation.

Preoperative Period

History

1. History of present illness

Clinical difference between KO and CC can be distinguished by the following characteristics:

a. KO

1) Conductive hearing loss may be present.

2) Otorrhea is rare.

3) Bilateral pain can occur.

4) It is often seen in young or middle-aged individuals.

b. CC

1) Unilateral chronic and dull ache

2) Otorrhea is common.

3) Bleeding from the ear canal

4) Normal hearing

5) Older individuals

2. Past medical history

a. KO

1) Excessive cerumen accumulation

2) Medical illness: There is an association with abnormal or immotile cilia conditions—chronic sinusitis and bronchiectasis, particularly in children.[3]

b. CC

1) Idiopathic

2) Secondary:

a) Congenital

i) Auditory atresia

b) Acquired

i) Recurrent infections in the ear canal

ii) Recurrent disruptions of external auditory canal skin

iii) External auditory canal/stenosis

iv) Posttraumatic or postoperative external auditory canal wall defects

Physical Examination

An examination of the ear using a microscope is the most important part of the physical examination for both conditions.

1. KO

a. Accumulation of large plugs of circumferential, desquamated, laminar keratin in the ear canal due to a defect in lateral epithelial migration (Figs. 128.1 and 128.2)[4]

b. Widening of the bone wall of the ear canal secondary to constant circumferential pressure induced by the keratin plug resulting in bony resorption, without focal erosion of the bone

c. Canal epithelium typically remains intact but can become thickened or inflamed.

d. Tympanic membrane is usually intact but may be involved

e. Conductive type of hearing loss

2. CC

a. Invasion of squamous tissue into a localized area of the bony canal with localized osteitis, focal erosion, and bone sequestration[5]

b. Trapping and tunneling of epithelium may occur beneath the skin of the external auditory canal.

c. The most commonly reported site is the posteroinferior aspect of the canal (Fig. 128.3); however, it can extend into the middle ear and mastoid.

d. Surrounding epithelium can appear ulcerated with bleeding and granulation tissue present at the site of bone erosion (Fig. 128.4).

Imaging

A high-resolution CT scan of the temporal bone scan can help to differentiate the two conditions.

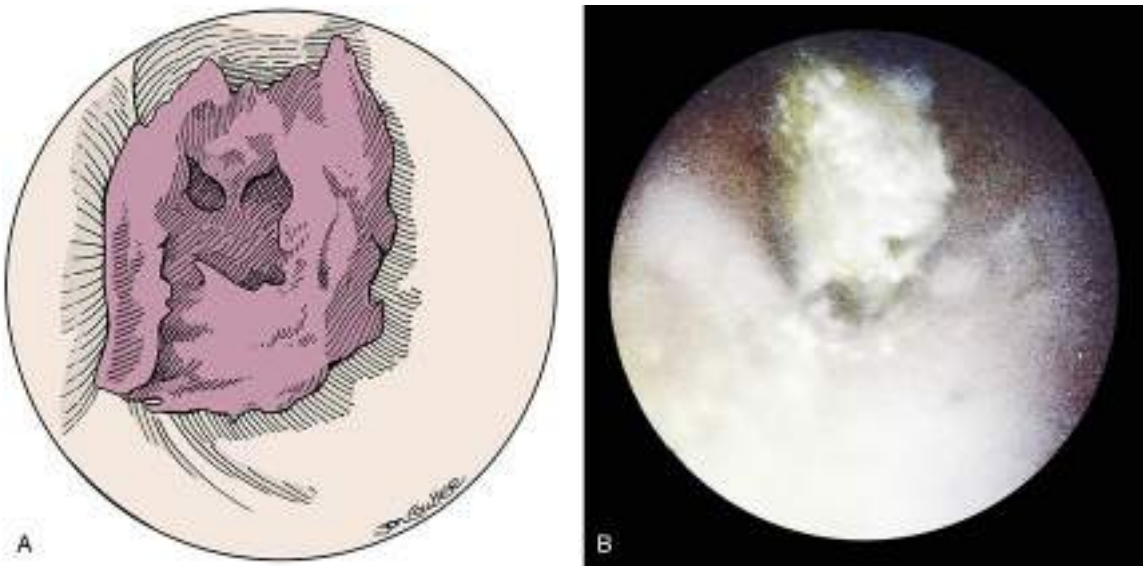

FIG. 128.1 **A** and **B,** Views of the external auditory meatus showing complete obstruction with a keratin plug.

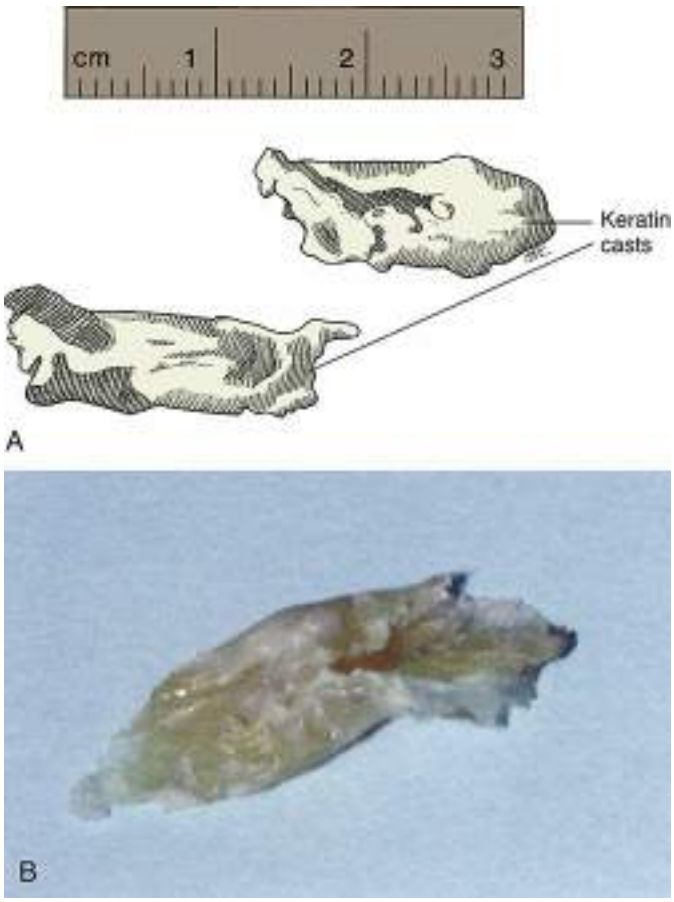

FIG. 128.2 **A** and **B,** Keratin plugs after removal from the ear canals.

1. KO
   a. Widening of the external auditory canal
   b. Intact bony contour of external auditory canal
   c. Possible disease progression into the middle ear space via a diseased or perforated tympanic membrane
2. CC
   a. Focal bone erosion of the external auditory canal
   b. Identify the extent of disease invasion into the mastoid from the erosion and destruction of the posterior bony external auditory canal.
   c. Identify the potential for involvement of the facial nerve.

Indications

1. Persistent “clogged” ear sensation with otalgia, otorrhea, and hearing loss

2. Inflammatory granulation tissue in the external auditory canal that requires a biopsy to rule out other pathologies, including carcinoma of the auditory canal or malignant otitis externa. This is more commonly seen in cases of CC.

3. CT of the temporal bone can identify tissue extension into middle ear and/ormastoid space, with or without facial nerve involvement.

Contraindications

1. Medical comorbidities with increased risk for general anesthesia

2. Greater risk when surgery is performed in the only hearing ear

Preoperative Preparation

1. Audiogram to determine hearing threshold

2. CT scan of the temporal bone to determine disease extension in relation to important anatomic landmarks and the integrity of the bony external auditory canal

3. KO: emollients and lubricants to soften the keratin plug a few days in advance for ease of removal

4. CC: topical antibiotic ear drops to minimize epithelial infection at the site of bony canal erosion

Operative Period

Anesthesia

1. General: In instances where the KO has been long standing and there is extensive widening of the medial external auditory canal, removal of squamous debris can be difficult and not well tolerated by the patient.

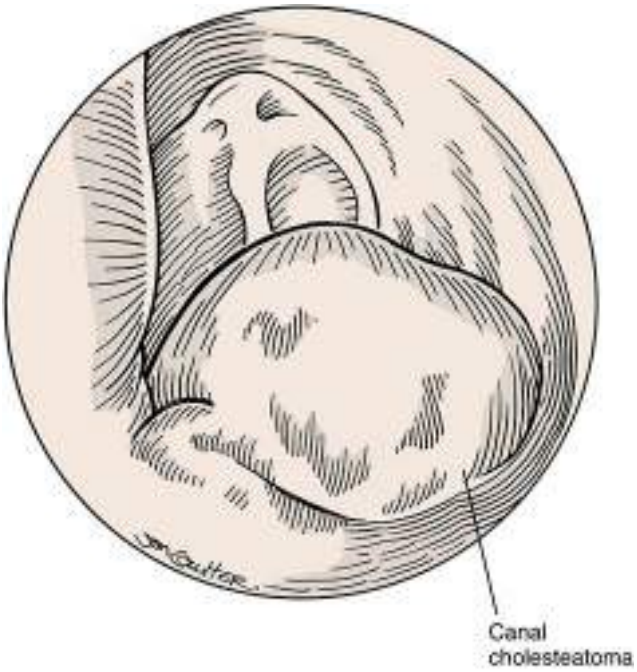

FIG. 128.3 Otoscopic view of a canal cholesteatoma forming in the inferior canal wall.

FIG. 128.4 Otoscopic view of exposed and eroded bone after removal of a cholesteatoma matrix.

For these cases, débridement can be performed under intravenous (IV)

sedation or general anesthesia in the operating room. Rarely, canalplasty has been described for intractable KO.

For more extensive CC complicated by recurrent or persistent infections with mastoid bone involvement, a formal tympanomastoidectomy is almost always required to excise the trapped epithelium and cholesteatoma in the mastoid bone. This will require general anesthesia.

2. Awake sedation: Débridement can be performed under awake sedation.

3. Local: rarely performed as the ear canal is too sensitive for the patient to tolerate local anesthetic injection without any sedation

4. None: Both KO and small CC can be managed conservatively in the office without anesthesia administration, if pathology is well visualized and easily accessed for débridement. It is not uncommon to require repeated office visits.

Positioning

Supine: The patient is positioned on his/her back, and the head is turned away from the surgeon placing the ear under direct microscopic view.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Monitoring

Facial electromyography (EMG) monitoring is advisable if drilling of the medial canal wall or mastoid is anticipated.

Instruments and Equipment to Have Available

1. Operating microscope

2. Middle ear set

3. Otologic surgery drill and drill bits

4. Suction and irrigator

5. Dermatome for harvesting a split-thickness skin graft

Key Anatomic Landmarks

1. The external auditory canal is divided into a medial two-thirds with the bony canal covered by a very thin layer of skin adherent to the underlying periosteum and a lateral one-third cartilage canal covered with thick skin. This division connects at the isthmus (narrowest portion), and the ear canal terminates at the tympanic membrane.

2. The mastoid segment of the facial nerve can be located just medial to the posterior inferior tympanic annulus.

3. Recognize the medial extent of the CC and its proximity to the tympanic membrane and middle ear.

Prerequisite Skills

1. Familiarity with the temporal bone, external auditory canal, and middle ear anatomy

2. Experience with the ossicular chain and facial nerve pathway in the temporal bone

3. Familiar with middle ear instruments and the use of an otologic drill

4. Microsurgical dissection skills and experience with reconstruction of the ear canal, middle ear, and mastoid

Operative Risks

1. Injury to the facial or chorda tympani nerves

2. Drilling through the bony external auditory canal into the mastoid

3. Injury to the tympanic membrane

4. Injury to the ossicles

5. Postoperative external auditory canal stenosis

6. Failure to excise the CC completely

Surgical Technique

Limited disease can be addressed by a transcanal procedure. For more extensive disease in either condition, a postauricular tympanoplasty approach under general anesthesia is safer and provides better exposure.

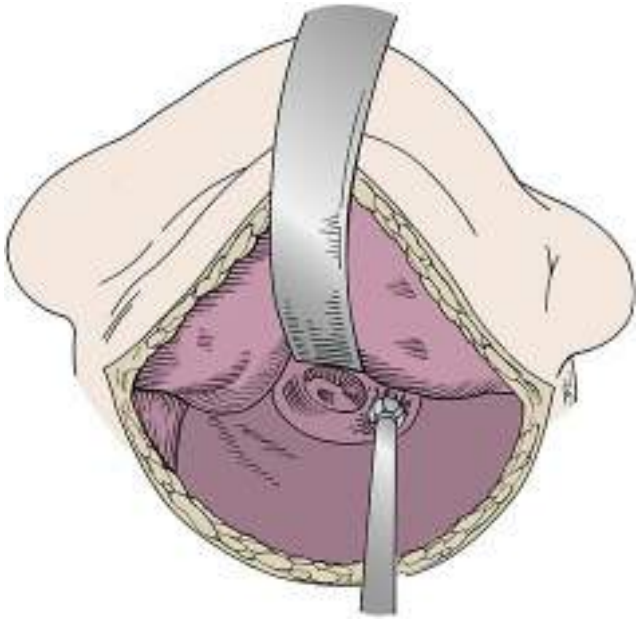

FIG. 128.5 Postauricular approach for the resculpting and grafting of a canal wall defect.

1. Incisions in the ear canal are made at the 12 and 6 o'clock positions connected vertically, creating a conchal flap extended to the level of the defect in the ear canal. A standard postauricular C-shaped skin incision, a vascular strip extending to the level of the canal defect, is made, and the pinna is reflected anteriorly with a tracheotomy tape and self-retaining retractor (Fig. 128.5).

2. After exposing the bony canal erosion defect, the transition between healthy and unhealthy tissue is demarcated. Unhealthy tissue is débrided, and healthy skin adjacent to the defect is elevated for optimal

exposure of the healthy underlying bone.

3. Using appropriately sized cutting and diamond drill burs, devitalized bone of the ear canal is carefully removed until healthy bleeding bone is encountered. The canal defect is contoured to a smooth surface avoiding pits and craters (Fig. 128.6).

4. For larger CC that erodes the posterior bony ear canal and extends into the mastoid bone, facial nerve involvement must be considered, even with normal preoperative facial nerve function. *Consequently, a transcanal approach in which the nerve is not definitively identified may present greater risk for facial nerve paralysis.*

5. The sac extending into the mastoid air cells must be completely excised in order for the operation to be curative. *Sometimes, a canal wall down tympanomastoidectomy is necessary if reconstruction of the canal wall cannot be achieved.*

6. After removal of diseased skin and bone, the final surgical step is relining the denuded area of the exposed bony canal. If minimal coverage is required, temporalis fascia can be used to line the bony canal tucking the edge of the fascia beneath the surrounding healthy skin. If greater coverage is required, a split-thickness skin graft (up to 0.008 inches thick) can be harvested from the outer thigh or upper inner aspect of the arm.

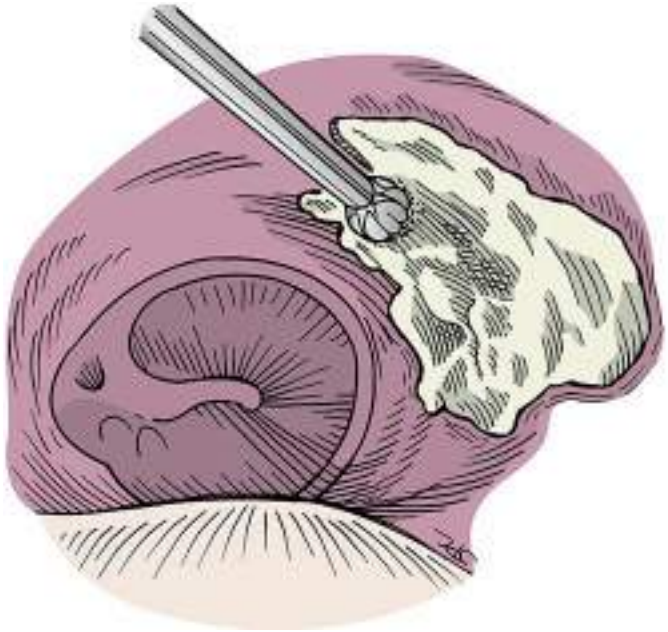

FIG. 128.6 Use of cutting and diamond burs to remove sequestrum and expose fresh, viable bone.

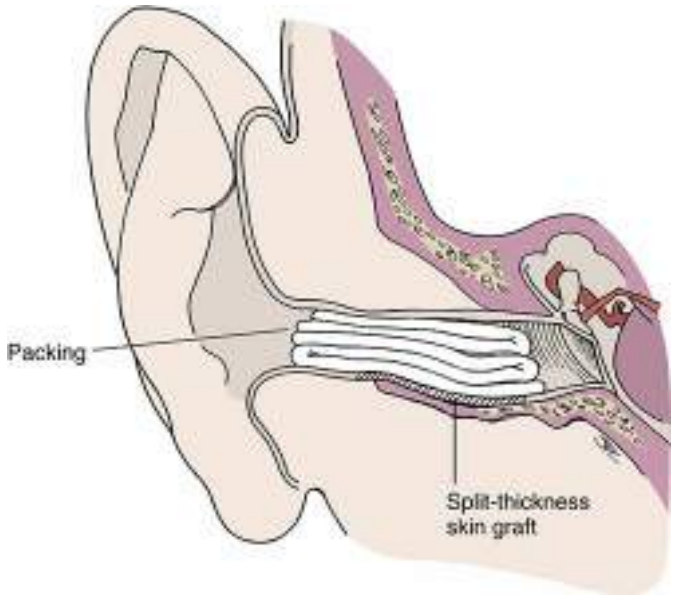

FIG. 128.7 Packing is placed in the canal to stabilize the split-thickness skin graft.

7. If large aerated mastoid air cells are exposed after performing a tympanomastoidectomy, fascial or adipose tissue should be used to obliterate the air cells prior to applying a skin graft. This will enhance survival of the graft, minimize potential development of a draining fistula from the mastoid air cells, and diminish the risk of recurrent cholesteatoma.

8. Elevated healthy adjacent canal skin is replaced, and the conchal or vascular strip is returned to its original position. A strip of silk or rayon mesh is laid over the skin graft to protect it and prevent movement. Gelfoam soaked in antibiotic solution is layered into the canal for continuous ear canal packing followed by the instillation of antibiotic ointment (Fig. 128.7).

9. The postauricular canal incision is closed in the usual manner, followed by a mastoid dressing.

Common Errors in Technique

1. Inadequate exposure of the external auditory canal defect leading to failure to completely eradicate CC

2. Violating the bony canal wall. It should be repaired with adipose tissue, fascia, a cartilage graft or hydroxyapatite reconstruction to avoid a fistula from the ear canal to the mastoid. Larger defects may require converting the procedure to a canal wall down tympanomastoidectomy.

3. It is important to assure that the edges of a split-thickness skin graft are laid flat and not folded upon itself.

Postoperative Period

Postoperative Management

1. Use topical antibiotic ear drops to dissolve the Gelfoam packing. On follow-up visits, Gelfoam packing can be débrided, and the silk mesh will be removed.

2. Simple débridement of skin edges may be carried out in the office until healing is complete, which normally occurs within 6 to 10 weeks.

3. Desquamation from the skin graft is common and may continue even after appropriate healing. Topical mineral oil or antibiotic ointment may lessen the accumulation of desquamated epithelium and make serial débridement easier.

4. Pain medication, including narcotics, should be provided for postoperative pain management.

Complications

1. Failure to excise the CC adequately. This may be due to poor surgical exposure or deep extension of the disease into the mastoid cells and will result in persistence or recurrence of disease. Erosion or aggressive drilling into the mastoid air cell system may require a canal wall down tympanomastoidectomy.

2. Injury to the mastoid segment of the facial nerve. With the use of facial nerve monitoring, this should be a very rare occurrence. Appropriate

management options depend on the type and degree of facial nerve injury. (See Chapter 138 on facial nerve injury and decompression.)

3. Injury to the tympanic membrane and ossicular chain. This will require reconstruction of the tympanic membrane using a fascial graft and ossicles using an incus interposition or prosthesis. (See Chapter 132.)

4. Large bony canal defect requiring reconstruction with a cartilage graft or hydroxyapatite

5. Exposed bony external auditory canal secondary to failure of the skin graft to take

6. External auditory canal stenosis secondary to scar formation requiring a revision canaloplasty procedure

Alternative Management Plan

1. KO: Ototopical steroid drops may reduce the rate of epithelial cell turnover and consequently decrease the frequency of microscopic débridement.

In the majority of cases, KO can be managed effectively by removing the keratin plug in the office, if done at regular intervals.

Surgical intervention to remodel the external auditory canal may be necessary for intractable cases.

2. CC: For limited lesions, local curettage with the application of topical antimicrobial drops may be suitable. Focal areas may be managed with intraoperative curettage and débridement with repair of the epithelium using a postauricular fascial graft. Occasionally, formal tympanomastoid surgery and canalplasty (as described above) will be necessary for more extensive disease.

Discussion

Evidence-Based Medicine Questions

a. What is the underlying pathology of KO and CC?

KO is a plug of keratin, secondary to an abnormality of epithelial

migration, causing obstruction and expansion of the bony external auditory canal.

External auditory CC is invasion of squamous epithelium with localized periosteitis and bone erosion/sequestration.

b. What are the histological differences between KO and CC?

KO consists of subepithelial inflammation without bony erosion and keratin squamous epithelium layered in a lamellar pattern.

CC consists of keratin in loosely packed and random distribution with sequestration of the adjacent bone.

Editorial Comment

Both KO and ear CC are relatively rare otologic diseases. Given that they are disorders of the skin of the ear canal they may create difficulty in definitively diagnosing the processes. Distinguishing features of KO are the often bilateral nature of the disease and the prevalence for occurrence in young patients. Thickening of the keratin layer of the skin in the ear canal can also involve the epithelial layer of the tympanic membrane. This may present with a sensation of fullness in the ear and a conductive hearing loss. Complete ear canal involvement results in a cast outlining the contour of the ear canal and tympanic membrane, which, when extracted, can appear as a cylindrical bullet casing. Fortunately, the use of emollient oils or topical steroid drops can decrease the adhesiveness of the desquamated lining that fails to properly migrate. Removal of the cast reveals the widened ear canal and better visualization of the tympanic membrane.

CC can be focal in origin and respond to débridement in the office. Topical ear drops can reduce the surrounding inflammation and granulation tissue, which may result in otorrhea and bleeding. Some patients can tolerate local curettage following an injection of local anesthetic. Conservative treatment with meticulous removal of the lesion may be all that is necessary to maintain control. Often patients must be taken to the operating room for additional sedation and comfort. Discrete areas of epithelial burrowing and erosion can be removed with a curette for débridement and biopsy. A small microdrill can be used through an ear speculm to smooth and contour irregularities of the bone or spicules

created by the erosive skin. As described, this exposed bone must be covered with fascia or a split-thickness skin graft.

More extensive CC can progress medially and burrow under the tympanic annulus and enter the middle ear. It can erode the bony canal posteriorly entering into the mastoid or more rarely anteriorly into the glenoid fossa. Such aggressive invasion should not be managed conservatively and merits operative removal and reconstruction.

Review Questions

1. What imaging modality is helpful to differentiate between the two disease entities?

   a. Radiograph of the skull

   b. **CT of the temporal bone**

   c. Magnetic resonance imaging of the internal auditory canal

   d. Positron emission tomography scan

2. What important key feature(s) on the imaging study helps to differentiate between the two disease entities?

   a. Erosion of bony external auditory canal (EAC)

   b. Widening of bony EAC

   c. Invasion into middle ear cavity and mastoid cavity

   d. **All of the above**

3. What is the first-line management option for KO?

   a. Topical antibiotic ear drops

   b. **Débridement of keratin plug from external auditory canal in the office**

   c. Tympanomastoidectomy

   d. Canal wall down tympanomastoidectomy

4. What important landmark needs to be monitored to avoid facial nerve injury when performing a canalplasty?

   a. Drilling the anterior superior ear canal wall

   b. Drilling the scutum at the superior ear canal wall

   c. **Drilling the posteroinferior ear canal wall**

   d. Drilling the inferior ear canal wall

5. When treating for EAC cholesteatoma (EACC), what is an important step?

   a. **Excisional biopsy with histologic examination of the ulcerated skin edges to rule out malignancy that can mimic EACC**

   b. Obtain skin graft from the inner arm or thigh

   c. Completely eradicate underlying bone by extending into the mastoid air cells

   d. Obliteration of mastoid air cells

Otitis Media, Myringotomy, Tympanostomy Tube, and Balloon Dilation

Sanjay Prasad, and Roya Azadarmaki

Abstract

A poorly functioning eustachian tube (ET) impairs middle ear ventilation leading to inefficient sound conduction and development of otitis media. Altered angulation of the ET in infants and adenoid enlargement in young children predispose this population to otitis media. In addition, children with craniofacial and cleft palate disorders, with anatomic aberrations and physiologic dysfunction of the ET, are more likely to suffer from otitis media. In adulthood, inflammatory conditions such as rhinosinusitis, upper respiratory infection, and laryngopharyngeal reflux play a greater role. In addition to patient history, diagnosis of otitis media and eustachian tube dysfunction (ETD) involves pneumatic otoscopy and flexible or rigid endoscopy. Contemporary management may require observation alone, use of antibiotics/decongestants/antihistamines, myringotomy and tube surgery, or balloon eustachian tuboplasty (BET) and depends on the severity of the clinical situation. BET is in its infancy with promising results for ETD. This chapter presents a literature review, current indications, and video clips demonstrating surgical technique.

Introduction

Otitis Media

Acute otitis media (AOM) and chronic otitis media with effusion are conditions well known to all otolaryngologists. Infants are predisposed to otitis media because of their immune-compromised state and altered angulation of the eustachian tube (ET). Later in life, adenoid enlargement with ET obstruction may also play a role. Children with craniofacial and cleft palate disorders are also more likely to develop otitis media because of altered anatomy and physiologic function of the ET.

- AOM refers to rapid onset of middle ear inflammation.
- Recurrent AOM is defined as three episodes of AOM in 6 months or 4 episodes in 12 months with at least 1 episode occurring in the past 6 months.[1]
- Persistent AOM is defined as an infection that fails to resolve with proper antibiotic therapy or when two episodes of otitis media occur in 1 month.[1]
- Chronic otitis media (OM) with effusion refers to an effusion that persists longer than 3 months.[1]
- With severe chronic OM, tympanic membrane retraction and middle ear atelectasis occur.
- Eosinophilic OM implies viscous eosinophilic middle ear fluid (allergic mucin).

Eustachian Tube Dysfunction

Dysfunction of the ET can result from anatomic, physiologic, or inflammatory causes. The middle 8 to 12 mm of the cartilaginous ET serves as a valve that is collapsed at rest and opens with contraction of the tensor veli palatini muscle.[2] Mucosal inflammation from rhinosinusitis, upper respiratory infection, laryngopharyngeal reflux, and exposure to "second-hand" smoke can prevent opening of the valve and results in poor ventilation of the middle ear.

Key Operative Learning Points

1. Tympanostomy tubes are placed in the pars tensa of the tympanic membrane away from the posterior superior quadrant to avoid injury to

the ossicular chain and chorda tympani nerve.

2. Tympanostomy tubes should be positioned for easy office evaluation.

3. The torus tubarius marks the nasopharyngeal opening of the ET and is posterior and slightly inferior to the posterior aspect of the inferior turbinate.

4. Lateralization of the inferior turbinate with a Freer elevator or serial balloon dilations can improve access of the posterior nasal cavity in narrow passageways.

5. The catheter in eustachian tuboplasty should not extend beyond the isthmus at the time of dilation. Dilation is focused on the valvular portion of the cartilaginous ET.

Preoperative Period

History

1. History of present illness
   a. Presence of fever, otalgia, otorrhea, headaches, nausea and vomiting, anorexia, sleepless nights, ear tugging, subjective hearing loss, and balance disturbance
   b. Presence of ear popping, fullness, discomfort with barometric challenge, or autophony
   c. Duration of middle ear effusion if previously diagnosed
   d. Number of episodes of AOM
2. Past medical history
   a. Prior treatment: Previous history of antibiotic, allergy desensitization, nasal steroid, nasal antihistamine, oral antihistamine, oral steroid, or use of a topical or oral decongestant
   b. Medical illness: Concurrent rhinitis, rhinosinusitis, adenoid hypertrophy, laryngopharyngeal reflux, craniofacial disorders, syndromes, ciliary dysfunction, granulomatous disease, tympanic membrane rupture or perforation, cholesteatoma and tympanic membrane retraction, and atelectasis

c. Surgery: History of previous myringotomy, tympanostomy tube placement, middle ear and mastoid surgery, or ET surgery

d. Family history: History of parents or siblings with tympanostomy tubes

e. Social history: Exposure to tobacco smoke directly or through second-hand exposure

f. Medications:

1) Antibiotics

2) Nasal or oral steroids

3) Nasal or oral antihistamines

4) Topical or oral decongestants

5) Antireflux medication

Physical Examination

Examination may reveal a normal tympanic membrane, retraction pocket with or without cholesteatoma, severe atelectasis, or adhesive otitis media. Nasopharyngoscopy may reveal peritubal inflammation or adenoid hypertrophy (Fig. 129.1).

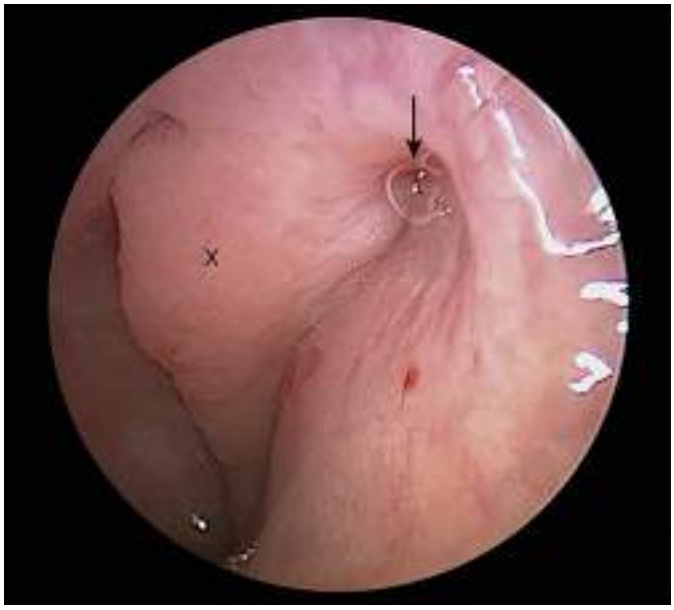

FIG. 129.1 Endoscopic view of the nasopharyngeal opening of a left eustachian tube showing significant peritubal inflammation. *X*, posterior cushion lined with hypertrophic mucosa. *Arrow*, collapsed lumen of the eustachian tube with secretions.

An ideal test to measure ET function has yet to be designed. The appearance of a retracted tympanic membrane (TM) on microscopy, presence of negative middle ear pressure on tympanometry, and absence of normal ET opening during nasopharyngoscopy with the patient swallowing may suggest ET dysfunction.

1. Pneumatic otoscopy and otomicroscopy: This is the gold standard test for otitis media. Patients are evaluated for an opaque, bulging, or perforated TM, active otorrhea, TM atelectasis and retraction with or without cholesteatoma, and TM mobility.

2. Flexible endoscopy: To assess for ET mucosal hypertrophy and inflammation, adenoidal hypertrophy, sinonasal disease, laryngopharyngeal reflux, or other forms of inflammatory or granulomatous disease

3. Rigid endoscopy: A 30- or 45-degree rigid endoscope can be used. Evidence of hypertrophic inflamed mucosa and hyperemia along the anterior and posterior cushions, excessive mucus, or adenoidal hypertrophy impacting on the posterior cushion of the ET can be seen in patients with ET dilatory dysfunction (see Fig. 129.1). Videoendoscopy is helpful to differentiate obstructive disease from dynamic dysfunction. Having the patient repeat the letter "K" and swallow or yawn causes contraction of the levator veli palatini. Palatal elevation leads to medial rotation of the posterior cushion as contraction of the tensor veli palatini acts on the lateral cartilaginous lamina to open the ET. During the active phase, the resting S-shaped lumen opens to a more rounded patent one.

Testing

Audiogram

- Conductive hearing loss can result from chronic effusion or ossicular chain erosion from chronic atelectasis.

Tympanometry

- A type B or C curve may be seen in chronic or recurrent middle ear disease.

Imaging

Myringotomy and Tube Placement

A computed tomography (CT) scan of the temporal bone is recommended when cholesteatoma, granulation, acute mastoiditis, tumors, tegmen defect, encephalocele, or vascular anomalies are suspected.

Balloon Eustachian Tuboplasty

CT scan of the temporal bone is recommended prior to balloon eustachian tuboplasty (BET) to rule out anatomic abnormalities of the skull base especially dehiscence of the carotid artery encroaching on the tubal lumen. Sinonasal disease should also be evaluated.

Indications

Myringotomy and Tympanocentesis

- Obtain cultures in patients with AOM accompanied by high fever and sepsis and in patients with complications of OM. Tube insertion is recommended.
- Pain and pressure relief of AOM (not commonly performed)

Myringotomy and Tube Placement

Tympanostomy tube insertion is the most common ambulatory surgery performed in children in the United States. This procedure helps to improve middle ear ventilation and can help patients with poorly functioning ETs.

Common indications include persistent otitis media with effusion resulting in hearing loss, recurrent otitis media, or persistent otitis media that fails to resolve with conservative treatment. Based on guidelines by the American Academy of Otolaryngology-Head and Neck Surgery, tympanostomy tubes are recommended in children aged 6 months to 12 years, with bilateral otitis media with effusion for 3 months or longer with documented hearing loss, and in children with recurrent AOM with effusion on one or both sides.[1] The guidelines also recommend treating at-risk children with baseline sensory, physical, cognitive, or behavioral problems with otitis media with effusion and recurrent AOM.[1] The guidelines do not address treatment of patients with retracted TMs, complications of otitis media, or barotrauma.

Indications for tube placement:

- AOM that fails to resolve with antibiotic therapy
- Recurrent AOM with presence of effusion and children with high fevers and discomfort regardless of clinical examination
- AOM with complications such as coalescent mastoiditis, meningitis, intracranial abscess, sigmoid sinus thrombosis, and facial nerve paresis. Mastoidectomy may also be needed.
- Chronic OM with effusion and documented hearing loss for 3 months or longer
- Chronic OM with adherent or nonadherent TM atelectasis, ossicular chain erosion, and TM retraction with or without cholesteatoma
- Eosinophilic otitis media: For ventilation and topical steroid treatment

FIG. 129.2 Severe atelectasis with a natural type II/III tympanoplasty. Ventilation of the middle ear aims to lateralize the tympanic membrane off the promontory and ossicles.

- ET dysfunction with aural fullness, ear popping, and otalgia not responding to conservative therapy
- ET dysfunction with otalgia and hearing loss with barometric challenge as with air travel or hyperbaric oxygen therapy

Balloon Eustachian Tuboplasty

- Chronic and persistent otitis media with effusion (OME)
- Nonadherent TM atelectasis
- Symptomatic ET dilatory dysfunction including conductive hearing loss, otalgia, and aural fullness with pressure change
- Symptomatic patients with type B or C tympanograms
- Flight and scuba diving baro-challenge
- Past demonstration of symptom improvement with tube placement

In patients with adherent atelectasis, progression of disease can lead to ossicular chain erosion with type II or III tympanoplasty (Fig. 129.2) and in severe cases, cholesteatoma. Tube placement may not be possible and BET may not restore middle ear aeration. Tympanoplasty with tube

placement (with consideration for BET) may help restore middle ear ventilation, arrest progression, and improve ET function. Observation alone is also an option in some patients.

Contraindications

Myringotomy and Tube Placement

1. Cerebrospinal fluid (CSF): If clear fluid is encountered during myringotomy, the tympanostomy tube should not be placed.

2. Vascular anomaly: If a high-riding jugular bulb or aberrant carotid artery is suspected, great caution should be exercised and CT imaging obtained.

3. Anesthesia contraindications

Balloon Eustachian Tuboplasty

1. Dehiscent carotid artery in the osseous ET canal

2. Anesthesia contraindications

Preoperative Preparation

Audiogram and tympanogram

Operative Period

Anesthesia

Myringotomy and Tube Placement

- Topical: Phenol or trichloroacetate can be applied topically to the tympanic membrane using a fine cotton-tipped applicator. The tympanic membrane develops a white blanch. Patients may experience a burning sensation for up to several minutes. After a few minutes, myringotomy and tube placement can be performed.

- Local injection of the ear canal: 1% lidocaine with 1:100,000 epinephrine
- General: The procedure is performed under general anesthesia in children and anxious adults.
- Awake sedation: Alternative option

Balloon Eustachian Tuboplasty

- General: General anesthesia can be administered via laryngeal mask airway.

Positioning

Myringotomy and Tube Placement

- Local: Semirecumbent, supine position, or sitting with the head turned slightly away from the side of intervention
- General anesthesia or sedation: Supine position with the head turned slightly away from the side of intervention

Balloon Eustachian Tuboplasty

- Supine position with the head turned slightly toward the surgeon. The head of the bed may be turned 90 degrees.

Perioperative Antibiotic Prophylaxis

Tympanocentesis

- Clean-contaminated surgery
- Perioperative antibiotic prophylaxis is not recommended.

Myringotomy and Tube Placement

- Clean-contaminated surgery
- Perioperative antibiotic prophylaxis is not recommended.

Balloon Eustachian Tuboplasty

- Clean-contaminated surgery
- Perioperative antibiotic prophylaxis is not recommended.

Monitoring

Tympanocentesis

- None necessary

Myringotomy and Tube Placement

- None necessary

Balloon Eustachian Tuboplasty

- Cardiac monitoring is recommended.

Instruments and Equipment to Have Available

Tympanocentesis

1. Alden-Senturia trap (Storz Instrument Co.) attached to an 18-gauge needle

2. Tuberculin syringe and 18-gauge needle

Myringotomy and Tube Placement

1. Operating microscope or 0-degree endoscope

2. Ear speculums of various sizes

3. Cup forceps; cerumen loops; curettes, 3, 5, and 7F suction; and cotton-tipped applicators for removal of ear canal debris and cerumen

4. Myringotomy knife

5. Alligator forceps for tympanostomy tube guidance into the ear canal and myringotomy site

6. Curved pick and right-angled hook for completion of tube insertion and orientation

7. 3F, 5F, and 7F suctions to clear middle ear content and tube orifice

8. Selected tympanostomy tube(s)

Tympanostomy Tube Options

Tympanostomy tubes are typically made of plastic, although silicone, metal, and hydroxyapatite tubes are still used. Biocompatibility and resistance to clogging and extrusion are important factors.

Retention and patency are related to tube design (Fig. 129.3). Short-term tubes are typically retained from 6 to 12 months and long-term tubes retained more than 12 months. Short-term tubes are shaped like a grommet. They may have the configuration of an hourglass (Shepard-type tube) or have beveled inner flanges (Armstrong-type tube). The latter tend to be retained longer. Long-term tubes are typically T-tubes with long inner flanges to prevent early extrusion and are placed in patients who have a history of early extrusion or in patients with the need for prolonged middle ear ventilation. Sometimes the inner flanges need to be shortened.

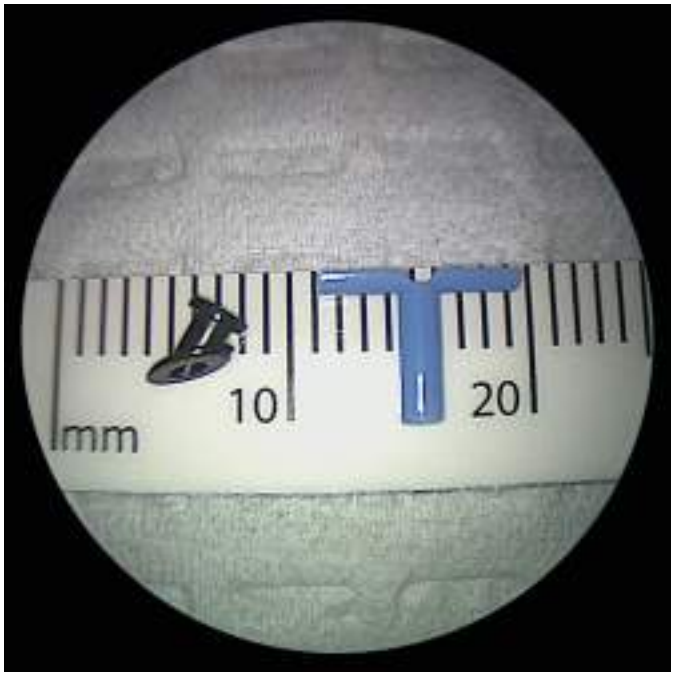

FIG. 129.3 Tympanostomy tubes. (*Left*, short-term Armstrong Beveled Grommet Tube. (*Reprinted with the permission of Medtronic, Inc. © 2016.*) *Right*, long-term Richards Modified T-Tube. (*GYRUS ACMI, with permission.*))

Balloon Eustachian Tuboplasty

1. 30- or 45-degree endoscope

2. Pledgets soaked in Afrin, 1:1000 epinephrine, or a decongestant of choice

3. Bayonet forceps and nasal speculum for pledget placement

4. Freer elevator

5. 9 or 10F suction

6. Balloon catheter system

7. 70-degree introducer for selected balloon systems

Key Anatomic Landmarks

1. Myringotomy and tympanostomy tube placement should be located in

the pars tensa and away from the posterior-superior quadrant, so as not to harm the ossicular chain (Fig. 129.4).

2. Torus tubarius: This marks the nasopharyngeal opening of the ET and can be identified posterior and slightly inferior to the posterior aspect of the inferior turbinate (Videos 129.1 and 129.2).

3. ET isthmus: This is the narrowest portion of the ET and marks the bony-cartilaginous junction. When advancing a balloon catheter, the isthmus can be felt as an area of resistance.

Prerequisite Skills

1. Dexterity using the operating microscope or otoendoscopes

2. Dexterity and experience using nasal endoscopes and balloon dilation procedures

Operative Risks

Both procedures are relatively safe; however, the following operative risks exist.

Myringotomy and Tube Placement

1. Minor bleeding: Avoid contact of the canal skin with instruments. This is usually controlled with topical use of cotton soaked with 1:1000 epinephrine.

2. Major bleeding: The ear canal should be filled with thrombin-soaked Gelfoam and the head should be slightly raised. Hypertension should be medically treated. If profuse bleeding persists, the ear canal should be packed tightly and prompt transfer to a tertiary care hospital should be considered.

FIG. 129.4 Endoscopic view of right tympanic membrane. *X*, posterior superior quadrant and area of the ossicular chain to be avoided at the time of myringotomy and tube placement.

3. Infection: Otorrhea should be treated with antibiotic drops.

4. Tympanic membrane perforation: An atrophic tympanic membrane is at risk for perforation.

5. Middle ear tympanostomy tube: Rarely, the tube may fall into the middle ear space. The tube should be removed through the myringotomy site. If the tube is not retrievable, a new tube should be placed. Management of the medialized tube is discussed in the complications section.

6. Avoiding the posterior-superior quadrant will prevent harm to the ossicular chain and chorda tympani nerve.

7. Risk of general anesthesia

Balloon Eustachian Tuboplasty

1. Injury to nasal structures including the septum and inferior turbinates with associated immediate bleeding and delayed scar band formation

2. False passage of the balloon catheter with laceration of the ET mucosal lining and soft tissue emphysema

3. Tympanic membrane rupture from the pressure associated with balloon dilation

4. Risk of general anesthesia

5. In theory, advancement of the catheter past the bony isthmus with dilation, in the presence of a dehiscent carotid canal, can cause injury leading to dissection, aneurysm formation, bleeding, stroke, and death. However, these complications have never been reported in the current era of BET. Clinically significant sinus tachycardia, bradycardia, and premature ventricular contractions (PVCs) have been experienced and are believed to be related to stimulation of the carotid plexus. In these situations, the procedure should be aborted.

Surgical Technique

Myringotomy and Tube Placement

1. Performed in the office or operating room

2. Using the operating microscope and appropriately sized ear speculum or 0-degree endoscope (4.0 mm or 2.7 mm), the ear canal and tympanic membrane are visualized.

3. Removal of cerumen and squamous epithelium at the time of the procedure will facilitate access and postoperative care.

4. With a myringotomy knife, an incision of approximately 2 mm is made. The site of the myringotomy should avoid the posterior-superior quadrant, avoid contact with the malleus handle, and not extend to the annulus.

5. The incision can be widened using alligator forceps if needed.

6. Middle ear effusion is aspirated using a 5F suction. A smaller suction should be used if there is risk of perforation due to TM atrophy. 7F suction with or without saline irrigation should be used if viscous fluid is encountered.

7. Cultures should be obtained when appropriate.

8. The tympanostomy tube is inserted into the myringotomy site.

9. The tube can be optimally positioned using a pick. Ideally, the middle ear mucosa should be visualized through the tube orifice.

10. Hemostasis can be achieved using cotton soaked in 1:1000 epinephrine. Hemostasis reduces the risk of postoperative tube obstruction.

11. Antibiotic-steroid drops are applied when middle ear effusion, infection, or bleeding is present to treat the disease process and prevent tube obstruction.

Operative Challenges in Myringotomy and Tube Placement

1. Atelectatic tympanic membrane: Injection of 0.1 to 0.2 cc of air with a 27-gauge needle can help aerate the middle ear and create an area for tube placement.

2. Stenotic meatus: Serial dilations of the stenotic meatus with increasing speculum size can be helpful. In cases where a small-diameter speculum is used, the tube can be placed into the medial ear canal independent of the ear speculum and then maneuvered to the myringotomy site.

Myringotomy and Tympanocentesis

Alcohol or betadine irrigation can be used to sterilize the ear canal before the myringotomy incision or tympanocentesis.

Myringotomy and culture: Steps 1 to 4 of the myringotomy and tube placement technique are followed. Once the myringotomy is made, the middle ear content is cultured using a sterile swab. A small syringe attached to a 3F or 5F Fraser suction can also be used to collect a specimen for culture.

Tympanocentesis: Steps 1 to 3 of the myringotomy and tube placement technique are followed. An 18-gauge Rosen suction needle attached to a tuberculin syringe or an Alden-Senturia trap system is subsequently used to aspirate middle ear content. The posterior-superior quadrant should be avoided.

Balloon Eustachian Tuboplasty

1. Following laryngeal mask airway intubation, the table is turned 90

degrees.

2. Cottonoids soaked in decongestant medication (Afrin, 1:1000 epinephrine) are inserted into the nasal cavity.

3. After removal of cottonoids, the nasal cavity is inspected using a 30- or 45-degree scope.

4. The balloon catheter tip is bent to 70 degrees prior to placement in the nasal cavity. The angle may need adjustment based on the anatomy.

5. The balloon catheter is guided to the posterior nasal cavity (tip up or down). With some balloon systems, a 70-degree curved guiding catheter is required to access the ET.

6. Serial balloon dilation between the septum and inferior turbinate or gentle lateralization of the inferior turbinate with a Freer may be necessary for exposure.

7. If the catheter and endoscope cannot fit through the same side, the angled endoscope can be used from the contralateral side.

8. Once the balloon catheter reaches the ET opening, it is rotated laterally into the ET. If a guiding catheter is used, it is appropriately positioned to allow for balloon insertion.

9. The balloon catheter can be used to gently rotate the posterior cushion medially to inspect the proximal ET lumen (Video 129.1).

10. The balloon is carefully advanced with care not to create a false passage. If resistance is encountered at the isthmus, the balloon should not be advanced.

11. The balloon is inflated for 2 minutes (Video 129.2 and 129.3).

12. Some patients experience PVCs and systolic hypertension, which is believed to be secondary to stimulation of the carotid sympathetic plexus. In these cases, the balloon should be immediately deflated and the procedure aborted.

FIG. 129.5 Endoscopic view of the lumen of the cartilaginous left eustachian tube post balloon dilation.

13. Once the catheter is removed, the lumen of the cartilaginous ET can be inspected for mucosal tears or false tracts using an angled scope (Fig. 129.5).

14. A micro-cottonoid soaked with Decadron, 10 mg/mL, can be placed into the lumen of the ET for several minutes when mucosal edema or hypertrophic mucosa is encountered.

In September 2016 the Acclarent Aera Eustachian Tube Balloon System was introduced as the first balloon catheter device with the U.S. Food and Drug Administration's approval for BET. Subsequently, in April 2017 the Entellus XprESS balloon dilation device system received the U.S. Food and Drug Administration's approval for the same indication.The Acclarent Aera Eustachian Tube Balloon system contains a guide and balloon catheter. The balloon dimensions with this device are 6 x 16 mm. The guide catheter tip is aligned with the ET's nasopharyngeal opening trajectory and the balloon catheter is advanced through the guide catheter. A marking point is set to indicate the level of balloon catheter advancement however advancement is stopped if resistance is encountered and the bony isthmus is reached prior to the expected mark.The Entellus XprESS balloon system approved for Eustachian tube dilation comes in different dimensions. We recommend that balloons with a length greater than 18 mm are not initially used until experience with the procedure and respect for the tactile feedback from the bony isthmus are achieved.The authors use the XprESS Entellus Balloon Device with dimensions of 6 x 18 mm. The malleable tip is bent to accommodate the angulation of the ET's nasopharyngeal opening. This is

normally achieved with a 55o to 70o bend.Balloon length of up to 18 mm is adequate to pass beyond the valve of the cartilaginous ET and short enough to minimize the risk of entry into the bony ET. (Videos 129.1 to 129.3).

Common Errors in Technique

Myringotomy and Tube Placement

1. Aggressive débridement or impingement of the canal wall with instruments resulting in canal wall hematoma and bleeding

2. Myringotomy that is too small resulting in difficulty with tube insertion

3. Improper loading of the tube onto the alligator forceps, leading to difficult insertion. Serrated alligator forceps offer a more secure grasp of the tube than a smooth forceps.

Balloon Eustachian Tuboplasty

1. Incorrect angulation of the catheter tip resulting in difficulty with ET insertion

2. Inadequate nasal cavity decongestion causing poor visualization

3. Not performing out-fracture of the inferior turbinate resulting in poor visualization

Postoperative Period

Postoperative Management

Myringotomy and Tube Placement

1. No ear drops are needed if there is no middle ear effusion, purulent secretions, or bleeding.

2. Steroid-fluoroquinolone drops or fluoroquinolone drops alone for 3

days in patients with serous effusion or bleeding

3. Steroid-fluoroquinolone drops or fluoroquinolone drops alone for up to 10 days in cases with mucoid or purulent effusion

4. Follow up in 1 to 2 weeks if mucoid or purulent effusion is encountered; otherwise, follow-up can be scheduled up to 4 weeks postoperatively.

5. Postoperative audiogram and tympanogram

6. Routine follow-up every 3 to 6 months after initial postoperative visit

7. Water precautions: Literature does not support the use of water precautions in the form of earplugs, headbands, or avoidance of water activities. We recommend water precautions if patients are exposed to lake, river, or ocean water or are involved in shallow diving. Water precautions should be recommended for individuals who develop otalgia or otorrhea after water exposure.

Balloon Eustachian Tuboplasty

1. No nose blowing for 1 week to avoid the risk of soft tissue emphysema.

2. Nasal steroid spray for a minimum of several weeks. Prolonged use is recommended with concurrent sinonasal disease and mucosal inflammation.

3. If a modified Valsalva maneuver, which involves the traditional Valsalva maneuver accompanied by a simultaneous swallow, cannot be performed after the first postoperative week, a Politzer maneuver can be attempted and may be helpful.

4. If a patient has undergone a tympanoplasty, mastoidectomy, and ossicular chain reconstruction in conjunction with the BET, we do not recommend the modified Valsalva maneuver for 3 to 4 weeks.

5. Follow up 2 to 4 weeks postoperatively.

6. Postoperative audiogram and tympanogram

7. Long-term monitoring after BET is required as efficacy and outcomes are still evolving.

Complications

Myringotomy and Tube Placement

1. Otorrhea (>20%)[1]: Treated with antibiotic drops with or without steroids. Patients with persistent otorrhea after culture-based treatment should be evaluated for cholesteatoma and other sources of middle ear/mastoid disease.

2. Tube obstruction (7%)[1]: Treated with drops or hydrogen peroxide

3. Granulation (4%)[1]: Treated with antibiotic-steroid drops. In patients with persistent granulation, the tube should be removed to resolve the foreign-body reaction.

4. Premature tube extrusion (4%)[1]: Seen in some patients with obstructive sleep apnea on continuous positive airway pressure (CPAP). Lowering the pressure setting may be helpful.

5. TM perforation following extrusion (1% to 6%)[1]: Observation, myringoplasty, or tympanoplasty can be recommended. A small perforation can be observed because it is functioning like a ventilation tube.

6. Middle ear tube (0.5%)[1]: Rarely the tube can fall into the middle ear. Tube retrieval should be attempted through the myringotomy site. In patients where retrieval is not possible or the TM has healed, exploratory tympanotomy with tube retrieval should be considered in the presence of an inflammatory reaction.

7. TM tube retention beyond 2 to 2.5 years: Tube replacement or tube removal with myringoplasty should be considered.

8. Myringosclerosis, tympanosclerosis, TM atrophy, and atelectasis changes are generally irreversible.

Balloon Eustachian Tuboplasty

1. False passage, typically along the anterior and medial ET wall

2. Epistaxis

3. Subcutaneous emphysema: Usually self-limiting; however avoidance of nose blowing will prevent exacerbation

4. Patulous ET

5. Tympanic membrane perforation from excessive middle ear pressure effect

6. Tinnitus

7. Cardiac dysrhythmia: PVCs, bradycardia, and clinically significant tachycardia should prompt the surgeon to abort the procedure.

8. Systolic hypertension: Usually responds to medical treatment

9. Worsening ET function from scarring: Very rare

10. Injury to the internal carotid artery: Very unusual in carefully selected patients

Alternative Management Plan

1. Culture-based antibiotic treatment in cases of recurrent AOM or persistent otitis media. Infectious disease consultation with possible intravenous antibiotics may be useful.

2. Aggressive medical treatment of concurrent laryngopharyngeal reflux and rhinosinusitis as a source of ET dysfunction and otitis media

3. Treatment of ET mucosal inflammation with topical nasal steroids alone or in conjunction with oral steroids

4. Adenoidectomy alone or in conjunction with tympanostomy tube placement and/or BET when adenoid hypertrophy is present

5. Myringotomy with tympanostomy tube placement and BET can serve as each other's alternatives.

6. Microdébrider eustachian tuboplasty in patients with concurrent hypertrophic and inflamed mucosa along the posterior cushion. This can be combined with tube placement and/or BET.

Evidence-Based Medicine Question

Is BET an effective procedure for improving eustachian tube function?

In addition to widening the opening of the ET, replacement of irreversibly damaged mucosa and submucosal lining of the ET with thin scar is believed to be the mechanism by which balloon dilation affects the ET and improves its function.[3] Kivekas et al. report that biopsies of ET lining in 13 patients before, immediately after, and in a few (5 to 12) weeks post balloon dilation revealed a reduced inflammatory effect on the mucosa and submucosa.[3]

A systematic review of nine case series revealed a need for randomized controlled trials to determine the efficacy of BET. However, several studies have shown promising outcomes with BET. Silvola et al. demonstrated an 80% BET success rate in 37 patients with a history of multiple tympanostomy procedures for otitis media with effusion, tympanic membrane nonadherent atelectasis, type B or C tympanograms, and in patients unable to perform the Valsalva maneuver.[4] Success was defined as the ability to perform the Valsalva maneuver postoperatively.[4] In 2015 Schröder et al. reported their outcomes in management of 622 patients and 1076 ETs in patients 7 to 84 years of age.[5] The overall success rate, based on ET scores, was over 70%, with 82% improvement at 5 years.[5] Overall the data are promising, suggesting a possible revolution in the management of ET dysfunction.

Literature on BET in children is currently limited. BET can be considered in individuals 7 years of age and older as the ET is close to adult length by this age. The safety and efficacy of BET in children less than 7 years of age have yet to be demonstrated. Use of shorter balloons should be considered in children.

Editorial Comment

Myringotomy with or without tubes is the most common procedure performed by otolaryngologists. Following the use of antibiotics for recurrent AOM, placement of myringotomy tubes is the mechanical means of ventilating the middle ear. This provides a short-term solution to problems attributed to poorly functioning ETs. Drainage of AOM that is causing complications such as mastoiditis and facial paralysis provides immediate benefit toward recovery. Ventilation is advocated for individuals with carbon monoxide toxicity or those following acute

barotrauma who cannot equilibrate their middle ear pressure. Ventilation tubes are placed prior to the initiation of treatment in the pressure chamber.

Various factors influence the ability of the ET to ventilate the middle ear including the horizontal orientation of the tube, compromised mucosal disease, or sinonasal inflammation causing dysfunction or obstruction. The advent of endoscopic surgery on ETs may hold promise toward providing a more physiologic means of reversing ET dysfunction. Additional experience with both children and adults will ascertain if such procedures are successful and their duration of efficacy.

Review Questions

1. Landmarks for the nasopharyngeal eustachian tube opening include all of the following except which option?

   a. **Posterior attachment of the middle turbinate**

   b. Posterior aspect of the inferior turbinate

   c. Posterior cushion

   d. Torus tubarius

2. Tympanostomy tube placement should be avoided in which of the following tympanic membrane quadrants?

   a. Posterior-inferior

   b. Anterior-inferior

   c. **Posterior-superior**

   d. Anterior-superior

3. Which of the following is a tympanostomy tube complication that is least likely to occur?

   a. Otorrhea

   b. Tube obstruction

c. Tympanic membrane perforation

d. **Tube falling into the middle ear**

4. Which of the following is the major vascular structure parallel to the osseous segment of the eustachian tube?

a. **Petrous carotid artery**

b. Cavernous carotid artery

c. Cervical carotid artery

d. Jugular bulb

Intracranial Complications of Otitis Media

Dennis J. Kitsko, and Kavita Dedhia

Keywords

brain abscess; complications; epidural abscess; lateral sinus thrombosis; meningitis; otitic hydrocephalus; otitis media; petrous apicitis; sigmoid sinus thrombosis; subdural abscess

Introduction

Complications from acute otitis media or chronic otitis media can be divided into extracranial complications (i.e., facial nerve paralysis, labyrinthitis, and subperiosteal abscess) and intracranial complications. Intracranial complications of otitis media include meningitis, epidural abscess, subdural abscess (empyema), brain abscess, lateral sinus thrombophlebitis/sigmoid sinus thrombosis, otitic hydrocephalus, and Gradenigo's syndrome (Fig. 130.1). On occasion, an intracranial complication may be the initial symptom in a patient with a history of untreated otitis media. It is also important to understand that multiple complications may often occur concomitantly, and the existence of one intracranial complication warrants investigation into the presence of others. Despite broad-spectrum antibiotics, complications of otitis media can result in high morbidity and even mortality, and surgical management is often necessary.

The spread of otitis media to intracranial structures may occur either directly or hematogenously. Direct extension can occur via multiple mechanisms: pre-existing congenital abnormalities (e.g., a Mondini deformity), posttraumatic bony defects from a fracture of the temporal bone, erosion of bony barriers as a result of cholesteatoma, normal

communicating vein pathways from the mastoid to the intracranial space, and spontaneous or iatrogenic dehiscence of bone. Historically, meningitis has been and continues to be the most common intracranial complication of otitis media in children and adults, both in developed and underdeveloped countries. Epidural abscess and lateral sinus thrombosis have been reported as the next most common complications in children. Brain abscess, a rare complication in children in developed countries, is seen more commonly in the adult population and in less developed countries.

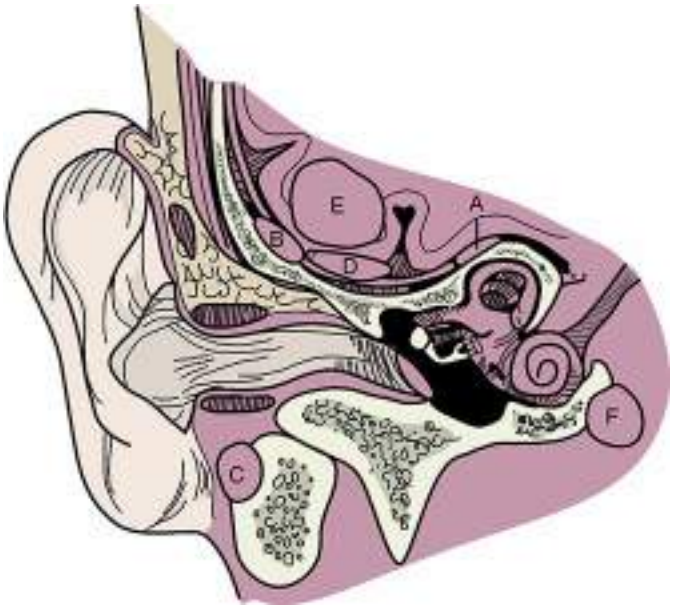

FIG. 130.1 Intracranial complications of otitis media include meningitis *(A)*, epidural abscess *(B)*, lateral sinus thrombosis *(C)*, subdural empyema *(D)*, brain abscess *(E)*, and petrous apicitis *(F)*. Adapted from Vazquez E, Castellote A, Piqueras J, et al: Imaging of complications of acute mastoiditis in children. Radiographics, 2003, 23:359-372.

Patients may initially have the classic signs of otogenic infection, such as foul-smelling otorrhea, otalgia, headache, fever, vertigo, and sudden hearing loss. As the disease progresses, later signs include changes in mental status, such as confusion, obtundation or seizures, and cranial nerve palsies. Many patients with intracranial complications will have multiple complications, such as meningitis in addition to an intracranial abscess, and the Otolaryngologist should seek to diagnose and treat all of

these complications. Patients may have concurrent intratemporal complications, such as subperiosteal abscess, labyrinthitis, and facial nerve paresis. When evaluating for the possibility of intracranial complications of otitis media, magnetic resonance imaging (MRI) provides better detail of intracranial structures than computed tomography (CT). The frequency of various intracranial complications in a number of case series is presented in Table 130.1.[1-5]

Key Operative Learning Points

- Meningitis due to otitis media is initially treated with myringotomy and tube insertion and antibiotics.
  - For those who fail conservative treatment, a complete mastoidectomy is performed when medically stable.
  - Close follow-up for possible sequelae, including labyrinthitis ossificans
- An isolated epidural abscess secondary to coalescent mastoiditis requires a mastoidectomy with unroofing of the affected bone.
  - Great caution is given not to enter the dura.
- Lateral sinus thrombosis requires a mastoidectomy.
  - A thrombectomy may be required if there is gross infection of the sinus.
- Subdural and brain abscesses are surgical emergencies and must be evacuated immediately, requiring neurosurgical intervention.
- Surgical management of otitic hydrocephalus depends on the extent of the disease.
- Initial management of petrous apicitis is a trial of intravenous (IV) antibiotics.
  - If no improvement or imaging shows coalescence and bone septate destruction, surgery is indicated.
  - Surgical intervention can range from a mastoidectomy with tympanostomy tube placement to performing a subtotal petrosectomy.

Preoperative Period

History

- Classic symptoms
  - Headache
  - Photophobia
  - Spiking fevers
  - Mental status changes
  - Nausea and vomiting

Physical Examination

- Classic physical signs, such as Kernig's sign, Brudzinski's sign, and nuchal rigidity are not consistently present.
- May have typical physical findings of acute otitis media, such as otorrhea or bulging of the tympanic membrane
- Clinical suspicion of a more chronic underlying cause should also be high, particularly in the setting of an otherwise innocuous otologic physical examination.
- Diagnosis is via lumbar puncture (LP).
- *Streptococcus pneumoniae* and *Haemophilus influenza* are the primary organisms.[6]
- MRI or fine-cut contrast-enhanced CT of the temporal bone can rule out other intracranial complications.
- Typical LP findings in bacterial meningitis
  - Elevated opening pressure
  - Elevated white blood cell count
  - Elevated protein
  - Decreased glucose

- Elevated cerebrospinal fluid (CSF) lactate

Imaging

- Due to the risk of LP-induced cerebral herniation, current practice guidelines recommend CT prior to LP in the setting of:
  - Immunocompromised state
  - History of central nervous system (CNS) disease (i.e., stroke)
  - New onset seizure
  - Papilledema
  - Altered level of consciousness
  - Focal neurologic deficit
- Empiric therapy should include a third-generation cephalosporin and vancomycin.
- Hearing should be monitored closely after meningitis with consideration given to early cochlear implantation if bilateral severe hearing loss is accompanied by radiologic evidence of labyrinthitis ossificans.

ICCOM, Intracranial complication of otitis media.

* Other includes cavernous sinus thrombosis, perisinus abscess, meningocele, petrous apex suppuration, internal jugular thrombosis, cerebritis, presuppurative encephalitis, and ventriculitis. Some patients had more than one intracranial complication.

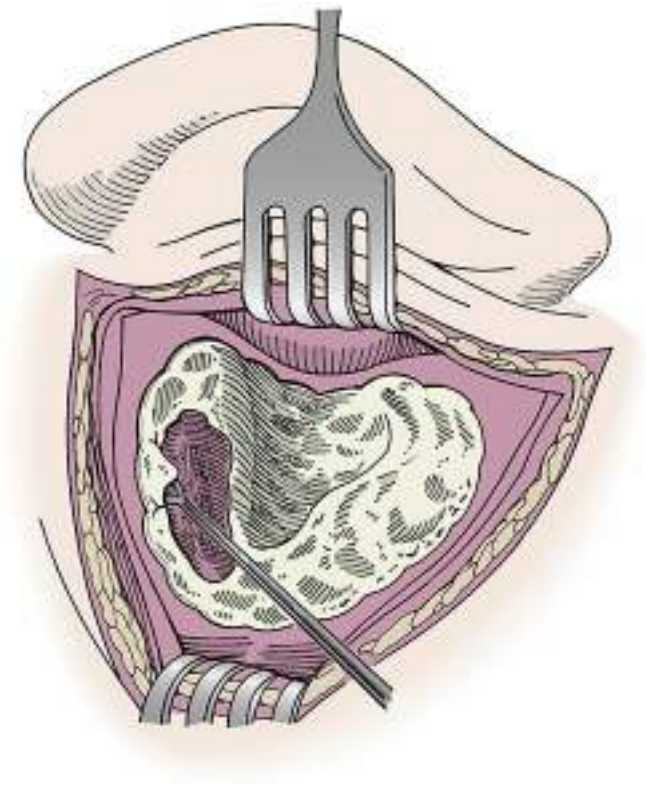

FIG. 130.2 Exposure and drainage of an epidural abscess with wide exposure of the middle fossa dura.

Surgical Technique

- Myringotomy and tube insertion are the initial management of choice.
- Close monitoring
- If the patient fails to respond to conservative management then a complete mastoidectomy should be performed when the patient is medically stable.

Epidural Abscess

Indications and Preoperative Period

- May occur secondary to acute coalescent mastoiditis or chronic suppurative otitis media with cholesteatoma erosion
- Otogenic source less common than paranasal sinuses
- May often be asymptomatic
- Signs and symptoms:
  - Low-grade fevers
  - Otalgia
  - Malaise
  - Deep temporal headache
  - Otorrhea
  - Bulging tympanic membrane
- Diagnosis made via fine-cut CT or MRI with contrast
- Consider MR venography to rule out lateral sinus thrombosis.

Surgical Technique

- An isolated epidural abscess secondary to mastoiditis can usually be evacuated by a complete mastoidectomy (see Chapter 134), with careful unroofing of the affected bony plates to expose but not enter the dura (Fig. 130.2).
- Adequate exposure will drain the abscess.
- Excess granulation tissue should be removed with blunt dissection.
- Purulent material and granulation tissue should be sent for immediate Gram stain, culture, and sensitivity testing.
- The mastoid is then irrigated with antibiotic solution.

Lateral Sinus Thrombosis

Indications and Preoperative Period

- May occur with an associated epidural or subdural abscess or otitic hydrocephalus (Fig. 130.3)[7]
- Symptoms:
  - Headache
  - Fever (classically, "picket-fence" spiking fevers)
  - Photophobia
- MRI and MR venography are considered the gold standard for diagnosis.
- IV antibiotic therapy should cover typical AOM flora but also cover gram-negative and anaerobic bacteria.

Surgical Technique

- Historically, the standard of care for lateral sinus thrombosis (LST) has been IV antibiotics and surgical intervention with or without anticoagulation.
- The surgical intervention consists of a tympanomastoidectomy with or without needle aspiration or thrombectomy (Fig. 130.4).
  - No improvement in prognosis has been noted after incising the sigmoid and removing the blood clot on recent studies.
  - Opening of the sinus plus removal of the clot is not necessary unless the sinus is grossly infected.
  - If incision and drainage and/or thrombectomy are performed, extraluminal packing of the sinus can help to control bleeding (Fig. 130.5).
- The role of postoperative anticoagulation is controversial.[8]
  - Preventing embolization and septic thrombi, possible reduction of neurologic sequelae, recanalization on follow-up imaging, and relative safety are some reasons cited by those supporting anticoagulation.

    - Some oppose routine use due to bleeding complications and evidence of recanalization without anticoagulation and recovery despite thrombus.[4]
- In cases of non-coalescent mastoiditis, a conservative approach, including immediate myringotomy, tube placement, and topical and IV antibiotics, is reasonable.
- The patient is monitored closely, and mastoidectomy and sigmoid sinus exploration are performed if the patient fails to improve.

Subdural Abscess (Empyema)

Indications and Preoperative Period

- Otitis media is a much less common source of subdural abscess than previously thought (9% in one large series).[5]
- Signs and symptoms:
    - Fever
    - Severe headache
- CNS findings:
    - Seizure
    - Somnolence
    - Eye deviation
    - Stiff neck
    - Sensory deficits
    - Hemiparesis
    - Papilledema
- High CSF pressure, pleocytosis, and increased polymorphonuclear leukocytes on LP

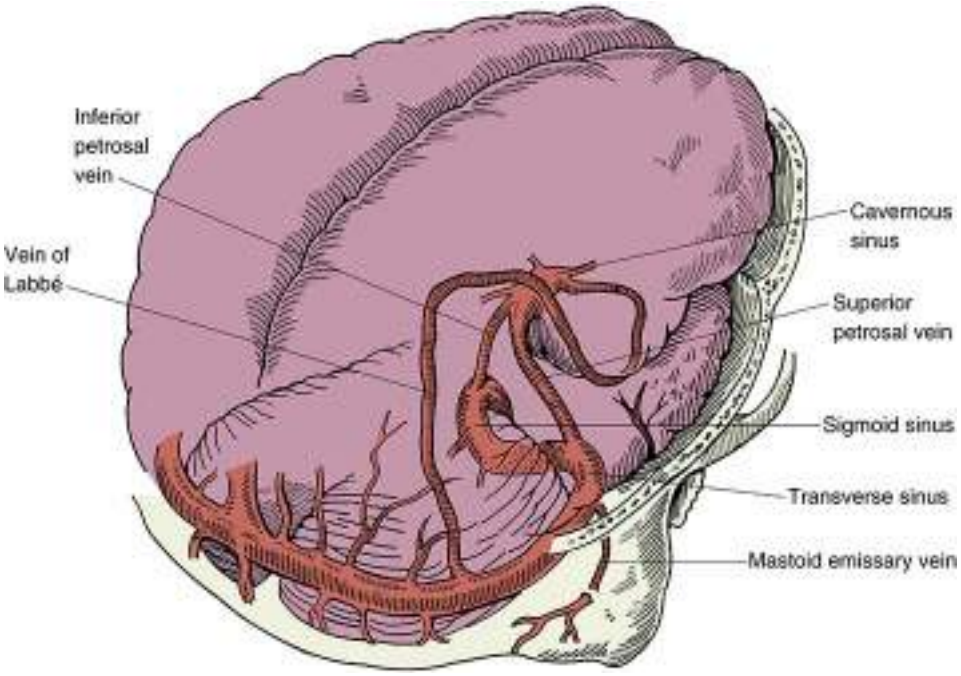

FIG. 130.3 Anatomic relationship between the dural sinuses and the temporal bone.

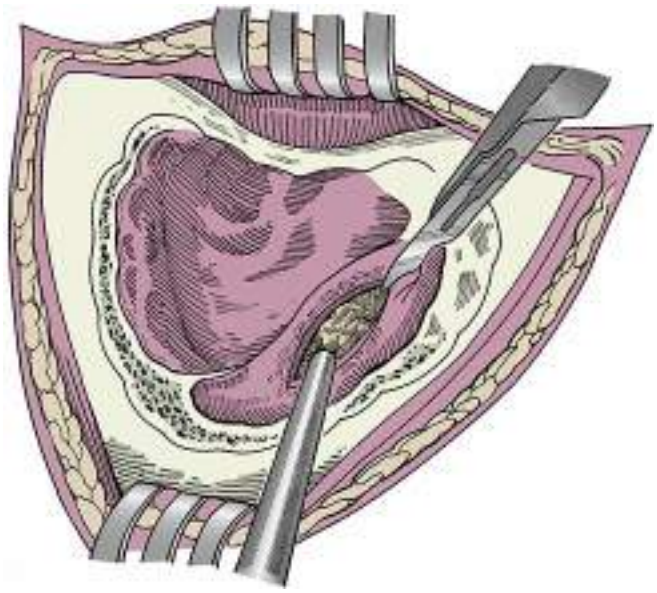

FIG. 130.4 Incision and drainage of a thrombophlebitic dural sinus.

- CT with contrast versus diffusion-weighted MRI for diagnosis

Surgical Technique

- Subdural empyema should be emergently evacuated and the frequently accompanying increase in intracranial pressure (ICP) carefully monitored via LP, along with IV antibiotics.
- Drainage can be achieved by burr holes, craniotomy, or CT-guided aspiration, in consultation with the neurosurgical service.
- A complete mastoidectomy with removal of excess granulation tissue is also indicated in these patients.

Brain Abscess

Indications and Preoperative Period

- Much more common in developing countries

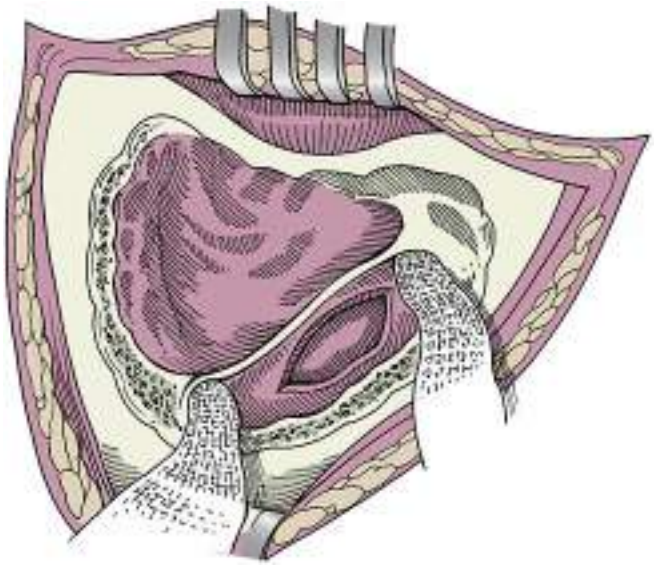

FIG. 130.5 Extraluminal packing is used to control bleeding from the dural sinus.

- Most commonly from an otogenic source and associated with cholesteatoma
- Temporal lobe is the most common location
- Indolent course may not include symptoms

- CNS signs:
  - Headache
  - Vomiting
  - Drowsiness
  - Seizure
  - Personality change
  - Meningismus
  - Vertigo
  - Nystagmus
  - Visual field deficits
- Papilledema, coma, and cardiovascular changes are ominous late signs.
- Mortality rates up to 40% have been reported.
- Broad-spectrum antibiotics are required.
- CT with contrast of the temporal bone and brain is diagnostic (may also consider MRI).
- Temporal bone imaging alone may miss an intracranial abscess; suspicion should prompt dedicated brain CT or MRI with contrast enhancement.

Surgical Technique

- The abscess itself must be addressed on an emergency basis before rupture, which can lead to septicemia and death.
- This is usually done by either burr holes or craniotomy by the neurosurgical team.
- After the abscess is addressed and the patient is stabilized, a mastoidectomy with removal of granulation tissue and purulent material is performed.
- Studies in the literature have described success by drainage of the abscess and treatment of the mastoid disease with a transmastoid approach.

- One study describes draining the abscess by a transmastoid approach by extending the mastoid posterior to the sigmoid, opening up the bony plate over the dura, and aspirating the contents of the abscess.
  - All of the patients were treated with long-term IV antibiotics; only one patient required further surgery to remove the residual abscess.
- Sennaroglu and Sozeri reported draining the abscess via mastoidectomy after preparing the dura with povidone-iodine, followed by irrigation and placement of drainage tubes, which are used for ongoing irrigation until the cavity shows collapse on follow-up CT.
- Antibiotics are adjusted to the results of the aspirated culture.

Otitic Hydrocephalus

Indications and Preoperative Period

- Believed to occur secondary to lateral sinus thrombosis, although the exact mechanism is unknown[9]
- Symptoms:
  - Nausea, vomiting
  - Diplopia
- Signs:
  - Papilledema
  - Ipsilateral abducens nerve palsy
- LP: High opening pressure with otherwise normal CSF findings
- MRI and MR venography will demonstrate sinus thrombosis.
- Medical management similar to lateral sinus thrombosis
- Long-term sequelae are rare, but vision loss has been reported.

Surgical Technique

- The goal is the eradication of ear disease in conjunction with lowering the ICP.
- High-dose IV antibiotics should be administered, but anticoagulants are controversial.
- The type of surgery depends on the extent of the disease.
  - Intervention ranges from only complete mastoidectomy with myringotomy and tubes to requiring drainage of perisinus abscess or removal of infected clot.
  - Consideration should be given for ligating the internal jugular vein only if symptoms do not resolve despite adequate surgical and medical intervention.
- ICP should be treated with a combination of mannitol, acetazolamide/other diuretics, and steroids.
- There is controversy as to whether these patients should or should not undergo repeated LPs.

Petrous Apicitis/Gradenigo's Syndrome

Indications and Preoperative Period

- Gradenigo's triad: suppurative otitis media, abducens paralysis, deep facial/retrobulbar pain
  - Only 42% may have the complete triad.
- The petrous apex generally communicates with mastoid air cells, providing a route of spread for infection.
- May occur with other intracranial complications
- Cavernous sinus and trigeminal ganglion may also be involved.
- CT with contrast can show bony erosion, fluid-filled opacification, and possibly abscess.
- MRI helps distinguish petrous apicitis from other lesions, such as cholesteatoma, cholesterol granuloma, and arachnoid cysts.[10]

Surgical Technique

- If a trial of IV antibiotics does not lead to the resolution of petrositis, or if imaging shows areas of coalescent bone erosion, surgical management is indicated.
- Several reports in the literature have reported detailed resolution of Gradenigo's syndrome with high-dose broad-spectrum antibiotics with or without myringotomy with tube placement.
- The petrous apex has been described as the least surgically accessible portion of the temporal bone.
- Mastoidectomy and tympanostomy tube placement may be sufficient to allow drainage of the petrous apex air cell tracts.[5]
- Surgical approaches to an inflamed petrous apex depend on the patient's hearing status and temporal bone anatomy and on the surgeon's training and include the infralabyrinthine, transcanal infracochlear, transsphenoidal, translabyrinthine or subtotal petrosectomy, and middle fossa approaches (discussed in Chapter 143).

Postoperative Care/Complications

- Postoperative complications and care following mastoidectomy are described in a previous chapter on mastoidectomy in Chapter 134.
- Monitor for CSF otorrhea/rhinorrhea, cerebral edema, seizure-increased ICP, and pneumocephalus.
- Consider intensive care unit monitoring for 24 hours postoperatively.
- Consider anticoagulation prophylaxis given prolonged bed rest and possible neurologic impairment.
- Neurosurgery and infectious disease consultation are recommended.
- Long-term IV antibiotics may be indicated.

Evidence-Based Medicine Question

What is the role of thrombectomy and anticoagulation in the management of lateral sinus thrombosis?

It is generally agreed that the initial management of lateral sinus thrombosis involves IV antibiotic therapy and tympanomastoidectomy. However, the role of surgical thrombectomy and/or postoperative anticoagulation is controversial. Manolidis[1] reported good outcomes with embolectomy or sinus resection. Ropposch et al.[2] and Sitton and Chun[3] recently showed that incising the sigmoid sinus and removing the clot had no improvement in prognosis. Regarding anticoagulation, Bradley et al.[4] showed no difference in mortality in the non-anticoagulated group versus anticoagulation. Proponents of anticoagulation suggest possibly increased recanalization rates, but this was not shown in a recent systematic review by Wong et al.[5] In addition, although anticoagulation is relatively safe, it is not without its own morbidity as shown by Funamura et al.[6] who had a patient with intracranial hemorrhage while on anticoagulation. Overall, it is unclear whether anticoagulation or thrombectomy truly affects recanalization rates in these patients, as all of the aforementioned series are very small. Better research is necessary before a definitive conclusion can be made.

Editorial Comment

Intracranial complications of acute and chronic otitis media have a higher incidence in the first 2 decades of life. This includes both extracranial and intracranial complications. Children remain more susceptible to otitis media likely due to lower resistance and more frequent exposure to the causative bacteria, particularly *S. pneumonia* and *H. influenza*. Persons presenting quite ill, with headaches and nuchal rigidity, are suspected as having meningitis. Prior to obtaining a needed LP, CT imaging initially should be obtained to verify the status of the intracranial space. Identifying a focal abscess warrants urgent neurosurgical consultation and drainage. Aspiration of the cavity provides fluid for Gram stain and culture.

Coalescent mastoiditis describes mucoperiosteal disease in the mastoid bone causing a breakdown of the septae or cell walls. This suggests an aggressive infection that can readily spread beyond the confines of the temporal bone. Many of the particular complications outlined in this chapter have a root source based on an infection in the mastoid. Evacuation of infected mucosa and opacified air cells along with middle ear ventilation with tympanostomy tubes are core to reversing the disease.

Review Questions

1. A 40-year-old male with a chronic draining left ear presents to your office with an intense headache and difficulty with abducting his left eye, and he is otherwise stable. How would you manage this patient?

   a. IV antibiotics

   b. IV antibiotics with myringotomy and tube placement

   c. CT only

   d. MRI only

   e. **CT and MRI**

2. A 7-month-old male with meningitis was recently discharged from the hospital. His parents noticed that he was not responding to sounds appropriately, and he previously passed his newborn hearing screen. An outpatient hearing test showed bilateral severe to profound hearing loss. An MRI was also ordered, which showed fibrosis in the cochlea. How would you manage this patient?

   a. Stat CT scan

   b. Repeat CT scan in 1 month.

   c. Repeat MRI in 1 month.

   d. Discuss hearing aids.

   e. **Discuss a cochlear implant.**

3. A 65-year-old male presents with high fever, headache, and nuchal rigidity. A CT scan is sometimes indicated prior to lumbar puncture in patients with suspected meningitis due to the risk of cerebral herniation. Current practice guidelines suggest a CT scan prior to a lumbar puncture in all of the following instances, except

   a. New onset seizure

   b. Papilledema

   c. Focal neurologic deficit

   d. **Chronic obstructive pulmonary disease**

   e. Immunocompromised state

4. Which intracranial complication is thought to be the cause of otitic hydrocephalus?

   a. **Lateral sinus thrombosis**

   b. Petrous apicitis

   c. Epidural abscess

   d. Subdural abscess

   e. Brain abscess

Myringoplasty and Tympanoplasty

Rebecca Chiffer, and Douglas Chen

Introduction

Myringoplasty and tympanoplasty are surgical procedures designed to address pathology of the tympanic membrane and the middle ear, respectively. Both procedures restore the integrity of a perforated tympanic membrane, while tympanoplasty also addresses pathology in the middle ear, such as chronic infection, cholesteatoma, or ossicular chain problems. This most often implies and requires raising a tympanomeatal flap to facilitate middle ear manipulation. Zollner[1] and Wullstein[2] provided a classification of tympanoplasty based on the type of ossicular chain reconstruction required.

Acute tympanic membrane perforation or laceration may occur from a variety of causes. Local trauma, such as a slap on the ear, a cotton-tipped applicator inserted too far in the external canal, or barotrauma can cause a perforation of the tympanic membrane. Water compression, either from diving, falling onto a body of water, a wave hitting the ear, or even forceful irrigation during cerumen removal can also cause trauma. After acute trauma, the tympanic membrane may heal spontaneously or may require myringoplasty only. In contrast, patients requiring tympanoplasty often have a long-standing history of hearing loss, tympanic membrane perforation, and/or chronic otitis media with or without otorrhea.

Tympanoplasty and myringoplasty aim to eliminate recurrent disease, provide a dry ear canal and middle ear space with an intact tympanic membrane, and maintain or improve hearing. Achieving an intact tympanic membrane eliminates the need for patients to maintain strict water precautions.

Key Operative Learning Points

- The most important factor in the success of tympanoplasty, regardless of method, is the skill and precision of the surgeon.
- Anticipate and inform patients who may not achieve successful tympanoplasty results, including those with multiple failed previous procedures, persistent eustachian tube dysfunction, severe contralateral ear disease, or abnormalities of the soft palate.
- In any technique, rimming the edges of the perforation is essential to ensure adequate healing.
- Cartilage butterfly grafts avoid canal incisions, though these must be precisely sized to the perforation to ensure a secure fit.
- Leaving remnants of squamous epithelium medial to the graft, or tucked edges of canal skin, can result in intratympanic or canal cholesteatoma.
- Inadequate enlargement of the bony canal, and/or placement of a lateral graft onto the anterior or inferior canal wall, creates a high risk of blunting.
- Injury to the chorda tympani nerve results in disturbance in taste noticeable to the patient.
- Diligent postoperative care is necessary to recognize and treat early or late complications.

Preoperative Period

History

1. History of present illness
   a. Hearing loss: Sudden versus gradual
   b. Drainage: Chronic or recurrent
   c. Trauma
   d. Pain should raise concern for other processes in the head and neck

and prompt a thorough evaluation.

e. Vertigo should be thoroughly investigated prior to surgery to avoid operating on an ear with an ongoing vestibulopathy.

2. Past medical and surgical history

a. Chronic or recurrent ear infections

b. Previous ear surgeries, including PE tubes

c. History of cleft palate surgery should raise concern for Eustachian tube dysfunction and chronic or recurrent infections.

3. Medications

a. Anticoagulants need to be addressed prior to surgery and stopped if possible.

4. Allergies

a. Severe seasonal allergies should raise concern for Eustachian tube dysfunction.

5. Social history

a. Smoking can lead to complications with general anesthesia and wound healing.

Physical Examination

Physical examination with a microscope enables thorough inspection of the canal and middle ear space.

1. Problematic ear

a. Size of perforation: Small, near-total, total

b. Location of perforation: Central versus marginal

1) Marginal perforations with a "trail sign," or keratin migrating from the edge, suggest squamous epithelium in the middle ear.

c. Draining versus dry

d. Evaluate status of middle ear mucosa, if possible: Cholesteatoma, mucosal hypertrophy, or extensive granulation tissue suggest the need for concurrent mastoidectomy.[3]

2. Contralateral ear

a. Look for signs of previous surgery and/or chronic Eustachian tube dysfunction, such as retraction of the tympanic membrane and negative middle ear pressure (atelectasis), otitis media with effusion, and/or tympanosclerosis, which may indicate chronic infections.

b. Evidence of otitis media with effusion or negative middle ear pressure (atelectasis) in the contralateral ear demonstrated to be poor prognostic findings in a study of pediatric patients by Collins et al.,[4] and surgery in these children was less successful.

Audiogram

Not all tympanic membrane perforations are accompanied by conductive hearing loss. Small perforations may be associated with normal hearing, whereas a near-total perforation may cause a 35- to 40-dB conductive hearing loss. This amount of hearing loss in the setting of a small perforation should raise concern for a disrupted or fixed ossicular chain. The potential need for ossicular chain reconstruction must be anticipated prior to surgery.

Patients with mixed hearing loss require a different approach. Although surgery may close the air-bone gap, a sensorineural component may still require amplification, and surgery may not be in the patient's best interest. If, however, a severe mixed loss precludes adequate gain and comfort from a hearing aid, surgical correction of the conductive component may better facilitate aural rehabilitation.

Imaging

1. Computed tomography (CT) scan: Not routinely necessary prior to tympanoplasty or myringoplasty, unless evaluating for cholesteatoma and/or concurrent mastoid disease

2. Magnetic resonance imaging (MRI): Not routinely necessary prior to tympanoplasty or myringoplasty; however, should be included if patient complains of chronic imbalance or vertigo or for evaluation of asymmetric sensorineural hearing loss

Indications

1. Repair of tympanic membrane (TM) perforation to lift water restrictions

2. Prevention of recurrent otorrhea and/or recurrent ear infections

3. Attempt to improve hearing

Contraindications

1. Extreme caution must be exercised if planning to operate on an only-hearing ear. Unless significant active disease exists, despite maximal medical therapy, aural amplification should be recommended.

2. Avoid operating on an ear with an active vestibulopathy.

Preoperative Preparation

1. An attempt should be made to achieve a dry ear prior to surgery with otic drops and/or systemic antibiotics.

2. Preoperative medical clearance prior to anesthesia is recommended for all patients.

3. Preoperative testing (laboratory tests, electrocardiogram, chest radiograph) per hospital guidelines

4. Informed consent

   a. Risks: Worsening of hearing or complete hearing loss, vertigo, temporary or permanent changes in taste due to disruption of the chorda tympani nerve, facial paresis or paralysis, infection, failure of the graft to heal causing persistent or recurrent perforation, and/or numbness of the superior auricle if undergoing a postauricular approach

5. Review of all previous otologic operative reports

   a. Reminder: After several procedures, local tissue for grafting may not be readily available and alternative sources should be considered, such as perichondrium, periosteum, or even tissue from the

contralateral ear.

6. Determine if the patient will be compliant and return for postoperative care.

Operative Period

Anesthesia

1. Sedation: Intravenous (IV) sedation with local anesthesia is an option for uncomplicated tympanoplasty or myringoplasty with limited dissection, as long as the patient is cooperative and willing to remain immobile.

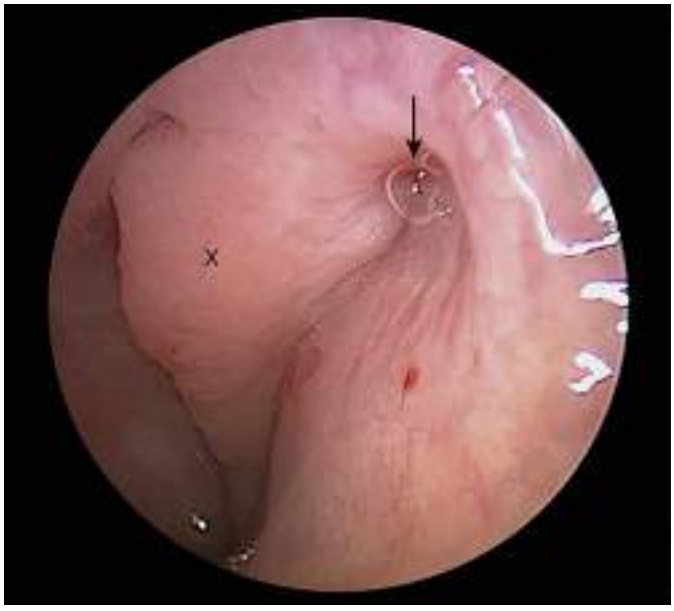

FIG. 131.1 With a Lempert speculum, local anesthetic is injected in a four-quadrant fashion into the external auditory meatus. The needle tip is placed just lateral to the bone-cartilage junction, and the solution is infiltrated until the skin blanches. Redrawn from Bluestone CD, Stool S: Atlas of Pediatric Otolaryngology, 3rd ed: Philadelphia, PA: WB Saunders; 1996.

2. General anesthesia: We perform the majority of our cases under general endotracheal anesthesia to ensure that the patient remains still for the entire procedure.

3. Local anesthesia: Four-quadrant external canal block injected at the bony-cartilaginous junction with 1% to 2% lidocaine with 1:100,000 epinephrine (Fig. 131.1). Additional injection behind the ear should be infiltrated for harvesting fascia or a planned postauricular approach.

Positioning

- Bed turned 180 degrees with feet toward anesthesia
- Supine with head turned to the contralateral side

Perioperative Antibiotic Prophylaxis

- Generally not indicated for routine tympanoplasty or myringoplasty
- For grossly infected ears or if a prosthesis will be placed, one dose of Ancef, or clindamycin if the patient is allergic to penicillin, may be given.

Monitoring

- We use facial nerve monitoring for nearly all otologic cases being performed under general anesthesia; however, nerve monitoring is elective and not considered the standard of care for myringoplasty or tympanoplasty.

Instruments and Equipment to Have Available

- Routine middle ear instrument set
- Ossicular prostheses if ossicular reconstruction is planned
- High-speed drill if a lateral graft for canaloplasty and/or mastoidectomy is planned

Key Anatomic Landmarks

- Temporal bone anatomy
  - Tympanomastoid and tympanosquamous suture lines
  - Linea temporalis
  - Bony-cartilaginous junction of the external auditory canal
- Tympanic membrane components
  - Pars tensa and pars flaccida
  - Outer epithelial layer
  - Middle fibrous layer
  - Inner mucosal layer
  - Fibrous and bony annulus
- Ossicles
  - Malleus: Head, neck, manubrium (handle), lateral process, anterior process
  - Incus: Short and long processes, body
  - Stapes: Capitulum, anterior and posterior crura, footplate
- Facial Nerve Anatomy
  - Tympanic and mastoid segments

Prerequisite Skills

- Surgeons should be proficient at raising tympanomeatal flaps, harvesting cartilage grafts, and precise middle ear dissection techniques.

Operative Risks

- Worsening of hearing or complete hearing loss
- Tinnitus
- Vertigo, usually temporary
- Taste disturbance due to injury to the chorda tympani nerve

- Facial paresis or paralysis: Allow local anesthesia to wear off before proceeding with further testing and/or exploration.
- Graft failure, causing persistent perforation or recurrent middle ear infections
- Infection of the skin incision

Surgical Technique

Surgical technique for tympanic membrane repair can be categorized as inlay, underlay (medial), and overlay (lateral) procedures. All of these techniques are successful in experienced hands. Inlay or medial grafts are generally chosen for patients with infrequent otorrhea, or for small nonmarginal perforations, or when there is minimal middle ear disease. Lateral grafts are preferred in cases of prior failed surgeries, total or near-total perforations, or in patients with severely diseased tympanic membranes with myringosclerotic plaques or remnants that must be resected prior to reconstruction.

Myringoplasty by definition addresses only the tympanic membrane, whereas tympanoplasty incorporates inspection of the middle ear and reconstruction of the ossicular chain when necessary. If limited mobility of the lateral chain and/or fixation of the incus-stapes complex is noted, then separation of the incudostapedial joint or further inspection for malleal head fixation may be necessary. Other common pathologic processes found in the middle ear include:

- Granulation tissue and hyperplastic mucosa
  - Require reconstruction of an aerated middle ear space and assessment of Eustachian tube patency, with a need for possible mastoidectomy
- Cholesteatoma
  - Requires complete and meticulous removal, with a need for possible mastoidectomy

FIG. 131.2 The edges of a fresh stellate perforation are everted from the medial surface of the tympanic membrane. When squamous epithelium is no longer present in the middle ear, the edges are reapproximated.

- Tympanosclerosis
  - A brittle chalk-like plaque found within the tympanic membrane, the ossicles, and on the medial wall of the middle ear. Sclerosis should be removed prior to tympanic membrane reconstruction if it is restricting the mobility of the TM.

Ossicular chain reconstruction and mastoidectomy details can also be found in Chapters 132 and 134, respectively.

Myringoplasty

- For small or acute traumatic tympanic membrane perforations or lacerations:
  - Unfold the edges of the TM to remove squamous epithelium from the medial surface (Fig. 131.2).
  - Place small pieces of Gelfoam soaked in ciprofloxacin solution, with or without dexamethasone, medial to the laceration or perforation.
  - Place a cigarette paper patch, Steri-Strip, or silk patch on the lateral surface of the TM (Fig. 131.3).

- For small chronic perforations:
  - Apply topical phenol or trichloroacetic acid to the edges of the perforation with a cotton-tipped or phenol applicator.
  - Freshen the margins of the perforation with a sharp pick to remove any squamous epithelium that may have migrated under the medial surface of the TM. This also stimulates bleeding from the local vascular supply (Fig. 131.4).
  - Apply a patch to the lateral surface of the tympanic membrane.
- If paper patching has failed, small central perforations may be repaired using autogenous tissue:
  - Prepare the perforation as noted previously; then use adipose tissue from the earlobe to dumb-bell through the perforation. Alternatively, use compressed and dehydrated loose areolar tissue or fascia from the postauricular region.
- For medial myringoplasty grafts, place Gelfoam through the perforation into the middle ear space to act as a bolster. Then place a fascia graft medial to the perforation and place Surgicel or Gelfoam lateral to the grafted perforation to further secure the graft. Fill the medial external canal with additional Gelfoam (Fig. 131.5).

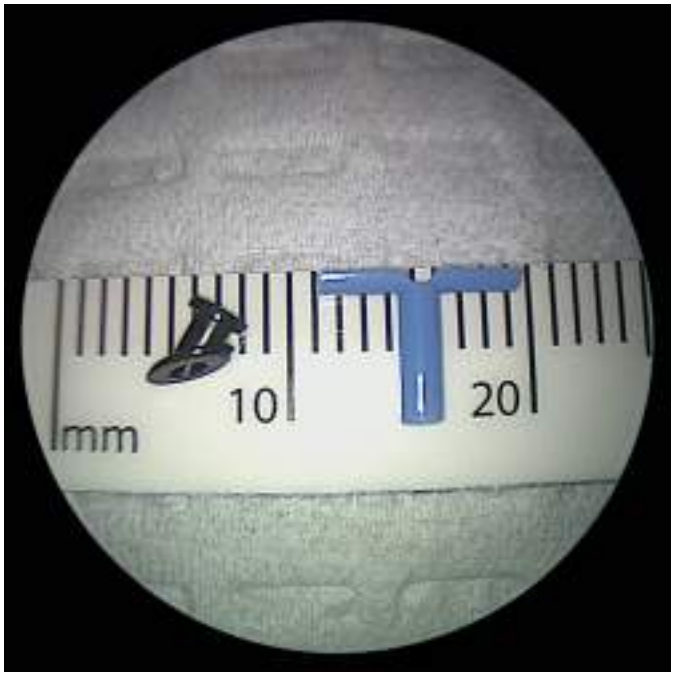

FIG. 131.3 The edges of the stellate perforation are approximated and supported with a cigarette paper patch or a Steri-Strip.

FIG. 131.4 The edge of the perforation is circumferentially freshened to remove epithelium from the medial margin and promote local bleeding. The *inset* emphasizes that the medial edge of the perforation must be removed to eliminate squamous epithelium from the middle ear.

Tympanoplasty

1. **Cartilage inlay technique (Videos 131.1 and 131.2)**

- Described in 1998 by Eavey, termed the cartilage butterfly graft for use in small to medium tympanic membrane perforations.[5] This is a transcanal approach with specific advantages:
  - Less postoperative pain since canal incisions are avoided
  - Immediate hearing improvement since canal packing is avoided
  - Shorter operative times, which generally translates to lower expense
- In order for this technique to be successful, all edges of the perforation must be visualized through the canal, either directly using an operating microscope or indirectly using a middle ear endoscope.

FIG. 131.5 **A,** Myringoplasty of the right tympanic membrane with a posteroinferior perforation. The edges of the perforation are freshened, Gelfoam is placed in the middle ear, and an areolar or compressed adipose tissue graft *(stippled area)* is placed through the perforation, positioned medial to the tympanic membrane, and supported by the Gelfoam. **B,** Gelfoam supports the graft on the medial surface of the tympanic membrane.

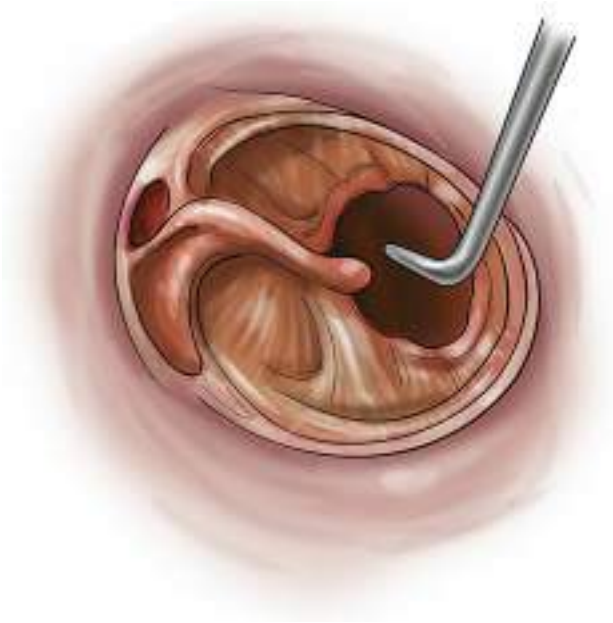

FIG. 131.6 A right-angled hook is used to estimate the size of the perforation. Note the exposed malleus and tympanosclerosis serve to interlock the graft. Adapted from Eavey RD: Inlay tympanoplasty: the cartilage butterfly technique. Laryngoscope 1998.108:657-661

- Note, although Eavey's original article describes this technique as a tympanoplasty, since this procedure is done through the TM and a tympanomeatal flap is not raised, some experts consider this a

myringoplasty technique.

- Positioning and local anesthesia are the same as described previously. Infiltrate the tragus with local anesthesia as well.
- Rim the perforation with a curved pick to remove a thin layer of squamous epithelium and freshen the edges for the graft. This step may slightly enlarge the perforation; be careful not to enlarge it beyond transcanal visualization.
- Precisely measure the perforation size with a right-angled instrument or a round knife (Fig. 131.6).
- Harvest tragal cartilage (Video 131.3):

FIG. 131.7 Tragal cartilage is harvested with perichondrium preserved on one or both surfaces. The graft size and shape are reproduced using the same right-angled hook previously used to measure the perforation but deliberately exaggerated by 1 to 2 mm. A blade scores the entire cartilage edge circumferentially, and the edges curl apart, creating an appearance similar to butterfly wings. Adapted from Eavey RD: Inlay tympanoplasty: the cartilage butterfly technique. Laryngoscope 1998.108:657-661

  - Make an incision in the posteromedial aspect of the tragus with a no. 15 blade, making sure to incise through the skin, soft tissue, and cartilage in one motion. This ensures a clean edge and preserves the tragal cartilage dome for cosmesis. Dissect the cartilage free from the soft tissue and remove using a sharp scissor. Perichondrium is left on one or both sides of the cartilage graft. Close the incision with 1 to 2 interrupted plain gut sutures.
- Size the cartilage:

- Cut the cartilage 1 to 2 mm larger than the perforation to allow for the trough. Use the same instrument that was used to size the perforation to size the cartilage.
- Cut the cartilage to the exact shape of the perforation. If the perforation is oval, for example, then the graft should also be oval.
- Sizing the cartilage is an important step; a graft too large will not snap into the perforation, whereas a graft too small will risk its falling into the middle ear.

- Cut a trough:
  - Use a no. 15 or curved beaver blade to cut a 2-mm deep circumferential trough into the edge of the cartilage, being sure to keep the flanges equal width the entire way around the graft (Fig. 131.7).
- Introduce the cartilage graft through the canal and carefully place into the perforation such that one flange is medial to the rim of the perforation and the other flange, with perichondrium, is lateral (Fig. 131.8).
- Check all edges to ensure that the medial flange is medial to the drum remnant in all locations, such that when the surgeon gently presses on the center of the cartilage graft, then entire drum moves.
- Slight variations to this technique have been described for large or marginal perforations.

2. **Lateral grafting technique**[6] **(Video 131.4)**

- Position as described previously and shave the hair 1 to 2 cm superior and posterior to the auricle. Prep and drape in usual sterile fashion and inject local anesthesia as described previously. Infiltrate the postauricular region as well.
- Under the operating microscope, rinse excess betadine and local anesthetic from the canal and middle ear, and create transmeatal vascular strip incisions along the tympanomastoid and tympanosquamous suture lines.(Fig. 131.9).
- A semilunar incision connecting the vascular strip incisions can be made, if the surgeon prefers, immediately lateral to the annulus. We advocate making only the vascular strip incisions, therefore allowing

the lateral epithelial layer of the tympanic membrane to be elevated off of the TM remnant with the vascular strip.

FIG. 131.8 The graft in place viewed transcanal with one edge elevated for purposes of illustration. From Eavey RD: Inlay tympanoplasty: the cartilage butterfly technique. Laryngoscope 108:660, 1998.

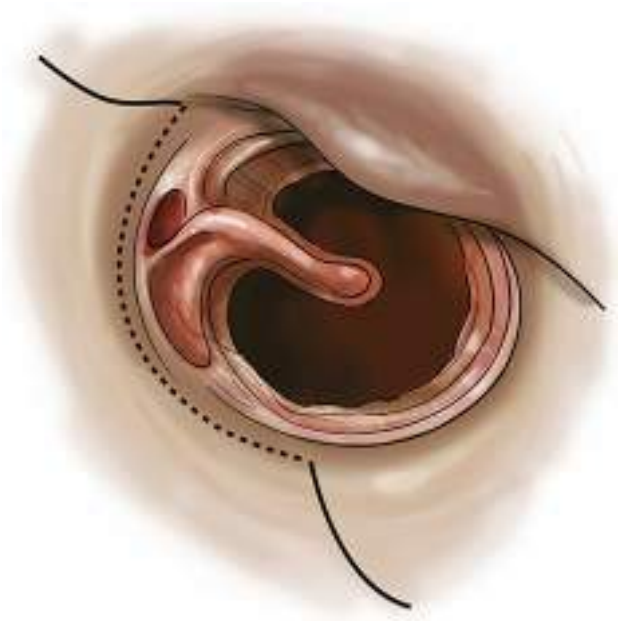

FIG. 131.9 Vascular strip incisions are made along the

tympanomastoid and tympanosquamous suture lines. From Fayad JN, Sheehy JL: Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 121.

- Make a postauricular skin incision several millimeters posterior to the postauricular crease to allow for proper skin closure at the end of the procedure. The inferior extent of the incision is just inferior to the lobule; always be careful not to extend beyond the mastoid tip and risk injury to the facial nerve.

FIG. 131.10 The periosteum and canal skin are elevated from medial to lateral starting at the annular ligament. From Fayad JN, Sheehy JL: Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

- Continue soft tissue dissection medially through the subcutaneous tissue with either a knife or electrocautery and anteriorly in the plane of the loose areolar tissue overlying the temporalis fascia until the posterior canal skin is several millimeters thick. Place a self-retaining retractor to facilitate exposure and hemostasis.

- Harvest temporalis fascia:
  - Make a 2-cm incision through the fascia, but not through muscle, at the inferior extent of the temporalis. Use a Freer elevator to elevate the fascia off the underlying muscle; then cut a 2 × 2 cm piece of true fascia to use for grafting.
  - Alternatively, the loose areolar tissue (fool's fascia) overlying the true fascia may be used as graft material if it is sufficiently thick and well defined.
  - Immediately spread the fascia on a cutting block and clean off any remaining muscle or adipose tissue; then press the fascia and allow it to dry under an operating lamp.
- Make periosteal incisions along the linea temporalis from the ear canal, anteriorly, to the skin incision, posteriorly, then carry the periosteal incision inferiorly, following the skin incision to create the shape of a "7" or a "T."
- Elevate the periosteal flap and place it within the self-retaining retractor with the auricle.
- Under the operating microscope, complete the elevation of the vascular strip with a Freer elevator. Reflect the vascular strip out of the ear canal and place it within the self-retaining retractor.
- Elevate the remaining canal skin and periosteum in a medial to lateral direction using a large round knife, starting at the annulus and elevating laterally to the bony-cartilaginous junction (Fig. 131.10). The canal skin is kept attached at the bony-cartilaginous junction and gently folded laterally out of the canal. In Sheehy's classic description, the outer squamous layer of the tympanic membrane remnant is elevated with the vascular strip; however, if this layer remains attached, it must be removed and discarded separately, either before or after enlarging the bony canal.
- Enlarge the bony canal with a size 3 cutting bur, followed by a size 2 diamond bur, along with continuous suction irrigation to remove the anterior and inferior bony canal bulges (Fig. 131.11).

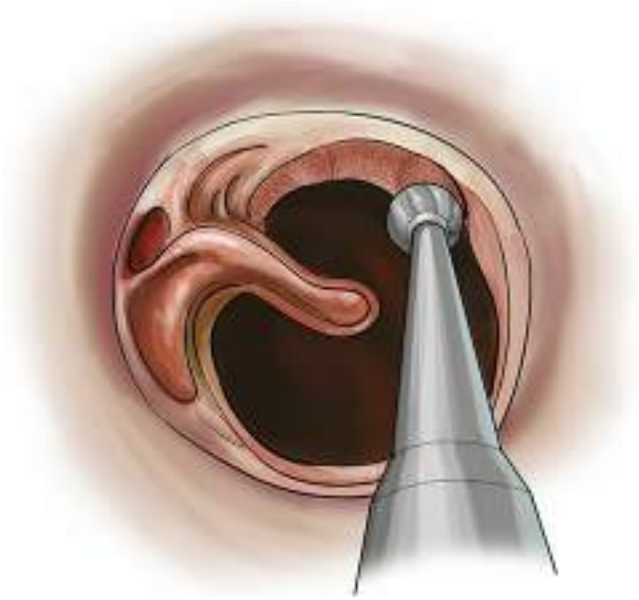

FIG. 131.11 A drill and continuous suction-irrigation are used to enlarge the bony canal and remove the anterior and inferior canal wall bulges. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

- It is very important to enlarge the canal medially and laterally enough to visualize the entire circumference of the annulus. Opening the anterior acute angle also helps prevent postoperative blunting. Care must be taken when drilling posteriorly to avoid the facial nerve and anteriorly to avoid drilling into the temporomandibular joint.

- Continue de-epithelialization:
  - Begin anteriorly with a round knife placed along the bony annulus and drum remnant, and scrape the squamous epithelium away circumferentially superiorly and inferiorly, leaving the annular ligament and middle fibrous layer of the drum remnant intact.
  - Remove squamous epithelium along the rim of the perforation with a small cup forceps.
  - Pay close attention to the de-epithelialization process, since any trapped skin that remains medial to the laterally placed graft is at risk of developing into a middle ear or intratympanic cholesteatoma.
- For a total or near-total perforation, or if the fascia graft is unusually

thin, fill the middle ear with small Gelfoam pledgets to bolster the graft.

- For large perforations, the graft will be placed medial to the manubrium of the malleus. For small perforations in which the drum remnant surrounds the manubrium, either the surgeon can separate the remnant from the manubrium, or the graft can be placed lateral to the manubrium in a "lateral patch" technique.
- Trim the dehydrated fascia graft to an oval shape, measuring approximately 1.3 × 1.5 cm, and cut a slit into the graft at the 12 o'clock position to allow for placement medial to the malleus handle (Fig. 131.12).
- Dip the graft in saline just prior to insertion, then place the graft lateral to the annulus and de-epithelialized TM remnant (Fig. 131.13).
- In the presence of a perforation surrounding the malleus handle, tuck the slit medial to the exposed umbo and manubrium; then bring the edges of the fascial slit laterally to overlap each other, or alternatively, fold the anterior flap posteriorly over the remaining malleus (Fig. 131.14). Sheehy describes placing the graft such that the apex of the slit comes into contact with the tensor tendon.
- Place the remaining fascia along the annulus edge anteriorly and inferiorly, paying close attention to keep the graft off the bony canal, as this will cause postoperative blunting. Any excess graft is brought onto the posterior canal wall.
- If the malleus is absent, Sheehy describes an alternate technique in which two slits are cut into the fascia in order to create a fascial flap that can be tucked under the scutum and into the epitympanum. The remaining lateral fascial flaps are then swung into position to overlap the superior aspect of the graft and create a secure seal over the middle ear (Figs. 131.15 and 16).
- Once the graft is in good position, carefully unfold and replace the canal skin onto the bony canal (Fig. 131.17). Care must be taken to ensure that the edges of the epithelium are not folded under, as this can cause postoperative epithelial cysts.
- Place a dry, rolled up (cigar-shaped) piece of Gelfoam into the anterior sulcus. Alternatively, place a properly sized piece of thick Silastic

sheeting lateral to the graft to keep it in good position during the healing process. Lay Gelfoam pieces onto the graft or Silastic.

- Release the self-retaining retractors and replace the vascular strip to its posterior-superior position along the bony canal. We recommend then placing one suture to close the postauricular periosteal flap and stabilize the auricle.
- Examine the vascular strip transmeatally using a Lempert speculum to ensure that it was replaced to its original position and all epithelial edges are everted.
- Fill the ear canal with Gelfoam packing and place a cotton ball in the outer meatus.
- Close the periosteal flap with interrupted absorbable sutures, and close the skin incision in layers with absorbable sutures followed by skin glue. A mastoid dressing is applied for 24 hours.

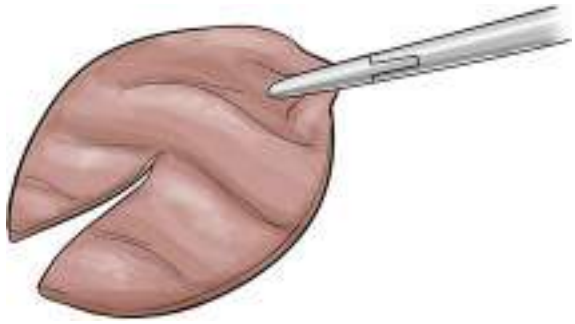

FIG. 131.12 The dehydrated fascia is trimmed to an oval shape, and a slit is cut to allow for placement medial to the manubrium. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

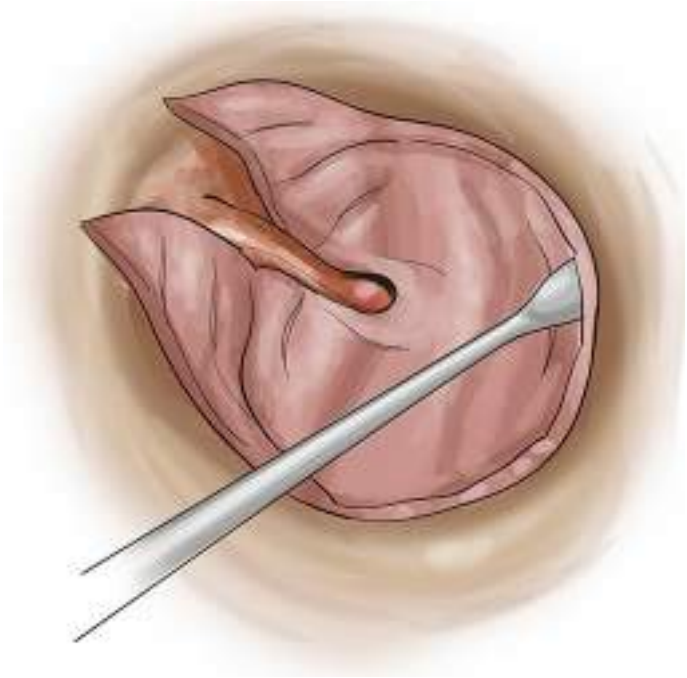

FIG. 131.13 The fascia graft is placed over the perforation, lateral to the annulus with the slit medial to the manubrium. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

3. **Medial grafting technique (Video 131.5)**

- Inject the external canal and rim the edges of the perforation as described earlier, to create fresh edges for the graft.
- Make vascular strip incisions, as described earlier, and connect with a semilunar incision approximately 4 mm lateral to the annulus.
- Make postauricular and periosteal incisions, and harvest a fascia graft, as described earlier.
- Retract the auricle and periosteum anteriorly with a self-retaining retractor, and elevate and retract the vascular strip out of the canal.
- Note: If the entire perforation can be visualized transcanal, then the surgeon may choose to proceed with medial grafting via a transcanal approach. A small postauricular incision is used to harvest fascia; however, the remainder of the procedure is performed via transcanal elevation of a tympanomeatal flap.

FIG. 131.14 The anterior flap can be folded posteriorly to cover the exposed manubrium. Alternatively, both flaps can be pulled to overlap each other, leaving only an exposed umbo. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

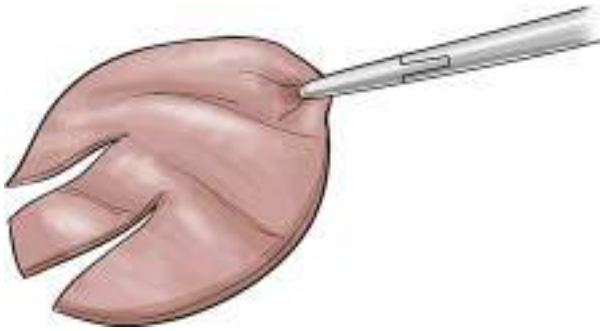

FIG. 131.15 In the case of an absent malleus, the fascia can be cut twice to create a flap to be tucked into the epitympanum. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

- Elevate the tympanomeatal flap and annulus with a round knife until the middle ear is entered. The chorda tympani nerve should be identified and preserved during this step.
- Inspect and palpate the ossicular chain as mentioned earlier.

- Dip a properly sized fascia graft in saline and place up against the medial aspect of the tympanic membrane perforation. Place Gelfoam packing within the middle ear space for support (Fig. 131.18).
- If the perforation incorporates the malleus handle, then the authors prefer the "over-under" grafting technique (Video 131.6):
  - Rim the perforation as before, and remove the periosteum and any drum remnant from the manubrium. It is helpful to make an incision through the periosteum of the malleus with a sickle knife in order to peel the tissue off from the umbo toward the lateral process. Once the manubrium is prepped, place the graft in the middle ear lateral to, or "over," the handle of the malleus and medial to, or "under," the annulus and drum remnant.

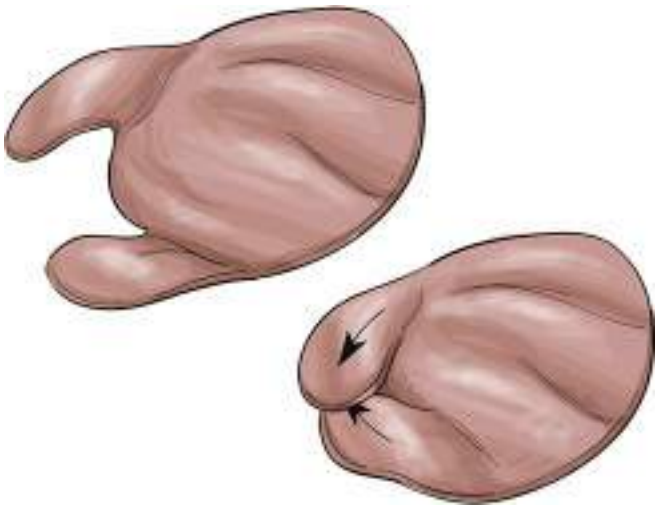

FIG. 131.16 Once the flap is tucked within the epitympanum, the edges are pulled to overlap each other and cover the edge of the graft. From Fayad JN Sheehy JL. Tympanoplasty—outer surface grafting technique. In Brackmann DE [ed]: *Otologic Surgery,* 3rd ed. Philadelphia, PA, Saunders, 2010, p. 123.

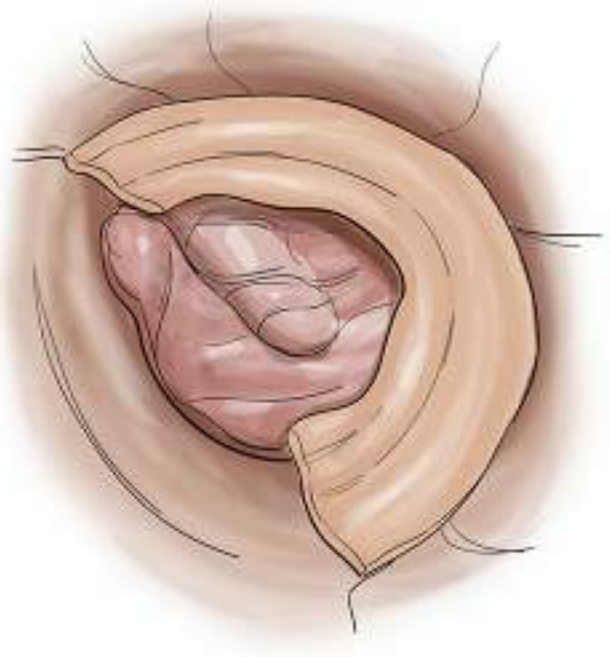

FIG. 131.17 The canal skin is replaced over the bone and is allowed to overlap the fascia by approximately 1 mm. From Fayad JN, Sheehy JL. Tympanoplasty—outer surface grafting technique. *In* Brackmann DE [ed]: Otologic Surgery, 3rd ed. Philadelphia, PA: Saunders; 2010, p. 123.

- Once the graft is in good position, return the tympanomeatal flap to its anatomic position, and place Gelfoam over the drum remnant and graft complex to hold it in position. If the over-under technique was used, then Gelfoam is also placed over the malleus handle to help adhere the new graft to the bone.
- Replace the vascular strip, and close the wound as described earlier. Place a cotton ball in the meatus and apply a mastoid dressing for 24 hours.

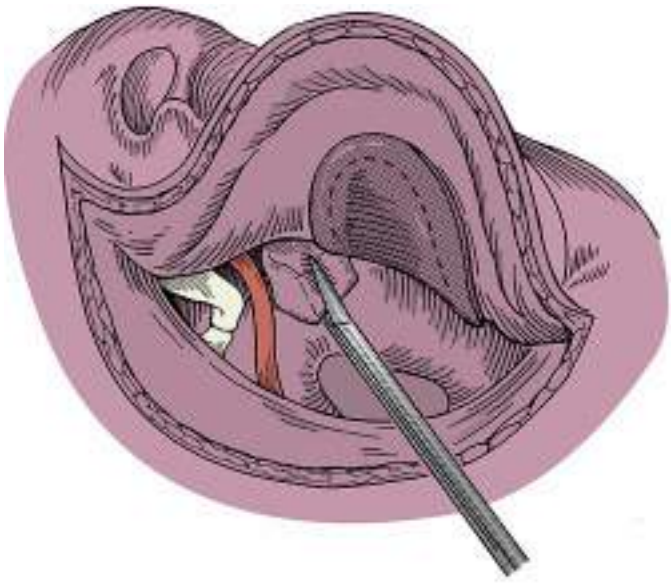

FIG. 131.18 Medial grafting technique. After the edges of the tympanic membrane perforation are freshened, a tympanomeatal flap is elevated. A tissue graft *(shaded area)* is positioned medial to the perforation and supported by packing Gelfoam into the middle ear.

Common Errors in Technique

- Inadequate rimming of the perforation will risk graft failure.
- Inadequate drilling of the bony canal during lateral grafting will inhibit exposure and risk postoperative blunting.
- Squamous epithelium left medial to the graft, or tucked under the canal skin flaps, will risk postoperative epithelial pearls or cholesteatoma.

Postoperative Management

- After myringoplasty, remove any packing in 7 to 10 days. After a lateral paper patch, monitor the patient until the patch migrates onto the skin of the bony canal wall, usually 6 to 12 weeks. Water precautions are maintained during this time.
- After cartilage inlay grafting, no drops are necessary and patients follow up in approximately 3 weeks. Water precautions are maintained until the graft heals, usually 3 to 4 weeks.

- After lateral or medial grafting, remove the mastoid dressing the next day. If skin glue was used, patients may get their postauricular incision wet in 24 hours; however, they should keep the inside of the ear dry from shower water by placing a cotton ball with Vaseline in the meatus. Topical eardrops are used twice daily, starting 1 week prior to their follow-up appointment, which is approximately 3 weeks after surgery. The drops help dissolve the Gelfoam packing and make it easier for the surgeon to suction out any remaining packing and blood clot on the first postoperative visit.
- After lateral grafting, the thick Silastic can be removed at the first postoperative visit or can be left in place as a stent for 6 to 8 weeks if there is concern for medial canal stenosis, blunting, or early graft lateralization.
- After lateral grafting, the ear canal may attempt to heal with cicatricial midcanal soft tissue stenosis, which can progress to complete stenosis and give the appearance of lateralization. Early in-office débridement and stenting should be performed if necessary, and any granulation tissue should be cauterized with silver nitrate.
- The tympanic membrane should be intact by the third postoperative week, and mobility can be checked with pneumatic otoscopy.
- Tuning fork testing can be performed on the first postoperative visit to obtain preliminary hearing results.
- Water restrictions are lifted once the graft appears well healed, usually by 2 months following medial grafting and by 3 to 4 months following lateral grafting.
- Audiometric testing is usually performed 2 to 3 months after surgery if the graft appears well healed.

Complications

- Graft failure
  - Results in recurrent or persistent perforation
  - More likely in patients who have had prior otologic operations and/or patients with significant mucosal disease or compromised

eustachian tube function

  - Identifying and counseling these patients preoperatively will lead to more realistic outcomes for both the patient and the surgeon.

- Lateralization
  - Usually occurs 6 to 12 months after lateral grafting
  - Occurs when the graft is not placed medial to the malleus
  - Patients will complain of reduced hearing.
  - Treatment usually requires reoperation.
- Blunting of the anterior sulcus
  - Occurs after lateral grafting in the anterior-superior quadrant from the formation of scar tissue
  - Patients complain of reduced hearing.
  - Prevented by complete removal of the anterior bony canal hump and ensuring the graft is placed directly onto the anterior annulus and not onto the anterior canal wall
  - Reoperation is necessary if hearing is significantly affected.
- Epithelial cysts
  - Canal cysts/pearls occur if skin flap edges are tucked under during closure.
  - Cysts can occur between the graft and the drum remnant if the squamous epithelium is not completely removed from the drum remnant prior to graft placement.
  - If noticed early, keratoma pearls can usually be opened and marsupialized in the office.

Alternative Management Plan

All patients should be offered the option of conservative management, including observation and/or amplification with a hearing aid.

If the conductive hearing loss is greater than 30 to 35 dB, the patient is often functionally compromised, and observation may not be reasonable.

Patients reluctant to undergo surgery may opt for aural amplification. Although this avoids the anesthesia and surgical risks, patients must accept the problems inherent with hearing aid use, including frequent battery replacement, instrument malfunction, background noise amplification, and occasionally noisy feedback.

Discussion

Evidence-Based Medicine Question

Is one tympanoplasty technique the best?

Outcomes of tympanoplasty cited in the literature average greater than 90% success rates regardless of method used, as long as the surgeon is skilled and careful in his/her technique. Rizer's large study in 1997 favors lateral grafts over medial grafts by a small but statistically significant margin,[7] although other authors found no significant difference. Other studies comparing all three methods (cartilage button, overlay, and underlay) cite no statistically significant difference in healing between techniques, with success rates ≥97%.[8] The question of which graft material is best was addressed in a recent systematic review, citing no statistically significant difference in hearing outcomes between materials, although cartilage, with or without perichondrium, gave a better morphologic outcome.[9] The general consensus in the literature is to consider cartilage tympanoplasty (i.e., button, island, or palisading) for high-risk perforations, such as those in an atelectatic ear or with cholesteatoma.[10]

The role of mastoidectomy in improving the success rate of tympanoplasty is controversial. McGrew et al.[3] found similar success rates in two groups of patients undergoing tympanoplasty with or without mastoidectomy; however, the authors note the need for revision surgery was decreased in patients who had undergone mastoidectomy at their initial procedure. We do not advocate routine mastoidectomy with tympanoplasty unless severe middle ear disease, or cholesteatoma, is found intraoperatively.

Editorial Comment

Myringoplasty and tympanoplasty remain the sole operative purview performed by otolaryngologists. There is a long learning curve to mastering interpretation of the tympanic membrane and middle ear findings and the operative techniques needed to successfully achieve an intact tympanic membrane, aerated middle ear space, and minimal conductive hearing loss. With experience in executing the intraoperative steps and managing the postoperative care, the surgeon comes to anticipate what intervention will be needed to achieve the desired outcomes.

The authors have shared their experience with operative repair of the tympanic membrane. They identified factors that are necessary to achieve successful grafting of the tympanic membrane. The status of the middle ear mucosa and functional integrity of the Eustachian tube are important issues that should be identified. Of paramount importance are the skills and experience of the surgeon. There are key steps in executing tympanic membrane repair that must be precise. In lateral graft techniques, placement of a healthy fascial graft onto but not extending beyond the annulus minimizes the complication of blunting and persistent conductive hearing loss. It was pointed out that despite restoration of the conductive component of a mixed hearing loss, amplification may still be necessary due to the residual sensorineural component. The patient should be made aware during the discussion of the procedure of the potential limitations of the surgery.

On occasion a staged procedure is necessary in which efforts are made to initially obtain an intact tympanic membrane and potential middle ear space by placing Silastic sheeting in the middle ear. Anticipating the need for this course of action should be shared with the patient when the operative procedure and postoperative course are explained.

As mentioned, surgery of the tympanic membrane is often done in conjunction with mastoidectomy and ossicular chain reconstruction. The reader is encouraged to review Chapters 132 and 134 for more information about ossicular chain reconstruction and mastoidectomy.

Review Questions

1. Which of the following is a contraindication for tympanoplasty?

   a. Active mucoid drainage

   b. **Occasional episodes of vertigo of unknown origin lasting less than 30 seconds**

   c. A 55 dB conductive hearing loss

   d. Mixed hearing loss

2. Rimming of the perforation is a required step in which of the following tympanoplasty techniques?

   a. Cartilage inlay grafting

   b. Underlay grafting

   c. Overlay grafting

   d. **All of the above**

3. Blunting after lateral grafting can be avoided by

   a. Adequate rimming of the perforation

   b. Removal of the fibrous annulus

   c. **Removal of the anterior bony canal bulge**

   d. Placement of the graft lateral to the manubrium

4. Which of the following is a risk factor for postoperative intratympanic cholesteatoma?

   a. **Inadequate de-epithelialization of the drum remnant**

   b. Concurrent mastoidectomy

   c. Separation of the incudostapedial joint

   d. A near-total perforation

Ossicular Chain Reconstruction

Douglas M. Hildrew, and Barry Hirsch

Introduction

Conductive Hearing Loss

Conductive hearing loss results from restriction of sound wave energy in displacing the basilar membrane of the organ of Corti. Conductive hearing loss not of middle ear or tympanic membrane origin can result from obstruction in the external auditory canal and possibly from fluid distention within the inner ear, such as that seen in early Meniere's disease. Inner ear conductive hearing loss also occurs when a "third window" exists in the otic capsule. Dehiscence of the superior semicircular canal provides a site for expansion of inner ear fluid, which prevents the fluid wave from providing full stimulation to the basilar membrane of the cochlea. This may result in conductive hearing loss even though acoustic reflexes will still be present.

Conductive hearing loss of middle ear origin may be congenital or acquired and results from ossicular chain fixation, erosion, dislocation, or fracture. Mass effect from reactive soft tissue processes, tumors within the middle ear, and cholesteatoma can also dampen the transmission of sound energy to the oval window. Ossicular chain reconstruction (OCR) reestablishes the sound-transforming mechanism to provide a mobile connection from the tympanic membrane through an aerated middle ear space to the perilymph via the oval window. This chapter focuses on the surgical techniques for OCR. Tympanic membrane grafting, surgery for stapes fixation secondary to otosclerosis, and chronic otitis media with cholesteatoma are addressed in other chapters (Chapters 131 and 133).

Tympanoplasty

The term *tympanoplasty* describes procedures that address the status of the middle ear from the tympanic membrane to the vestibule. OCR is frequently performed in conjunction with tympanic membrane grafting for eliminating middle ear and mastoid disease. Zollner and Wullstein were early pioneers in the concepts of middle ear reconstructive surgery.[1,2] Wullstein provided a classification system consisting of five types (I to V) of tympanoplasty that focus on reconstruction with the remaining ossicular chain. Each type refers to the most lateral intact structure that remains connected to the inner ear on which the tympanic membrane is grafted or the ossicular chain reconstructed. Type I tympanoplasty indicates that all three ossicles are present and mobile. Thus, OCR is not needed. In type II tympanoplasty, the tympanic membrane is grafted to an intact incus and stapes. In practice, the need for type II tympanoplasty is rarely encountered. According to Wullstein, a type III tympanoplasty exists when an intact mobile stapes superstructure is present and the tympanic membrane or graft remains directly on the stapes superstructure. Type IV tympanoplasty describes an absent or eroded superstructure, with the graft or tympanic membrane lying on a mobile stapes footplate. Type V tympanoplasty refers to a fenestration created in the horizontal semicircular canal (Fig. 132.1), a procedure no longer in active use today due to the superior outcomes afforded through other techniques—largely as a result of modern instrumentation, the otomicroscope, and a wide array of readily available commercial prostheses.

Use of this classification system was subsequently encouraged by Farrior,[3] who clarified the terminology by basing the type of OCR on the pathologic anatomy at the completion of surgery rather than the method of reconstruction used. According to Farrior, type III tympanoplasty refers to establishing continuity of the stapes to the more lateral tympanic membrane or malleus by interposing a sculpted ossicle, bone, or other alloplastic material. A type IV tympanoplasty denotes reconstruction of the ossicular chain from a mobile stapes footplate to the malleus, tympanic membrane, graft, or, rarely, the incus. Type V tympanoplasty has been subdivided into types Va and Vb. Type Va designates a true fenestration procedure into the horizontal canal, whereas type Vb implies that the footplate is fixed or absent. After the vestibule is sealed with a tissue graft, continuity is restored from the oval window to the incus, malleus, tympanic membrane, or graft. Technically, stapedectomy would

be characterized as a type Vb tympanoplasty, but this terminology is not proposed for otosclerosis surgery.

This classification system is supplemented by describing the method of reconstruction used for each case. This is applied particularly to type III tympanoplasty. A frequently performed type III tympanoplasty is an incus interposition with the patient's own incus (autograft). A type III tympanoplasty with stapes augmentation entails increasing the height of the stapes above the Fallopian canal when a canal wall–down mastoidectomy is performed and the malleus is absent. This technique frequently uses the body of the incus, the head of the malleus, or a cortical bone graft. The term *partial ossicular replacement prosthesis* (PORP) is used when a synthetic biocompatible prosthesis is positioned from the stapes superstructure to the tympanic membrane, graft, or malleus. Types IV and Vb tympanoplasty are performed with either a *total ossicular replacement prosthesis* (TORP) or the patient's own incus from the footplate or grafted oval window to the malleus, tympanic membrane, or graft.

Key Operative Learning Points

1. The surgeon should be prepared to manage all reconstructive problems within the middle ear by being familiar with the various techniques for OCR, should unanticipated problems arise.

2. Careful palpation plus inspection of the tympanic membrane and all ossicles is critical for determining whether myringosclerosis and tympanosclerosis, separately or in combination, have caused the conductive hearing loss.

3. To avoid restriction of movement, an interposed ossicle or prosthesis should not make direct contact with the surrounding tympanic ring or rest on the cochlear promontory.

4. Reconstruction of the ossicular chain demands a precise connection between the tympanic membrane, graft, or malleus and the stapes, footplate, or vestibule.

5. The terms *PORP* and *TORP* are used for a broad range of ossicular reconstruction prostheses and techniques and used synonymously with incus replacement prosthesis and incus-stapes replacement prosthesis.

6. In order to have effective continuity, anticipate the final resting place of the tympanic membrane and tension with the middle ear prosthesis.

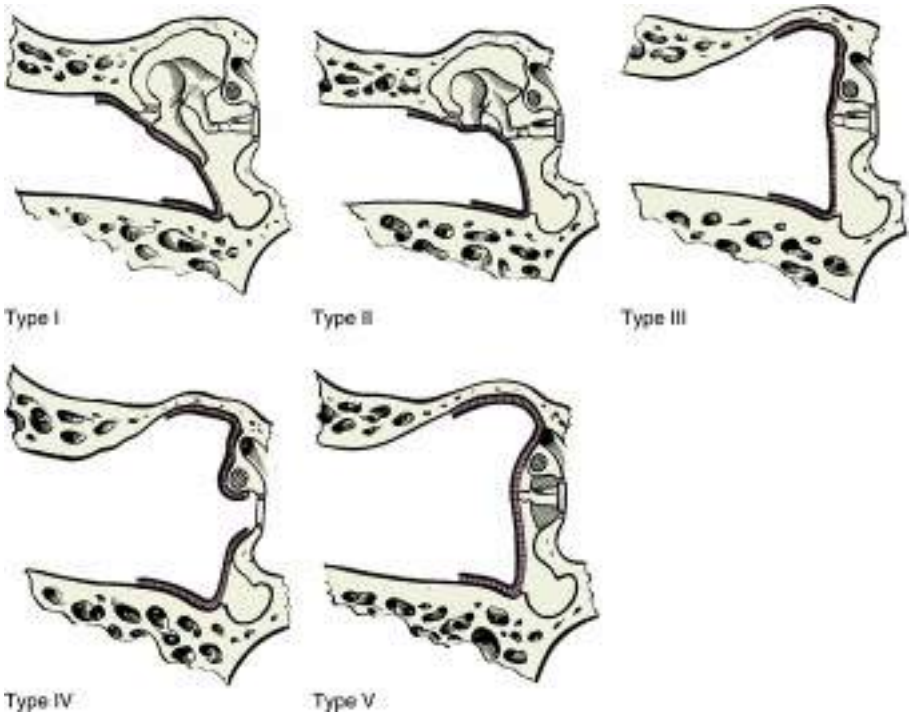

FIG. 132.1 The Wullstein classification of types of tympanoplasty. With permission from Kley W: Surgical treatment of chronic otitis media and its immediate consequences. In Naumann HH [ed]: Head and Neck Surgery, vol 3: Ear. Stuttgart, Germany: Georg Thieme; 1982, p 221.

a. The prosthesis should not only touch the tympanic membrane but should also be under slight tension to create minimal tenting of the tympanic membrane over the prosthesis (Fig. 132.2).

1) A prosthesis that is too short will have a tendency to fall or become displaced.

2) Excessive length of the prosthesis and/or poor Eustachian tube function sets the stage for extrusion of the prosthesis.

7. Reconstruction is done with the patient supine and the ear facing up toward the operating room ceiling. Anticipate the effect of gravity when they are upright.

Preoperative Period

History

1. History of present illness
    a. Risk factors: Previous surgery, Eustachian tube dysfunction, trauma, inflammatory/granulomatous disease, congenital malformation, cholesteatoma, middle ear tumors, and ossicular chain fixation resulting from tympanosclerosis
    b. Onset: Did this occur suddenly or slowly over time?
    c. Location: If this occurred suddenly, what/when was the scenario?
    d. Duration: Has hearing stabilized, or is it actively worsening?
    e. Character: What type of hearing loss is present and to what extent?
    f. Associated factors: Is there any associated tinnitus, aural fullness, distortions in hearing, pain, drainage, infection, vertigo, or instability?
    g. Relieving factors: Does anything seem to improve symptoms?
    h. Temporal factors: Is the hearing loss constant or fluctuating in nature?
    i. Other: Are there any other associated symptoms, like autophony or the Tullio phenomenon?
2. Past medical history
    a. Medical illness
        1) Is there a previous history of perforated tympanic membrane, pressure equalization tubes, otitis externa, otitis media, or cholesteatoma?
        2) Are there any known autoimmune, inflammatory, or granulomatous diseases?
        3) Is the Eustachian tube function compromised from allergy or other nasal disease?
    b. Surgical history
        1) If the patient has undergone previous otologic surgery, determine the extent and type. Obtaining previous operative reports may be of some value.

a) History of previous tympanoplasty, ossicular reconstruction, or stapes procedure

b) If there is a history of cholesteatoma, one should consider recurrent disease.

c) A previous canal wall–down procedure may put the facial nerve at risk for future surgeries.

d) Congenital anomalies could increase the risk of complications.

c. Family history

1) Explore otologic/audiologic history of immediate family

d. Smoking history: May compromise ventilation and healing

Physical Examination

1. Binocular microscopic otoscopy

a. Evaluation of both ears

1) The integrity of the tympanic membrane and middle ear space is evaluated.

2) It is important to examine the contralateral ear, which provides a means of predicting the likelihood of successful tympanoplasty and OCR when eustachian tube function is compromised.

FIG. 132.2 Hydroxyapatite partial ossicular replacement prosthesis making direct contact with the tympanic membrane. Note the very slight tenting over the prosthesis.

3) Fixation of the lateral ossicular chain is relatively uncommon.

a) While an astute clinician may detect decreased mobility of the malleus during pneumatic otoscopy, it is typically diagnosed at the time of exploratory tympanotomy.

b) The cause may be congenital, but delayed lateral chain fixation is probably due to tympanosclerosis secondary to chronic inflammation of the middle ear.

2. Tuning fork examination

a. Tuning fork testing with 256-, 512-, and occasionally a 1024-Hz fork is performed to determine whether conductive hearing loss is present and to estimate the degree of loss.

1) The most commonly used tuning fork frequency is 512 Hz.

3. Pneumatic otoscopy

a. Assess movement of both tympanic membranes.

4. Audiogram

a. Bilateral audiogram with air and bone conduction, speech reception threshold, and word discrimination done with recorded voice

1) Mandatory to determine the degree of conductive hearing loss and the quality of cochlear function (word recognition)

2) Patients demonstrating a large mixed hearing loss should be considered surgical candidates for OCR in order to bring hearing to an aidable level.

Imaging

1. CT scan

a. Most commonly ordered, dedicated axial temporal bone scan with fine cuts (0.6 mm); coronal and sagittal reconstructions

1) Superior for demonstration of the status of the otic capsule, ossicles, mastoid aeration, erosion, and middle ear space. Disruption of the ossicular chain can be demonstrated in these scans.

2. MRI

a. Superior demonstration of glial tissue, cerebrospinal fluid, and dura

b. Diffusion weighted imaging techniques can be used for diagnosis of cholesteatoma in difficult cases.

Indications

Conductive hearing loss may result from trauma, chronic Eustachian tube dysfunction, congenital anomalies, chronic otitis media, cholesteatoma, tumors of the middle ear space, or ossicular chain fixation resulting from tympanosclerosis. Physical examination may demonstrate an intact or perforated tympanic membrane.

1. Conductive hearing loss of known or suspected ossicular etiology

2. When the ossicular chain must be disarticulated for access to other middle ear pathology

3. Extruding prosthesis from previous surgery

Contraindications

1. An only hearing ear

2. Conductive hearing loss that is present due to middle ear tumors or infection with involvement of the dura or brain

3. Contracted middle ear space when aeration is compromised and OCR is not likely to improve hearing

4. Limited AB gap in revision cases; success is unlikely

5. Medical comorbidities

Preoperative Preparation

1. Primary inflammation of the skin of the external canal or inflammation secondary to disease from the middle ear requires medical management to optimize postoperative healing.

   a. A few weeks of topical and systemic antibiotics may be necessary.

   b. Patients with an intact tympanic membrane, no history of chronic ear disease, and progressive conductive hearing loss most likely have otosclerosis (see Chapter 133).

2. Review the chart for the history, physical findings, and audiometric results.

3. Review obtained images.

4. Review previous operative reports, if available.

5. Confirm the OR has the prostheses that may be necessary for OCR.

6. Medical status

   a. Patients with compromised health should have medical clearance by their PCP and evaluation by anesthesia.

   b. Discontinue anticoagulant and antiplatelet drugs if possible.

Operative Period

Anesthesia

1. Ossicular reconstruction is most commonly done under general anesthesia.

2. Monitored anesthesia care (MAC anesthesia) can be used in cases with a compliant patient and an experienced surgeon and anesthesiologist.

3. Minor adjustment or replacement of an existing prosthesis can be done under MAC.

Positioning

1. The patient is in supine position with the head rotated away from the affected ear.

2. Adjust the height of the table and microscope so that the surgeon is comfortable in a seated position, with his or her arms in a relaxed position and not fully extended.

Perioperative Antibiotic Prophylaxis

1. Procedure designated as clean or clean-contaminated

2. Preoperative antibiotics are routinely given.

   a. Cefazolin is most commonly used due to excellent staphylococcal and streptococcal coverage.

   b. In cases involving a penicillin allergy, consider clindamycin.

Monitoring

1. Routine anesthesia monitoring

Facial nerve monitoring is not routinely used for reconstruction of the ossicular chain unless combined with mastoidectomy or during repair of congenital aural atresia (see Chapters 134 and 208).

Instruments and Equipment to Have

Available

1. Binocular microscope
2. Complete mastoid and middle ear set
3. Monopolar and bipolar electrocautery
4. Full complement of otologic prostheses in stock

Key Anatomic Landmarks

1. Bony-cartilaginous junction of external auditory canal
2. Annulus
3. Tympanic membrane—pars tensa, pars flaccida
4. Chorda tympani
5. Ossicles or prosthesis that may be present
6. Facial nerve (horizontal segment)
7. Round window
8. Oval window
9. Jugular vein (beware high riding or dehiscent jugular bulb)
10. Pyramidal eminence
11. Cochleariform process

Prerequisite Skills

1. Binocular microscopic otoscopy
2. Thorough understanding of temporal bone anatomy
3. Tympanoplasty techniques
4. Stapedectomy and/or stapedotomy techniques

Operative Risks

1. Hearing loss and/or failure to improve hearing
2. Ossicular trauma
   a. Ossicular dislocation
   b. Unresolved conductive hearing loss
   c. Fractured stapes
3. Inner ear trauma
   a. Perilymphatic fistula
   b. Sensorineural hearing loss
   c. Tinnitus
   d. Vertigo
4. Perforation of tympanic membrane
5. Dysgeusia or ageusia
6. Infection

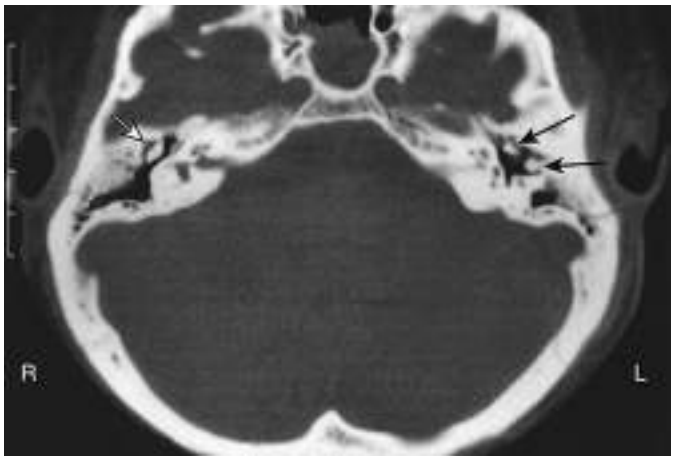

FIG. 132.3 The tympanomeatal incision for exploratory tympanotomy should be 4 to 5 mm away from the posterosuperior annulus. *L,* Left; *R,* right.

7. Facial nerve paresis or paralysis
8. Cerebrospinal fluid leak
9. Postoperative canal stenosis

Surgical Technique

The approaches to and methods for tympanic membrane grafting are reviewed in Chapter 131. Frequently, the preoperative status of the ossicular chain is unknown when correction of conductive hearing loss is undertaken. The surgeon must be prepared to have access to the entire ossicular chain.

- Tympanomeatal flap
  - The superior limb of the incision should be superior to the pars flaccida and approximately 5 mm from the posterosuperior annulus (Fig. 132.3).
    - The extension of the flap in this area permits removal of bone to provide exposure of the neck of the malleus, body of the incus, and the entire stapes footplate.
      - Removal of this bone permits extraction of the incus if necessary.
- Problems with the malleus

  A relatively uncommon source of conductive hearing loss is fixation of the malleus and incus, also known as lateral chain fixation. This may include ankylosis of the head of the malleus and body of the incus to the scutum, immobility of the incudomalleal joint, or calcification of the anterior malleus ligament restricting its movement.
  - Malleus fixation
    - Tympanomeatal flap designed to be superior to pars flaccida
    - Flap is elevated anterior to the neck of the malleus.
    - Palpation of malleus to confirm immobility
    - Separate incudostapedial joint
      - Palpate again to verify absence of otosclerosis.
    - Disarticulate the incudomallear joint with a curved pick to allow entire incus to be removed (Fig. 132.4) (see Video 132.1).
    - If malleus fixation persists, a 1-mm micro drill is used to divide the head of the malleus from its handle at the neck of the malleus.
      - Creates a mobile malleus handle

FIG. 132.4 The body of the incus is disarticulated from the head of the malleus and extracted with cup forceps.

- Malleus handle supported by attachment to tympanic membrane and tensor tympani tendon

- Incus is sculpted and interposed between the head of the stapes and the handle of malleus.
- A PORP can be placed on the stapes and make contact with the malleus handle or directly to the tympanic membrane (TM).

- Absent or deficient malleus handle
  - The surgeon must decide if the length of the malleus is adequate for reconstruction.
  - Satisfactory closure of the air-bone gap is compromised when the malleus is shortened beyond one-third of its length, unless the prosthesis makes direct contact with the tympanic membrane.
  - Incus interposition is sculpted to maintain sufficient height for connecting stapes superstructure to the intact or grafted tympanic membrane.
    - Improved transmission can be achieved by directing the position of the short process of the incus toward the center of the tympanic membrane.
  - Synthetic prostheses are used more commonly when the malleus

handle is absent.

- A PORP is used if a stapes superstructure is present (Fig. 132.5).
- A TORP is used if a stapes superstructure is absent but the footplate is present and mobile.

- Total or near-total perforation of tympanic membrane with missing ossicles (mobile footplate still present)
  - Tympanic membrane grafted, and TORP placed from footplate to newly placed graft
    - Challenges/complications
      - The final position of grafted tympanic membrane is not known.
        - Medialization of the graft is possible.
        - Lateralization of the graft is possible but less likely.
      - This presents potential uncertainty in choosing the appropriate length of a prosthesis.
  - An option is a staged procedure. The tympanic membrane is grafted, and a thick piece of Silastic sheeting (0.04 inch) is placed in the middle ear.
    - Ossicular reconstruction is then performed approximately 6 months later (staged procedure).

FIG. 132.5 Type III tympanoplasty with a partial ossicular replacement prosthesis when the malleus is absent (stapes to the tympanic membrane or graft).

- Fractured malleus handle
  - Occurs rarely
  - Preoperative pneumatic otoscopy may demonstrate hypermobility of the tympanic membrane and malleus.
  - Reconstruction performed either by incus interposition or with a PORP (see Video 132.2)

- Problems with the incus

The most commonly encountered abnormality in the ossicular chain involves the incus. More commonly, the long process and lenticular process of the incus are eroded or connected by a fibrous union. In patients with an intact mobile malleus and stapes, incus interposition is a commonly used method for OCR. A variety of techniques are available for modification of the incus to provide a mobile yet firm connection from the stapes superstructure to the malleus. The surgeon should note the status of the middle ear mucosa and the relationship of the malleus to the stapes. A cartilage interface with the TM is not necessary when using the incus for OCR.

- The incus can be mechanically sculpted to be interposed between the stapes and malleus (Fig. 132.6).
  - Relative anatomy
    - The stapes may be located directly medial to the handle of the malleus.
    - The malleus may be located anterior to the vertical plane of the stapes.
    - The height of the stapes relative to the promontory and facial nerve is noted.
    - This is especially important when performing reconstruction in a canal wall–down mastoidectomy.
  - Technique for removing the incus:
    - The autograft body of the incus is usually available for

reconstruction.

- It is often necessary to remove additional bone from the posterosuperior canal to extract the incus.

- A right-angled hook or curved needle is used to disarticulate any remaining attachments of the body of the incus to the malleus head.
- Cup forceps are used to grasp the proximal long process of the incus.
- A rotating downward maneuver is used to extract the incus from the attic.
- Avoid displacement of stapes and injury to chorda tympani.

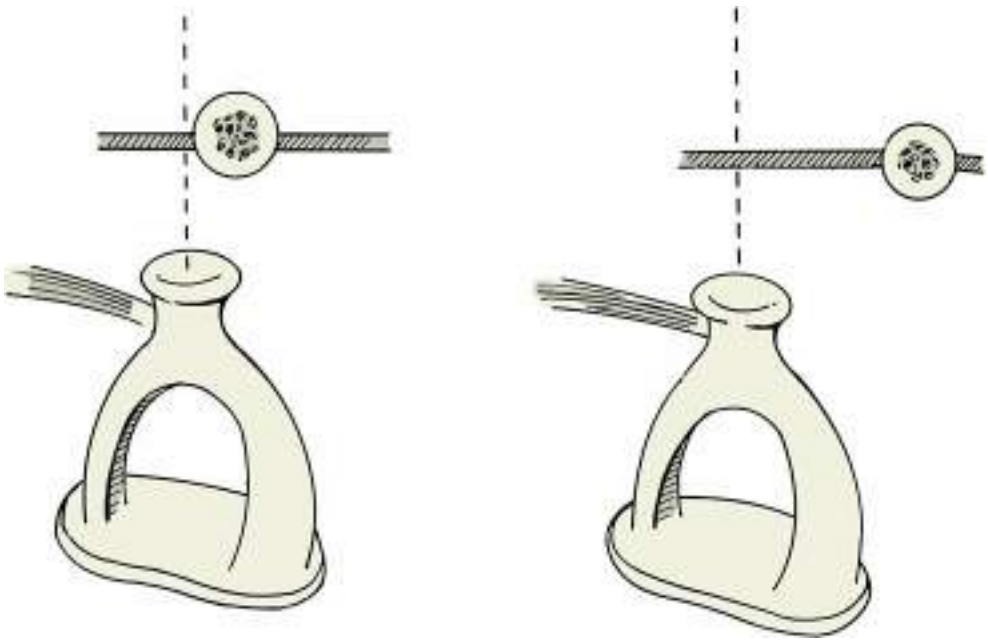

FIG. 132.6 The position of the malleus relative to the stapes determines how the incus will be sculpted to perform an interposition. *Left,* The malleus is located lateral to the stapes. *Right,* Reconstruction requires augmenting the vertical height of the stapes and its anterior span to the malleus.

- Sculpting the incus autograft
  - Various designs for sculpting an incus for interpositioning between the stapes and the malleus are demonstrated in Fig.

132.7.

- The incus should be held with an instrument such as a fine hemostat or forceps designed for holding ossicles.
- If a mastoidectomy had been performed, the same variable high-speed drill is used for incus sculpting.
- A battery-powered micro drill may also be used (see Video 132.3).
- When the stapes and malleus are in a nearly vertical plane, height is needed to connect the two ossicles (see Fig. 132.7A).
  - The acetabulum for the stapes head is drilled into the short process of the incus.
  - A groove for the malleus handle is created in the articulating surface of the body of the incus.
- When the malleus is located anterior to the vertical plane of the stapes, both height and horizontal span are needed (Fig. 132.8A; see also Fig. 132.7B).
  - The acetabulum for the stapes is created in the body of the incus near its junction with the long process (see Fig. 132.7B).
  - This is initially positioned under the malleus handle, and the malleus–incus complex is lifted and rolled onto the stapes superstructure (see Fig. 132.8A).
  - A more oval aperture can be drilled to accommodate the shoulder of the crura (see Fig. 132.8B).
- When considerable height needs to be bridged, the incus is configured as shown in Fig. 132.7C.
- Occasionally, the incus is eroded just at the incudostapedial joint.
  - Rather than removing the incus, an alternative method for reconstructing this joint is to use an Applebaum hydroxyapatite prosthesis.
    - This prosthesis fits on the stapes superstructure and supports the remaining long process of the incus (Fig. 132.9) (see Video 132.4).

- Another option is to use hydroxyapatite bone cement to reattach the long process of the incus to the stapes.[4]

- Insetting the incus
  - Care must be taken to ensure that the undersurface of the short process of the incus is not resting on the promontory of the cochlea.
  - With all interpositioning techniques, placement of the incus superior or inferior to the chorda tympani nerve can provide further support to the sculpted ossicle (see Fig. 132.8C).
- Synthetic PORP prosthesis
  - A PORP is used if the incus is inadequate, such as in the setting of significant erosion or infiltration by cholesteatoma.
  - Products containing hydroxyapatite for the interface with the TM and titanium with the stapes are well tolerated.
    - A cartilage interface between the dense hydroxyapatite prosthetic head and the tympanic membrane or graft is not needed. It is necessary, however, with a titanium-topped prosthesis.
  - An adjustable PORP can be shortened to provide the appropriate reconstruction.
- Reconstruction of the ossicular chain in patients undergoing a canal wall–down mastoidectomy may also require a type III tympanoplasty.
  - After the head of the malleus is removed, a connection from the stapes to the malleus handle is necessary.
    - This can be accomplished with incus interposition techniques or with a synthetic prosthesis.
    - The membrane could be grafted directly onto the stapes superstructure as described by Wullstein.
    - Greater surface contact is achieved when an ossicular prosthesis is placed on the stapes.
      - The body of the incus, the head of the malleus, or a small cortical bone graft harvested from the root of the zygoma or

the outer table of the squamosa portion of the temporal bone can be drilled to form a dome for the stapes superstructure.

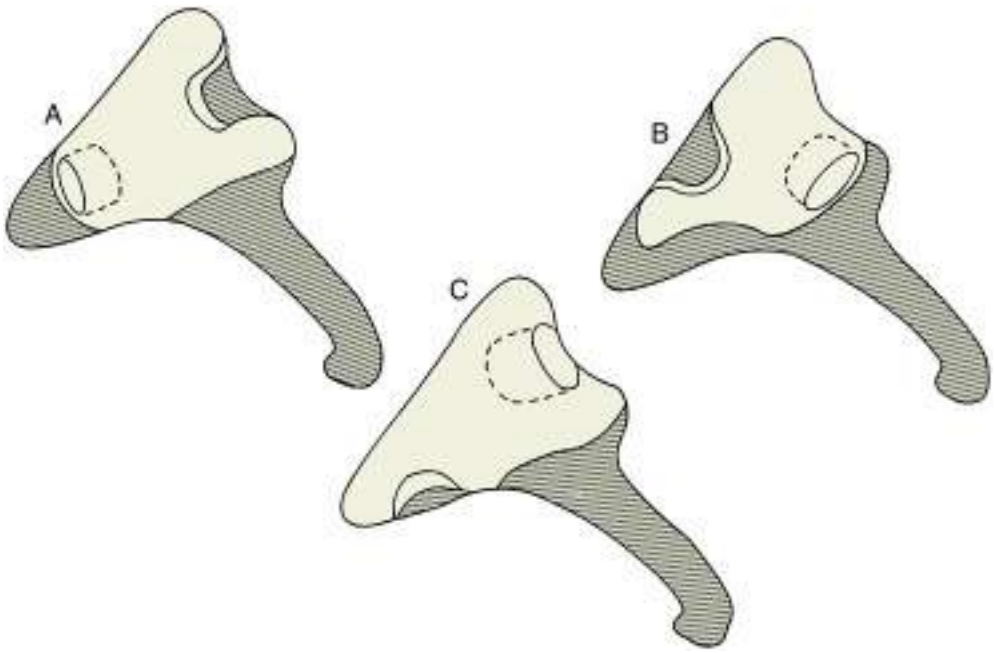

FIG. 132.7 The body of the incus can be sculpted in a variety of forms to accommodate each particular relationship between the malleus and stapes.

A, Gains vertical height. **B,** Gains some vertical height and mostly horizontal span. **C,** Gains mostly vertical height and some horizontal span.

- The concave surface of a conchal cartilage graft can also be used as a dome for the stapes superstructure. The height and surface area of the head of the stapes can be augmented to make better contact with the tympanic membrane. This can be done with a PORP or a hydroxyapatite (HA) mushroom cap prosthesis (Fig. 132.10).

- Problems with the stapes
  - If the stapes superstructure is partially eroded, interposing an ossicle or prosthesis from the stapes arch or one of its crura will probably fail. Reconstruction from the undersurface of the malleus to the

mobile stapes footplate provides a more secure connection of the ossicular chain. An autograft incus occasionally provides adequate length to meet these requirements. The distance should be measured before sculpting the incus. The length of the sculpted incus can be varied based on use of the short or long process from the footplate to the body of the incus. A groove in the articulating surface of the incus is further defined to secure the incus to the medial surface of the malleus (Fig. 132.11A).

- Additional length is available when the long process of the incus remains.
- The lenticular process is removed, and the groove for the malleus is drilled on the superior surface of the incus (see Fig. 132.11B) (see Video 132.5).
- Inserting the incus
  - The sculpted ossicle is placed on the footplate between the remaining crura.
  - While the malleus handle is lifted, the incus is rotated into position.
  - The chorda tympani nerve can be positioned to further stabilize the ossicular assembly.
- When the oval window niche is narrow and deep, the incus is often too wide to fit between the promontory and the facial nerve.
  - More commonly, a synthetic TORP is necessary.
  - We currently use a prosthesis with a dense HA head attached to an adjustable titanium shaft.
  - The TORP requires temporary support from the stapes footplate to the malleus or tympanic membrane (Fig. 132.12).
  - Titanium prostheses are available in fixed lengths or with adjustable shafts.
    - A sizing set is used to determine the proper length needed.
    - The video demonstrates use of a 5-mm sizing prosthesis to verify the appropriate length needed for the prosthesis to be implanted (Video 132.6).

- Wet Gelfoam is placed around the base of the shaft up to the level of the facial nerve if the malleus handle is present.
- When the prosthesis is in direct contact with the tympanic membrane, Gelfoam is positioned around the entire prosthesis to the level of the tympanic membrane (see Video 132.7).
- The base of the shaft can also be supported by fascia or a footplate shoe.[5]

- Problems with the footplate

The most common cause of fixation of the stapes footplate is otosclerosis. If a fixed footplate is identified while repairing a perforation of the tympanic membrane, it is best to stage the reconstruction to avoid opening the vestibule to a potentially contaminated middle ear space. The same philosophy applies to extensive tympanosclerosis of the footplate when a tympanic membrane perforation or chronic otitis media is present.

- Tympanosclerosis describes deposition of sclerotic plaque after recurrent acute or chronic otitis media.
  - This calcification can restrict the tympanic membrane and ossicular chain.
    - It can be confirmed by gentle palpation of the stapes while observing for a round window reflex.
- If the tympanic membrane is perforated, it should be repaired and the operation staged for a subsequent procedure.
  - Healing is typically complete within 4 to 6 months, at which time the footplate can be safely addressed.
  - There is controversy about how to best manage the stapes when it becomes fixed by tympanosclerosis.

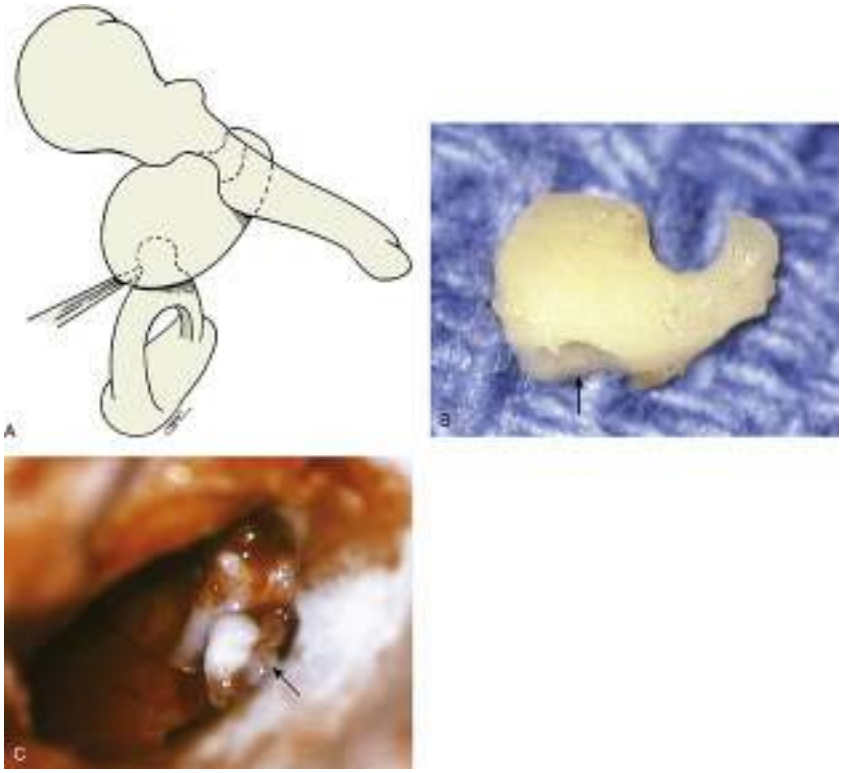

FIG. 132.8 **A,** Incus interpositioning to gain some height and mostly horizontal span. **B,** The sculpted incus has an oval aperture that fits snugly on the stapes *(arrow).* **C,** In a left ear, the incus has been positioned superior to the stapes and medial to the malleus handle. The chorda tympani nerve provides additional support *(arrow).*

- Options include not intervening surgically and providing amplification, performing stapes mobilization, or removing a portion of the footplate (partial stapedectomy) and placing a prosthesis.
- The concern for mobilization is based on the possibility of refixation of the stapes by new plaque formation.
  - If the status of the ear disease is stable, both short- and long-term hearing results are similar, thus indicating that refixation is unlikely to occur after mobilization.
  - The sclerotic plaque can also be removed away with fine microdissection from the footplate.
- It has also been shown when tympanosclerosis affects the footplate, stapedectomy in a sterile middle ear is a safe and

effective procedure.[6]

- In cases of chronic otitis media with cholesteatoma, the stapes footplate may be eroded.
  - If the vestibule is opened inadvertently or by disease, OCR is warranted at that time.

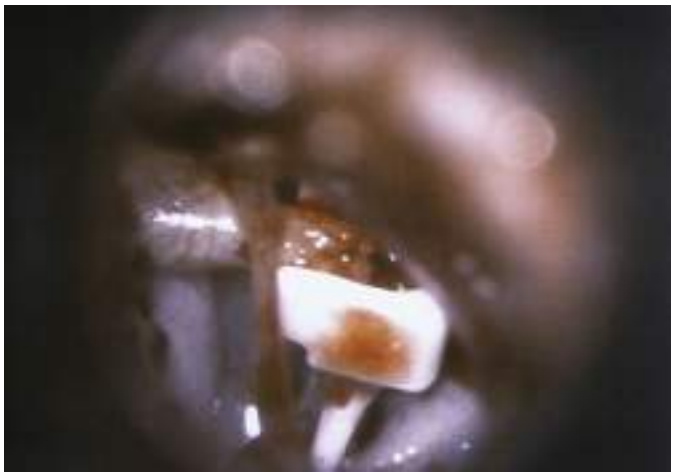

FIG. 132.9 Intraoperative photograph of an Applebaum prosthesis placed between the stapes and an eroded long process of the incus.

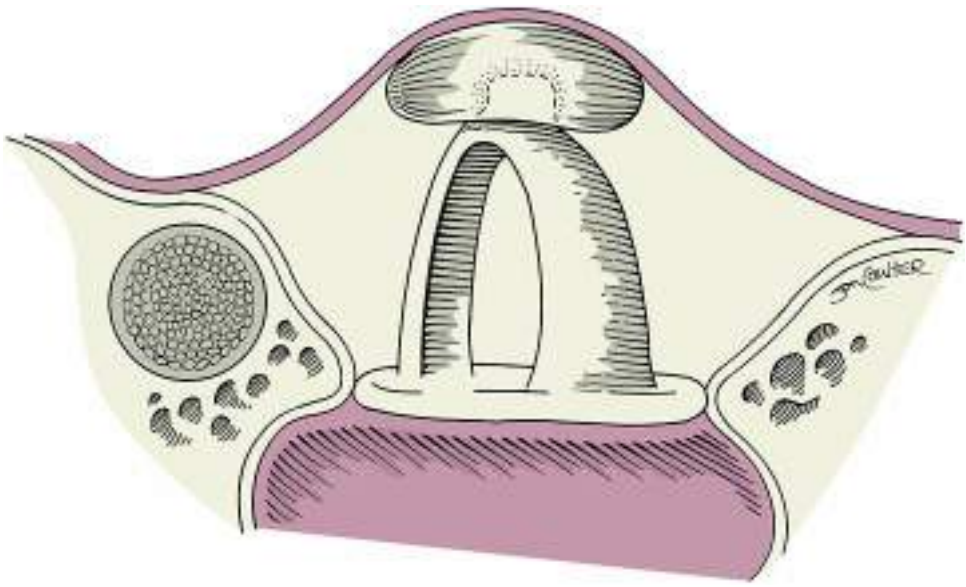

FIG. 132.10 Ossicular chain reconstruction in a canal wall–down cavity. The stapes has a greater area of contact

with the tympanic membrane or graft. This is a type III tympanoplasty with stapes augmentation.

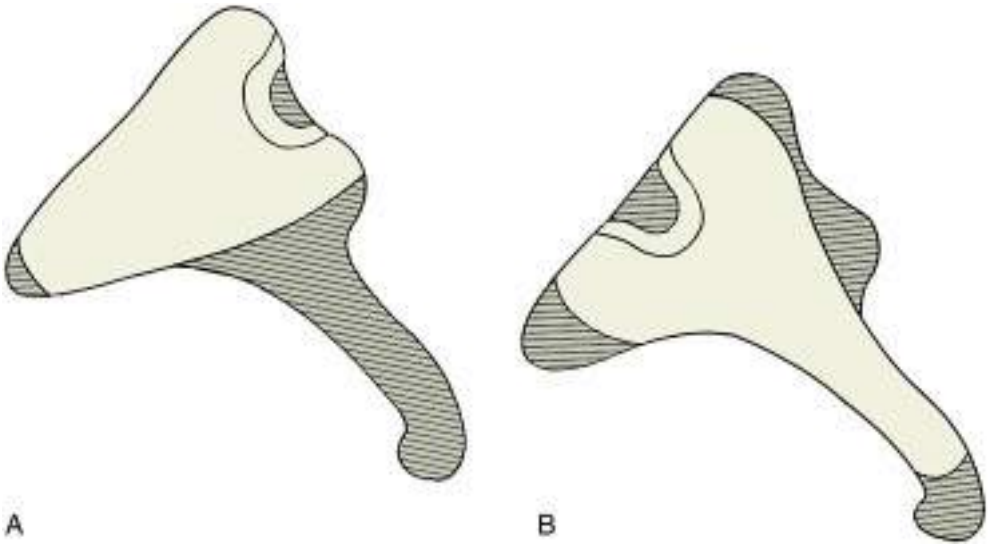

FIG. 132.11 Techniques for sculpting the incus for a type IV tympanoplasty.

A, The short process of the incus is flattened. The long process is removed and a groove drilled for the malleus handle. **B,** The long process is flattened, and the notch for the malleus handle is on the superior surface of the incus.

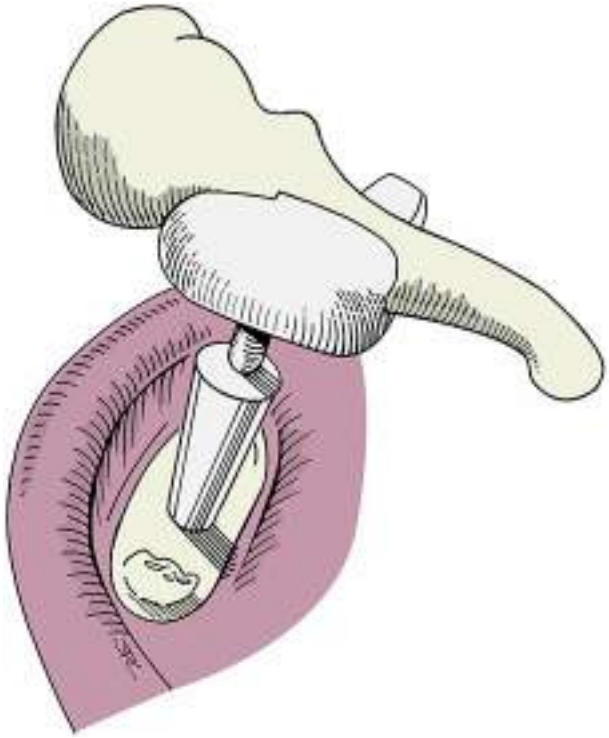

FIG. 132.12 Type IV tympanoplasty from the footplate to the malleus with an incus-stapes replacement prosthesis (total ossicular replacement prosthesis).

- It is rare to have such extensive disease yet still have an intact incus.
  - Reconstruction is frequently done from the vestibule to the malleus, tympanic membrane, or graft (type Vb tympanoplasty).
- The vestibule is covered with a thin but strong graft that will support a prosthesis.
  - True fascia is obtained from the temporalis muscle.
  - The graft is air-dried, cut to approximately 3 to 4 mm, and placed over the vestibule.
- The shaft of the prosthesis is placed in the center of the graft, and the head is positioned under the malleus handle or directly to the grafted tympanic membrane (Fig. 132.13).
- The grafted tympanic membrane may heal in a more medial position when exposed to the negative pressure of the middle ear space.

- This puts further demand on the support needed from the oval window graft.
- If there is concern that the prosthesis may sublux into the vestibule, a perichondrial graft is harvested from the posterior conchal cartilage or the tragus and placed over the open oval window.

Common Errors in Technique

- Normal mobility must be confirmed by palpation of the malleus and incus because lateral ossicular chain fixation may be missed by an inexperienced surgeon.
- Reconstruction with a partially eroded stapes (type III tympanoplasty) may not provide adequate support of a PORP, and the reconstruction may need to be taken medially from the footplate.
- Excessive manipulation of the stapes when tympanosclerosis is present on the footplate may result in fracture, unanticipated removal of the stapes, or footplate fenestration.
- A prosthesis will become displaced unless there is adequate tension between its medial site of contact (footplate or stapes) and the tympanic membrane or intervening cartilage.
- Excessive removal of the scutum without the support of a block of cartilage may result in retraction into the attic and development of cholesteatoma.
- A prosthesis that rests on the promontory or abuts the bony canal wall dampens needed vibration and sound transmission.

Postoperative Period

Postoperative Management

1. Activity
   a. Patients are instructed to keep the ear free of water and avoid blowing the nose or other forms of Valsalva maneuvers.

b. Patients should avoid significant changes in atmospheric pressure, such as during an air flight, for several weeks postoperatively.

c. Minimize vigorous head movement in the postoperative period. Parents are encouraged to restrict pediatric patients from engaging in gymnastic or other excessive physical activities.

d. Patients undergoing a type V reconstruction (prosthesis to the vestibule) are to avoid heavy lifting.

2. Packing

a. Patients with an intact tympanic membrane who are undergoing OCR have packing of Gelfoam or a silk sleeve supported by small cotton balls with ointment. The packing is removed 7 to 10 days postoperatively.

b. Patients requiring lateral graft tympanoplasty (tympanic membrane reconstruction) usually have an outer and inner rosebud packing in place.

1) The outer pack is removed in 1 week, and topical eardrops are prescribed.

2) The second medial pack is removed 1 week later. Topical drops are continued twice daily for 1 week.

3) Patients are seen a few weeks later to assess healing of the canal and tympanic membrane.

- When the tympanic membrane inflammation has resolved and it is thin and mobile, audiometric testing is performed.
    - A residual conductive hearing loss of 15 to 20 dB is still considered a success in the setting of a Type III or IV tympanoplasty.

Complications

1. General surgical risks

a. Bleeding, infection, pain, scar, damage to adjacent structures, need for revision procedures

2. Otologic risk factors

a. Hearing loss (permanent or temporary, sensory or conductive), dizziness, instability, vertigo, middle ear infection, extrusion of prosthesis, dislodgement of prosthesis, ossicular erosion, tympanic membrane perforation, cholesteatoma perilymphatic leak, taste disturbances, facial nerve weakness

Alternative Management Plan

1. Frequent aural toilet for chronic otitis media with perforation
2. Amplification
   a. Traditional hearing aids
   b. Bone-anchored hearing aid

Discussion

Evidence-Based Medicine Question

Is it the middle ear disease or the reconstruction material that determines the functional outcome in OCR?

In a recent retrospective case review of 110 patients, it was found that the success rate was highly correlated with the pathophysiologic status of the middle ear and did not depend on the type of replacement, regardless of the technique used.[7]

Editorial Comment

This chapter addresses the concepts and techniques of OCR. The procedure has been executed for the past 65 years, with the biggest change being the design and materials of the prostheses used. Time has shown this to be an evolving process trying to maximize successful surgery and hearing results. The concept of staging a procedure for the purpose of optimizing the position of the tympanic membrane and health of the middle ear space has become increasingly important in patients with chronic otitis media or cholesteatoma.

The ongoing influence of Eustachian tube function must be anticipated

during the postoperative and long-term periods following tympanoplasty and ossicular reconstruction. The learning curve for execution can be brief, but achieving consistent well-healed outcomes, with excellent hearing results, is the career focus of otolaryngologists performing this surgery.

Barry Hirsch

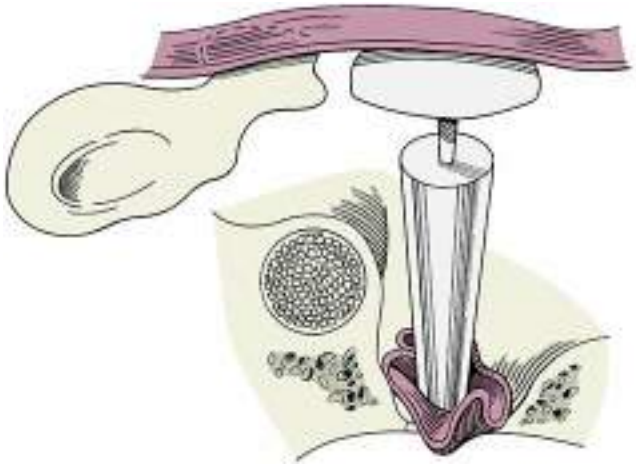

FIG. 132.13 Type Vb tympanoplasty with a total ossicular replacement prosthesis. A graft covers the vestibule on which the shaft of the prosthesis is embedded. The head of the prosthesis tents the grafted tympanic membrane. The malleus handle is absent.

Access the review questions online at http://www.expertconsult.com

Review Questions

1. What type of pathology would not cause a conductive hearing loss?

   a. Myringosclerosis

   b. Superior semicircular canal dehiscence

   c. **Perilymphatic fistula**

   d. Malleus fixation

2. A good result for a type I tympanoplasty is closure of the air-bone gap within 5 to 10 dB.

a. **True**

b. False

3. A good result for a type III tympanoplasty is closure of the air-bone gap within 15 to 20 dB.

a. **True**

b. False

4. What is the typical time span for waiting before performing a second stage procedure to correct a conductive hearing loss?

a. 3 months

b. **6 months**

c. 12 months

d. 18 months

5. What type of hearing loss is expected with superior semicircular canal dehiscence, and what would you expect the acoustic reflex to reveal?

a. Sensory hearing loss, acoustic reflex absent

b. Sensory hearing loss, acoustic reflex present

c. Conductive hearing loss, acoustic reflex absent

d. **Conductive hearing loss, acoustic reflex present**

Otosclerosis

Alexander Rivero, and Noriko Yoshikawa

Introduction

Definition

Otosclerosis is a disease of the otic capsule characterized by both resorption and bony deposition with associated neovascularization. This abnormal bony growth of the otic capsule will eventually result in fixation of the ossicles, frequently at the stapes footplate or the incudostapedial joint. The disease was first identified by Valsalva in 1704 and later termed *otosclerosis* by Politzer in 1894.[1] Histologically the sclerotic foci appear as dense mineralized bone or well-vascularized bone that appears spongiotic. The characteristic blue mantles of Manasse represent the most recently remodeled bone.[1]

Epidemiology and Etiology

Most cases of otosclerosis appear to be familial, inherited in an autosomal dominant fashion with variable penetrance, and are more common in females (frequently reported as a 2:1 ratio). The mean prevalence is 0.2% to 0.4%, with a mean presentation in the third decade of life. Several polymorphisms in the COL1A1, BMP2, BMP4, TGFB1, and RELN genes have been associated with sporadic otosclerosis. Altered expression of the bone specific osteoprotegerin is believed to play an inflammatory role in otosclerotic foci.[2] There have been multiple studies finding immunohistochemical evidence of virus-induced inflammation in temporal bones with otosclerosis suggesting a role in pathogenesis.[3] Hormonal changes have also been implicated, as is seen in the development of clinical otosclerosis during pregnancy. Despite these

findings, the overall pathophysiology of otosclerosis remains unclear and is likely multifactorial.

Racial/Ethnic Presentation

The vast majority of patients with otosclerosis are Caucasian and of European descent. Recent studies have found an increasing incidence (perhaps due to increase in diagnosis) of otosclerosis in both Japanese and Chinese patients though the disease process seems milder in these populations.[4] Autopsy dissections of temporal bones demonstrate histologic evidence of otosclerosis 10 times more frequently than clinical otosclerosis, suggesting a certain amount of otosclerosis is tolerated without symptomatic correlation.[3] This may help elucidate the increase in diagnosis in other races and ethnicities, as well as explain their lack of clinical presentation. Case reports of presentation in other races have been published, although the incidence remains low for these populations.

Treatment and Outcomes

The surgical treatment of otosclerosis involves bypass of the fixed stapes footplate. This may be accomplished via stapedotomy or stapedectomy. As laser and microdrills have been introduced, the precision of stapes surgery has improved, and surgeons have largely adopted stapedotomy as the standard of care.

Good outcomes for this surgery have been well documented.[5-9] The guidelines of the Committee on Hearing and Equilibrium recommend an air-bone gap closure of less than 10 dB as an effective measure of success of surgical intervention. Several systematic reviews have demonstrated the safety and efficacy of laser-assisted stapedotomy, resulting in improved visualization due to bloodless intraoperative view, less risk of mobilization of the footplate, and avoidance of inner ear injury.[5,7-9]

Key Operative Learning Points

- Preoperative counseling is essential, particularly in cases with mixed hearing loss.

- Optimize a bloodless field with a good local injection and topical epinephrine, if needed.
- Presence of stapedial reflexes should lead one to consider superior semicircular canal dehiscence (SCCD).
- Adequate surgical exposure is key for safety and efficiency.
- Separation of the incudostapedial joint should be performed in the posterior to anterior direction to take advantage of the countertraction provided by the stapedius tendon.
- Avoid suctioning over the stapedotomy.

Preoperative Period

History

1. History of present illness
   a. Conductive hearing loss: Clinical otosclerosis arises from the bony deposition causing ossicular fixation typically resulting in unilateral or bilateral conductive hearing loss. Mixed and purely sensorineural hearing loss (resulting from cochlear otosclerosis) may also be present, though these presentations are rare. Tinnitus may be associated with hearing loss.[6]
   b. Patients typically present in their third decade, though this may range from patients in their teens to those in their sixties.[2]
   c. Hearing loss is inevitably progressive, given continued bone resorption and deposition.
2. Past medical history
   a. Assess for history of vertigo, particularly symptoms suggestive of Meniere disease or SCCD. The Tullio phenomenon, vertigo induced by loud noises, may suggest SCCD.
   b. Anesthesia risk factors: Cardiopulmonary disease, renal or liver failure
   c. Alcohol dependence or substance abuse

3. Past surgical history

   a. Previous ear surgery. Previous stapes surgery increases risk of poor hearing outcomes and vertigo.

4. Family history

   a. Family members with middle-age onset hearing loss or having had surgery for hearing loss

5. Medications

   a. Anticoagulation—Surgeons should reinforce the discontinuation of medications that inhibit coagulation approximately 7 days prior to surgery.

   b. Seasonal allergies—Optimize medications and timing of surgery.

6. Psychosocial consideration

   a. Ability to comprehend an informed consent

   b. Employment—Particularly if the patient's job involves frequent flying or heavy lifting, make plans for restrictions in the postoperative period.

Physical Examination

1. Typically the examination of the ear is normal. Bilateral otomicroscopy should be performed on all patients with suspected otosclerosis. Confirmation of normal external auditory canals and healthy appearing tympanic membranes should be performed. This helps distinguish any other external or middle ear pathology as sources for possible conductive hearing loss.

2. Schwartz sign: Occasionally, slight redness may be seen behind the tympanic membrane due to the increased vascularity over the promontory during active remodeling or otospongiosis.

3. Tuning fork examination is also critical. Classic findings for conductive hearing loss using 256 and 512 Hz tuning forks involve a negative Rinne in which bone conduction is greater than air conduction (classically termed "flipped forks") and a Weber examination that lateralizes to the affected ear (if one ear has greater conductive loss than the other). These

findings suggest that at least a 15 dB air-bone gap will exist on formal audiometric testing.

Audiometric Findings

1. Conductive hearing loss—An air-bone gap of at least 20 dB should be appreciated prior to offering surgery. Hearing loss less than this should prompt nonoperative management and re-evaluation at a later date.

2. Carhart notch—An audiologic finding consisting of a discreet decrease in bone conduction at 2000 Hz thought to result from loss of the resonant frequency of the ossicular chain. Other conditions such as middle ear effusion and primary malleus fixation may lead to similar findings, and thus Carhart notch is suggestive but not pathognomonic of otosclerosis (Fig. 133.1).

3. Stapedial reflexes—In cases of early otosclerosis, the stapedial reflexes may still be intact. However, the presence of preserved stapedial reflexes should lead one to consider alternate diagnoses such as superior canal dehiscence, where conductive loss can also be present due to a "third window" effect.

Imaging

1. Imaging is not necessary for routine conductive hearing loss.

2. A CT scan is indicated if conductive hearing loss with intact reflexes is present to rule out SCCD.

3. CT scan findings in otosclerosis may include a lucency of the otic capsule near the oval or round window, resulting from demineralization during the active otospongiosis phase. Extensive cochlear demineralization may result in the double ring or halo sign. A mixed loss is often present (Fig. 133.2).

4. MRI with gadolinium may enhance active foci of otospongiosis.

Indications

1. Progressive conductive hearing loss the in setting of absent reflexes

2. Air-bone gap greater than 20 dB in at least three frequencies

3. Tympanosclerosis with stapes footplate fixation

4. Trauma-induced footplate fracture or subluxation

Contraindications

1. Tympanic membrane perforation. It is necessary that an intact tympanic membrane be present prior to stapes surgery. This helps prevent contamination of the vestibule by external ear flora. Similarly, it is recommended that patients with ventilation tubes undergo removal of the tubes and healing of the tympanic membrane prior to stapedotomy.

2. Air-bone gap less than 20 dB in at least three frequencies

3. Meniere disease: Relative contraindication due to increased incidence of vertigo and sensorineural hearing loss

4. Active external or middle ear disease

5. Only or better hearing ear

Preoperative Preparation

A standard preoperative history and physical examination are pertinent. Appreciating several factors preoperatively may help lead to a successful operation.

1. Neck mobility—The ability to manipulate patient positioning intraoperatively is key to providing optimal visualization. A lack of mobility may inhibit the patient's ability to undergo surgery.

2. Narrow external auditory canal—Recognizing this early may help direct the approach. An ear canal that accommodates a 5.0-mm speculum is sufficient for surgical intervention. Smaller canals or those with large anterior lips may require a postauricular approach or a 12 o'clock releasing incision in the incisura.

3. As is key with any operative procedure, an appropriate informed consent process should be undertaken. Patients should be counseled on risks and expectations. The list is outlined below in the "Operative Risks"

section. A detailed version of the operative risks discussed with each patient is provided in Table 133.1.

4. In cases of mixed hearing loss, patients should be aware that improvement in their hearing will be limited to the level of their underlying sensorineural hearing loss. For patients who are unsure whether they would like to proceed with surgery, the alternative of a hearing aid trial should be presented. This allows the patient to remain functional while determining whether surgical correction is appropriate for them.

5. A key operative principle of otologic surgery remains true in stapedotomy and management of otosclerosis—always operate on the poorer hearing ear. Conversely, avoid operating on the only hearing ear.

Operative Period

Anesthesia

Local versus general. Understanding a patient's mobility and comorbidities may help guide the determination of local monitored anesthesia care versus general anesthesia with endotracheal intubation. In patients with poor mobility or who are unable to sit still for an extended period of time, general anesthesia may prove more useful. Similarly, in patients who have extensive comorbidities where general anesthesia poses a greater risk, local sedation should be considered.

1. Local anesthesia with sedation. Benefits of this include being able to verify hearing improvement intraoperatively. Patients can also report vertigo. However, patients may be startled and move during surgery. This also may not be well tolerated in patients with poor neck mobility.

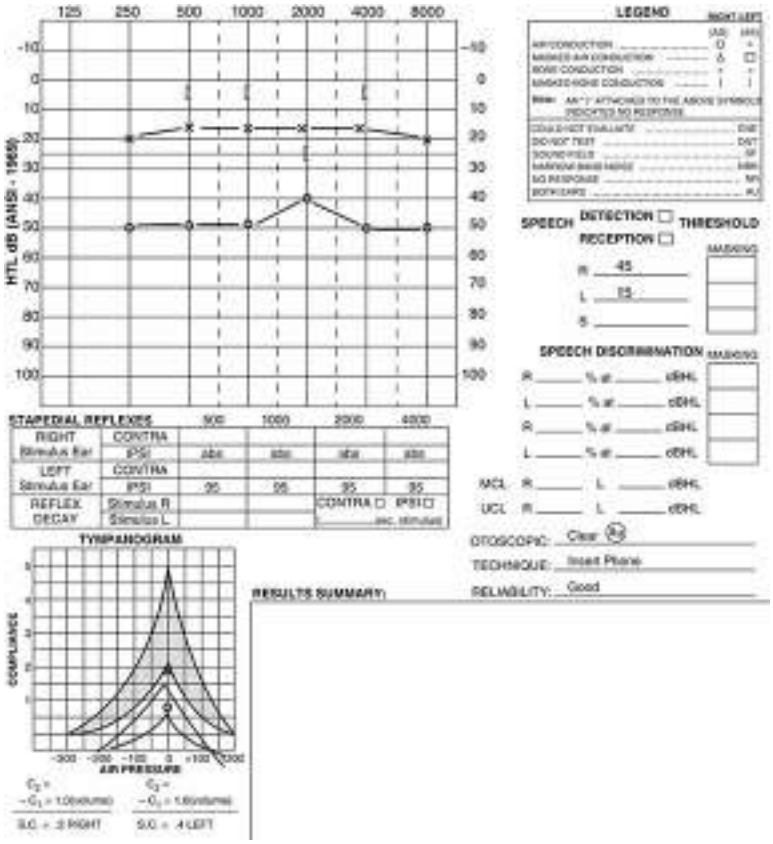

FIG. 133.1 Audiogram showing right conductive hearing loss and a sensorineural dip at 2000 Hz indicative of Carhart notch.

2. General anesthesia allows for more ease of positioning and reduces the risk of unexpected movements, though it also precludes intraoperative verification of hearing improvement or vertigo complications.

Positioning

1. Patients are typically positioned in the supine position with the head turned away, exposing the operative ear.

2. If lateral neck rotation is limited, then table tilt can be employed. A horseshoe headrest, or a positioning bump/roll under the torso and hip on the operative side, can improve access.

3. Pad arms and knees.

4. If a vein graft is to be taken, the contralateral hand should be positioned with padding under the wrist and fingers, exposing the

dorsum of the hand. This area should be prepped and draped carefully so to not contaminate the area as the primary drape is being pulled over the body.

Perioperative Antibiotic Prophylaxis

Not indicated[10]

Monitoring

Facial nerve monitoring is not indicated. The risk of facial nerve injury is very low. However, if the patient is under general anesthesia, it is advisable to not use long-acting paralytics so that stimulation of the nerve would be an option if concern arose during the case.

Instruments and Equipment to Have Available

1. Otologic surgery set

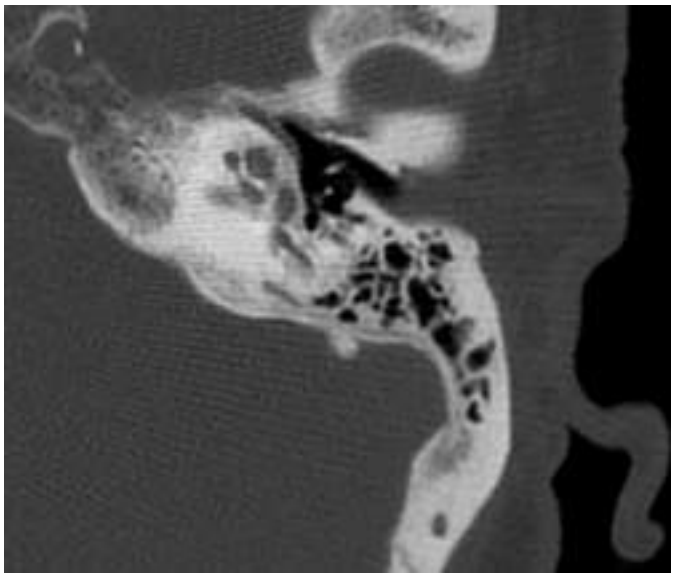

FIG. 133.2 Extensive cochlear demineralization may result in the double ring or halo sign.

2. Stapes specific instruments such as curettes, measuring rod, footplate picks

3. Laser and micro-otologic drill (e.g., Skeeter)

4. Crimper if necessary for prosthesis

5. Operating microscope

6. Stapes prostheses

Key Anatomic Landmarks

1. Horizontal segment of the facial nerve

2. Pyramidal eminence

3. Promontory

4. Malleus/cochleariform process

5. Round window, if in view

Exposure of these five anatomic landmarks will ensure that the stapes and lenticular process of the incus are adequately visualized.

Prerequisite Skills

1. Microsurgical fine motor skills

Operative Risks

1. Hearing loss (See Table 133.1 for Detailed Review)

2. Tinnitus

3. Dizziness/vertigo/imbalance

4. Taste disturbance and dryness of the mouth

5. Facial paralysis

6. Extrusion of prosthesis

7. Tympanic membrane perforation

8. Wound infection

9. Brain complication and cerebrospinal fluid leak

Surgical Technique: Stapedectomy With Bucket-Handle Prosthesis

1. Inject the canal with 1% lidocaine with 1:100,000 or 2% lidocaine with 1:50,000 epinephrine with a 27-g needle. Care should be taken to inject slowly to avoid ballooning of the skin. A blanch should be seen extending down onto the tympanic membrane; this is best seen if injection is performed under the microscope. Injection should be performed circumferentially, ending with the anterior canal to minimize blood dripping into the field. This step is still performed even when the patient is under general anesthesia to assist with vasoconstriction.

TABLE 133.1

Detailed List of the Operative Risks Reviewed With Patients Prior to Surgery for Otosclerosis

Risks	
Hearing	Surgery may fail to improve hearing. Rarely, further loss of hearing develops due to the extent of the disease or problems in the healing process; this may be permanent. In 1% of patients, a severe loss of hearing may result in the operated ear; if that happens, nothing further can be done to correct the loss.
Tinnitus	Tinnitus (head noises) may be more pronounced after surgery and usually correlates with the further impairment of hearing. It is usually not corrected by surgery.
Dizziness	Dizziness may occur due to irritation of the inner ear structures. Some unsteadiness may persist for weeks postoperatively. Rarely is the dizziness severe and prolonged.
Taste disturbance and mouth dryness	Taste disturbance and dryness of the mouth are common for a few weeks following surgery. In 5% of patients, this disturbance is prolonged or permanent.
Facial paralysis	Rarely, temporary paralysis on the operated side of the face may occur. This usually subsides spontaneously. If it is prolonged, further surgery may be considered.
Extrusion of prosthesis	Sometimes a prosthesis made of synthetic material is used to reconstruct the bony chain of hearing. The body will occasionally reject a foreign material. Reoperation may be necessary.
Perforation	A perforation may develop in the eardrum after surgery. A perforation may be due to infection or problems in the healing process. Often it will heal spontaneously; if it does not heal, further surgery may be an option.
Wound infection	Infection (drainage, swelling, and pain) may develop following surgery due to poor healing. Rarely, a more serious infection can extend to the fluid around the brain causing meningitis. Prolonged hospitalization or additional surgery may be necessary to treat the infection.
Cerebrospinal fluid leak	On rare occasions, the fluid surrounding the brain may leak after surgery. This leads to a risk of meningitis and hospitalization with possibly further surgery to close the leak.
Brain complications	Meningitis, brain abscess, and stroke were commonly caused by ear disease prior to the use of antibiotics. They can still occur with or without surgery but have become very rare.

2. Tympanomeatal flap incisions are made at 12 o'clock and 6 o'clock, connecting in the posterior lateral ear canal. (Fig. 133.3) This flap should be made long enough to cover the defect that will be made by curetting the scutum (Fig. 133.4).

3. Elevate the flap.

4. Lift the annulus inferiorly to avoid unintentional trauma to the chorda tympani.

5. Identify the chorda tympani nerve.

6. Curette the scutum for adequate exposure of the previously mentioned

landmarks. Care should be made to avoid injury to the chorda tympani. Leaving a thin lip of bone adjacent to the chorda, to be removed at the end, can help protect the chorda during the majority of this step (Fig. 133.5).

7. Palpate the ossicular chain by gently lifting laterally on the malleus, looking for movement of the incus; then push on the distal incus and look for compression at the incudostapedial joint or for movement of the stapes.

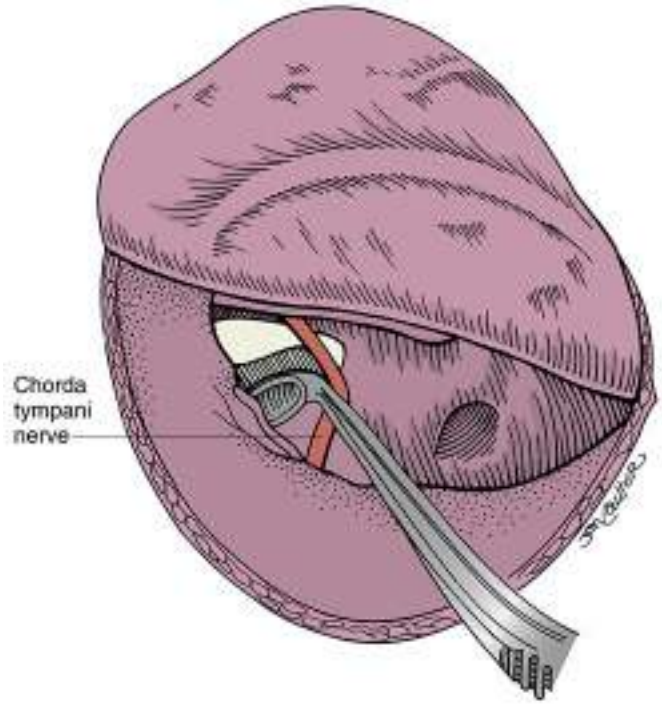

FIG. 133.3 Correct incision in the canal allows adequate removal of bone and exposure of the ossicular chain.

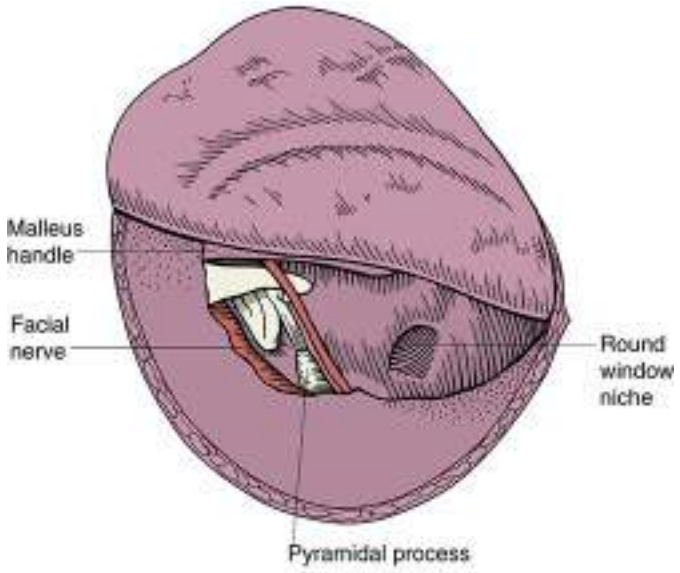

FIG. 133.4 Curetting the posterosuperior bony canal wall with preservation of the chorda tympani nerve.

8. Separate the incudostapedial joint. This can be achieved using an IS joint knife or angled pick. This should be done from a posterior to anterior direction to utilize the stabilization/counter traction provided by the stapedius tendon (Fig. 133.6).

9. Palpate the ossicular chain again to ensure it *is* the stapes that is fixed and the lateral chain is mobile.

10. If performing a large stapedotomy or a stapedectomy, harvest a soft tissue graft or vein graft and allow it to dry. The vein graft is taken from the dorsum of the contralateral hand. A straight vein section without branches can be marked, injected, and prepped for potential use. Make an incision through the dermis transverse to the axis of the vein. Spread bluntly with tenotomy scissors parallel to the vein, and isolate the vein. Tie off the vein with 4-0 Vicryl or chromic sutures; 1 cm in length is ideal to allow for redundancy, but a smaller graft can still be used. Clean any adipose tissue or adventia off of the vein, thread it over one tine of the tenotomy scissors, and cut the lumen open. Lay the vein out to dry (Fig. 133.7A to C).

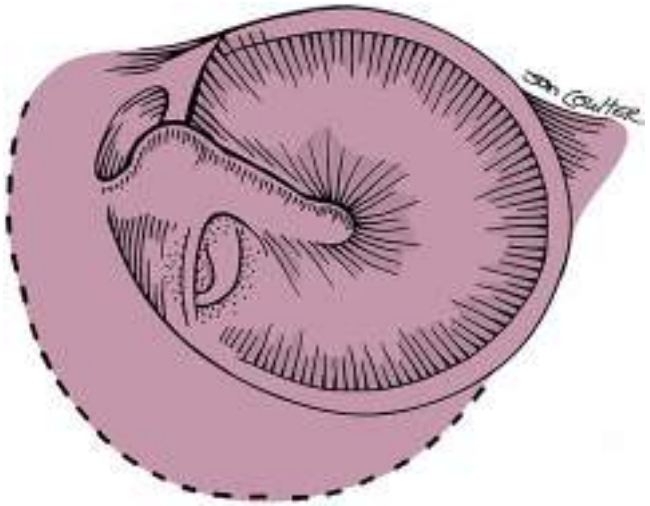

FIG. 133.5 Demonstrating adequate middle ear exposure for management of any conductive problem encountered.

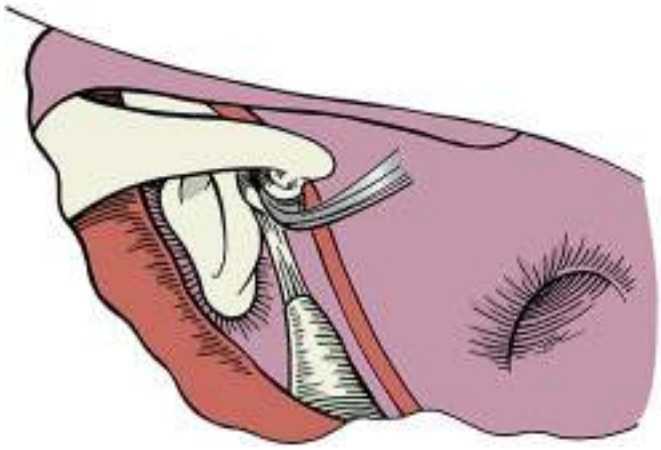

FIG. 133.6 Separation of the incudostapedial joint while being careful to preserve the lenticular process of the incus.

11. Test the laser on a tongue depressor to ensure that the laser is focused and aligned with the aiming beam, if present, and the burn is satisfactory.

12. A fenestration or control hole has two functions: first, to identify a perilymphatic gusher, and second, to allow access for a hook or pick to extract a floating footplate (Fig. 133.8).

13. Divide the stapedial muscle tendon. The laser or Bellucci scissors are useful instruments for this step (Fig. 133.9).

14. Laser the posterior crus of the stapes (Fig. 133.10; Video 133.1).

15. Down fracture the stapes superstructure inferiorly onto the promontory with a Rosen pick. Push the freed superstructure down onto the promontory and remove it with cupped or alligator forceps (Fig. 133.11).

16. Measure distance and select prosthesis. The measuring technique varies for different prostheses. For the classic bucket-handle type prosthesis, measure from the vestibule to the medial edge of the incus (Fig. 133.12). If measuring is done prior to the stapedotomy, measure from the footplate to the mid-thickness of the incus.

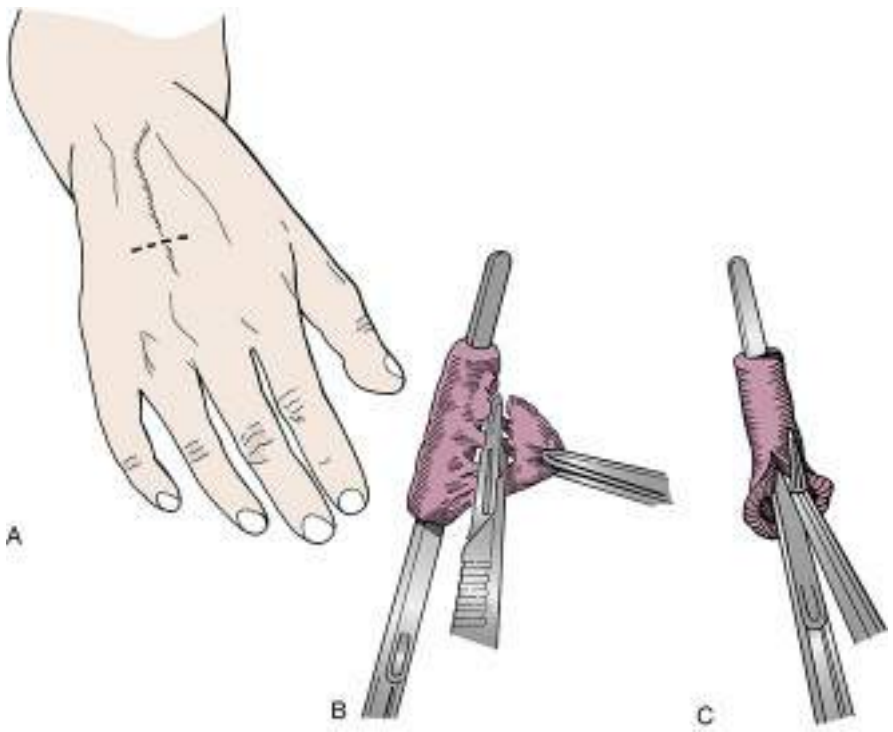

FIG. 133.7 **A,** 2-cm transverse incision is made on the dorsum of the hand for harvesting the vein graft. **B,** Removal of connective tissue from the vein graft. **C,** Opening the vein graft.

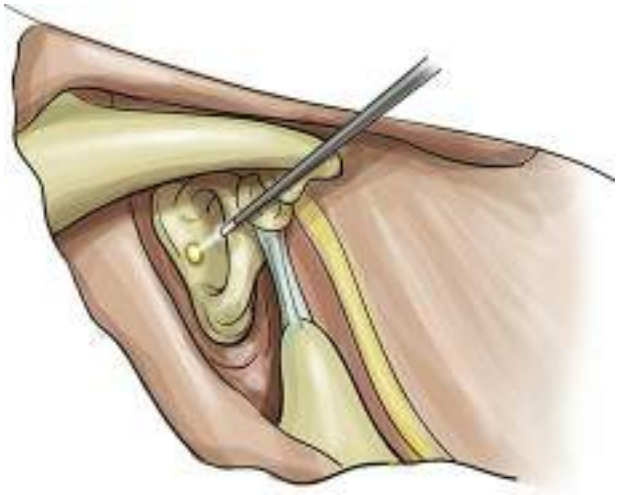

FIG. 133.8 Fenestration of the superior central area of the stapes footplate with a laser.

17. Make the stapedotomy. The laser is used to enlarge the fenestration control hole by vaporizing the edges of the hole creating a rosette pattern. This helps prevent floating fragments of footplate bone. A footplate pick or rasp can be used to remove fragments or to enlarge the stapedotomy (Fig. 133.13).

18. Place vein graft. Trim the graft so the edges are clean. The vein graft should cover the stapedotomy completely and ideally drape onto the facial nerve as well as the promontory. Typically this is about 5 × 4 mm. Push the vein down in the center, over the stapedotomy, to help "visualize" where the prosthesis should go, even though the stapedotomy is covered (Fig. 133.14).

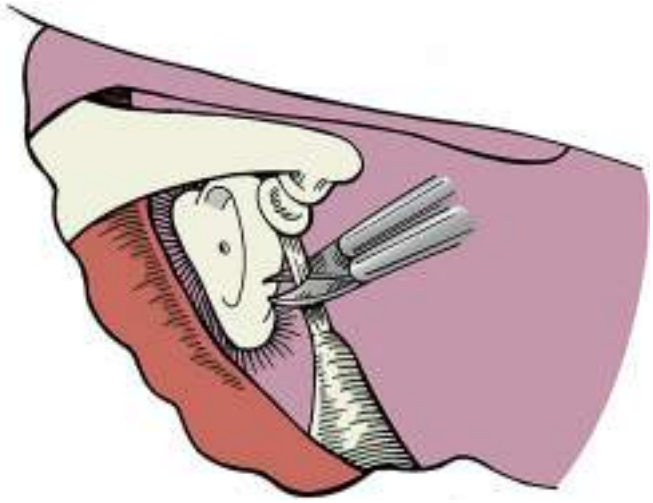

FIG. 133.9 Sectioning of the stapedial tendon.

19. With alligator forceps holding the posterior lip of the bucket with the handle inferiorly, place the piston end into the depression made in the vein graft overlying the stapedotomy. Rest the bucket against the incus, and remove the alligator forceps. Using a right-angle hook to gently retract/stabilize the incus, and with a Rosen needle in the well of the bucket, gently push the prosthesis medially to slip the bucket well under the lenticular process of the incus (Fig. 133.15). Elevate the bucket handle over the distal end of the incus. If the bail of the handle is loose, a small piece of vein can be placed over the bucket handle to help secure it in place.

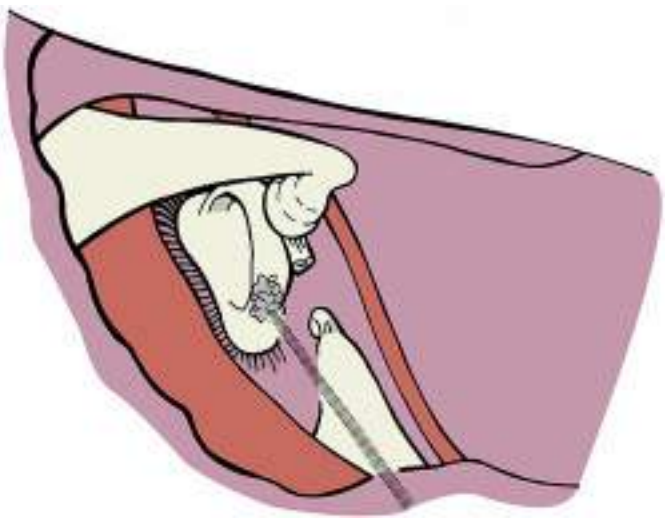

FIG. 133.10 Vaporization of the posterior crus with the

laser.

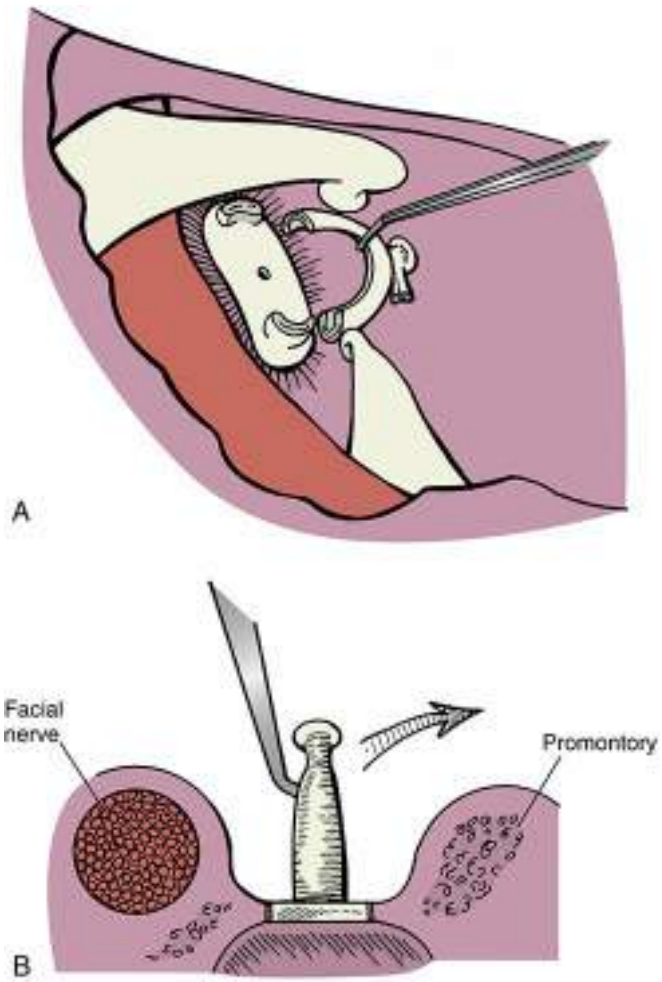

FIG. 133.11 Down-fracturing of the stapes superstructure toward the promontory. **A,** Surgeon's view. **B,** alternate view with relation to the facial nerve.

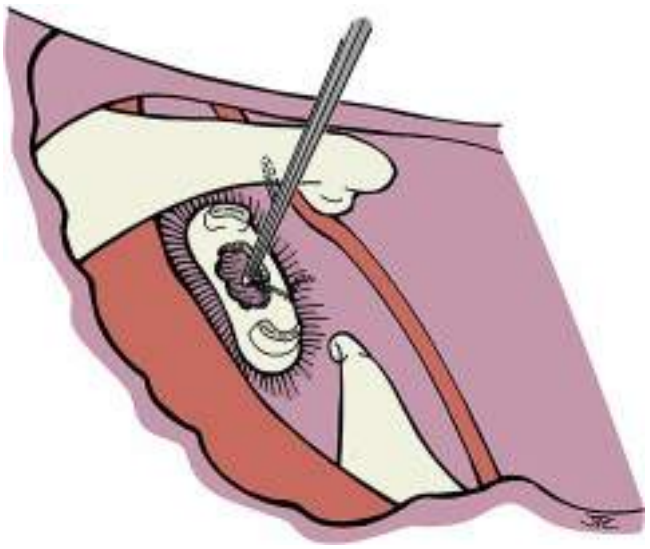

FIG. 133.12 Measurement is from the vestibule to the undersurface of the incus for the Robinson prosthesis.

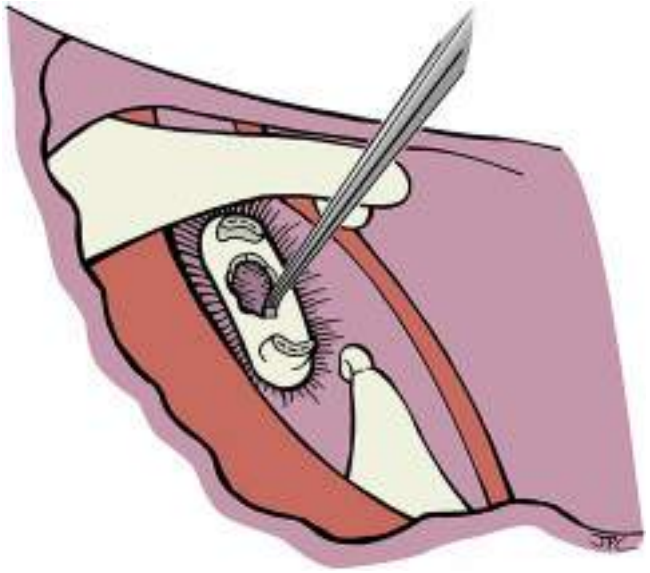

FIG. 133.13 Removal of the central area of the footplate.

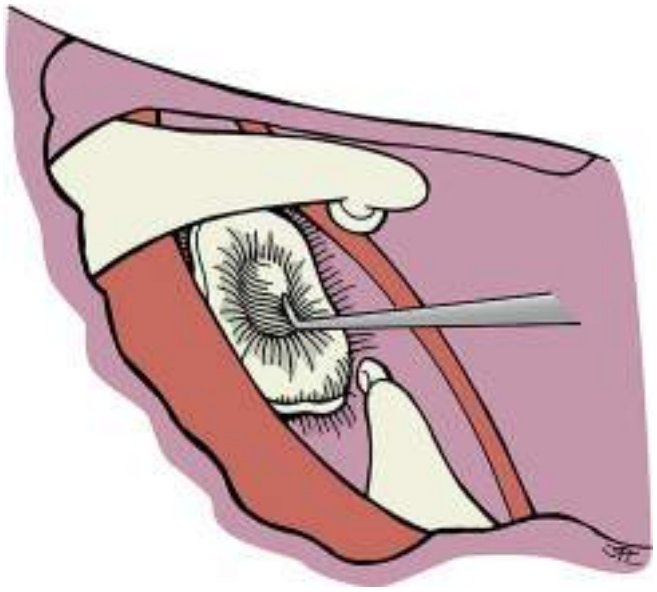

FIG. 133.14 Placement of the vein graft over the stapedotomy in the footplate.

FIG. 133.15 Placement of the Robinson prosthesis using a two-handed technique.

20. Check the mobility of the prosthesis—Look for a round window reflex; replace the tympanomeatal flap with care to ensure the edges are not curled under. If awake, check hearing.

21. The flap can be stabilized with Gelfoam soaked in Floxin laid over the

incision line.

Surgical Technique—Stapedotomy With Crimped Wire Piston Prosthesis

1. Steps 1 to 16 are identical in this technique. When making the stapedotomy, the size of the opening of the footplate is created to be 0.1 mm larger than the diameter of the piston. Intraoperative judgment is advised.

2. The piston is then placed in the oval window fenestra, and the wire or ribbon is crimped over the incus. Crimping is most easily performed using a specialized crimping instrument. Nitinol prostheses (e.g., SMart pistons by Olympus) are crimped using the laser to heat the hook portion, causing the prosthesis to tighten and curve around the incus. Care should be taken to avoid overcrimping. Overcrimping may lead to necrosis of the long process of the incus in the long term.

3. Some otologic surgeons then place a drop of freshly drawn blood or Gelfoam around the fenestra and prosthesis to further seal the stapedotomy and gently support the prosthesis in place.

4. Confirmation of prosthesis placement and flap closure as described previously in steps 20 and 21

Common Errors in Technique

1. Insufficient length of the tympanomeatal flap, which fails to cover the posterior bony canal wall in the setting of needed extra curettage of the scutum

2. Improper exposure of the necessary landmarks may lead to increased operative time.

3. Mis-identifying the IS joint. Take care to feel and identify the joint space before trying to separate the IS joint. A novice mistake is to assume the IS joint is more lateral than it is and accidentally cutting the lenticular process. This is more pertinent when a bucket prosthesis is used.

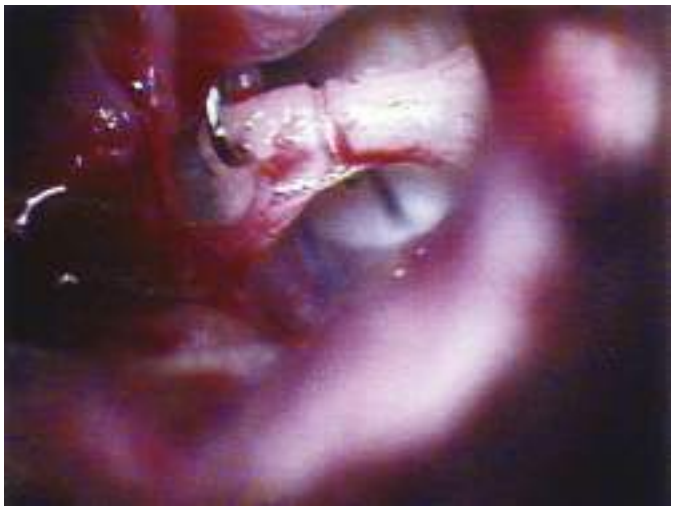

FIG. 133.16 Left ear showing a crimp-on prosthesis that had eroded the long process of the incus.

4. Excessive mobilization of the incus

5. Inadequate crimping of wire-piston prosthesis. Failure to crimp or tighten the hook adequately can lead to mobilization of the prosthesis and erosion of the long process of the incus from excessive motion. Overcrimping may lead to necrosis of the long process of the incus (Fig. 133.16).

6. Suctioning near the vestibule. Even when there is blood in the oval window niche, the suction should be pointed away from the vestibule to remove the blood.

Postoperative Period

Postoperative Management

1. General

   a. Ambulatory surgery—Patients will be discharged the same day. Consider one night admission of older patients with poor mobility or advanced comorbidities.

   b. Avoid brisk head movements.

   c. Avoid heavy straining/lifting or nose blowing.

   d. Air travel should be avoided until the ear is well healed.

e. Patients should return for follow-up in 1 to 2 weeks for removal of the packing.

f. Postoperative audiogram is typically done between 1 and 3 months postoperatively; however, there can be continued mild improvement after that point.

g. MRI—Patients should be notified of what type of prosthesis they have and the MRI compatibility for the particular prosthesis.

2. Medications

a. Appropriate pain control with low-dose combination acetaminophen and opioids may be necessary.

b. Postoperative antibiotics are not indicated.

Complications

1. Tympanic membrane perforation: If an iatrogenic perforation is small, then the surgeon can consider intraoperative medial graft tympanoplasty. However, if the perforation is large, then one should consider performing only the tympanoplasty and return at a future date to complete the stapedectomy/stapedotomy so as to reduce risk of vestibular contamination.

2. Nerve injury: Both the chorda tympani and facial nerves are at risk during this procedure. In order to avoid injury to the chorda tympani, care should be taken with elevation of the tympanomeatal flap, annulus, and entering the middle ear. Clear identification of the nerve makes injury less likely. In rare instances, the chorda tympani carries a tortuous course and may disrupt the operative view; then consideration to complete sectioning should be given. In this case, or in the case of iatrogenic injury to the nerve, care should be taken to reapproximate the nerve fibers at the conclusion of the case. Most patients will complain of temporary dysgeusia, which usually resolves over the course of several months. Injury of the facial nerve is rare. In cases where the nerve is dehiscent or overhangs the oval window, usually fastidious technique can ensure appropriate stapedotomy without injury to the nerve.

3. Ossicular dislocation: Careful elevation of the tympanomeatal flap can helps to avoid this possible complication. Ossicular dislocation may also

occur in cases of aggressive palpation of the ossicles. More commonly, this issue arises when the incus is laterally displaced during placement of the prosthesis.

4. Vertigo and sensorineural hearing loss: Aggressive manipulation of the stapes can result in damage to the vestibule and cochlea, resulting in sensorineural hearing loss. Furthermore, misplacement of the prosthesis or excessive loss of perilymph can result in significant vertigo.

5. Floating stapedial footplate: This occurs as a result of down-fracture of the stapedial superstructure with resultant detachment of the remnant annular ligamentous attachment of the footplate and its displacement into the vestibule. A floating footplate can be avoided if, prior to down-fracturing, a control fenestration hole is made in the footplate. The control hole facilitates extraction of the footplate if needed with a right-angle hook. If a control hole is not made, drilling of the promontory may be necessary to engage large fragments of the footplate and subsequent extraction (Fig. 133.17A and B). Smaller fragments should be left in place, as they rarely cause hearing loss though may contribute to positional vertigo. Multiple attempts to externalize the footplate or suctioning over the vestibule may lead to untoward outcomes, including increased risk of postoperative vertigo and iatrogenic sensorineural hearing loss. If the floating stapedial footplate is not easily removed, consider applying the tissue graft and prosthesis and terminating the surgery.

6. Perilymphatic gusher: Occasionally a widely patent cochlear aqueduct may lead to excessive flow of perilymph after the vestibule is opened with the stapedotomy. In this case, the head of the bed should be elevated to decrease flow. Some authors suggest suctioning of the fluid until the reservoir at the cerebellopontine cistern is exhausted. Ultimately, a fascia, fat, or vein graft is placed over the oval window and the prosthesis positioned to hold it in place (Fig. 133.18A to C). Rarely is a lumbar drain necessary to aid in decreasing flow postoperatively.

7. Reparative granuloma: This is a rare complication occurring in approximately 0.1% of cases. Typically it occurs 1 to 6 weeks postoperatively and can be associated with vertigo, sensorineural hearing loss, and roaring tinnitus. Treatment options include steroids and antibiotics versus exploratory surgery in which the granulation tissue, prosthesis, and graft (if used) are removed and replaced.

Alternative Management Plan

As previously discussed, alternatives to surgery include dispensing of a hearing aid. Patients are able to remain functional while deciding if they want surgery. There is some literature suggesting the use of sodium fluoride and, in rare cases, bisphosphonates in the treatment of cochlear or progressive otosclerosis. Sufficient level 1 evidence is lacking to support use of these treatments, although they remain as an alternative when having a comprehensive discussion with patients.

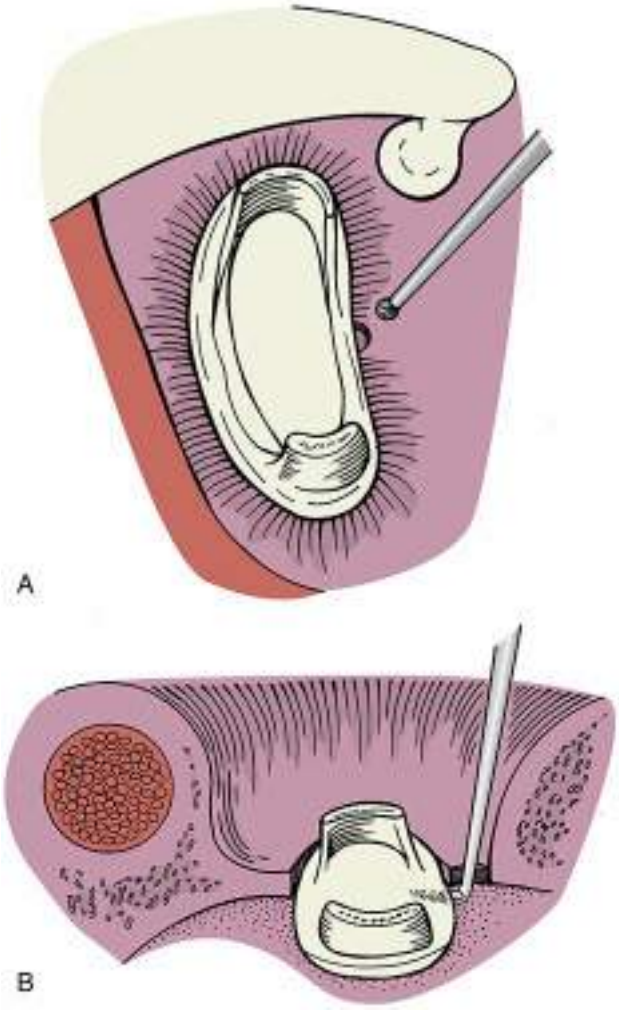

FIG. 133.17 **A,** Creation of a small "rescue hole" in the vestibule for removal of a floating footplate. **B,** Insertion of a fine right-angled pick through the rescue hole for retrieval of the footplate.

Discussion

Evidence-Based Medicine Question

Stapedotomy versus stapedectomy—What other options exist?

More important in a historical context, stapedectomy refers to the complete removal of the stapes footplate. Currently, most otologic surgeons perform fenestration of the footplate, leaving most of it intact, a term known as *stapedotomy*. There are many variations of this surgery. We perform the surgery with a CO_2 laser, since laser appears to be a less traumatic method of entering the vestibule and carries a lower risk of footplate mobilization when compared with conventional methods, such as microdrill or manual perforation. We feel that the CO_2 laser has the advantage over other lasers of being absorbed by water and thus does not penetrate deep into the vestibule. A systematic review by Wegner et al. suggests that lasers carry a lower risk of sensorineural hearing loss and footplate fractures compared with conventional methods; however, studies are limited by bias and variability in methods.[7] These findings regarding improved hearing outcomes were further corroborated by Fang et al., although unfortunately they were unable to perform subgroup analysis on different laser types (KTP, Ar, Erb-YAG, CO_2) due to the small number of studies.[8] A study by Szyfter et al. comparing Er-Yag and CO_2 lasers did not show a significant difference in hearing outcomes. Farrior et al. looked at Teflon-wire pistons versus stainless-steel bucket stapes prosthesis and did not see a statistically significant difference in hearing improvement. There was a nonrandomized study by Bittermann et al. that examined vein graft versus non–vein graft and did find better results with a vein graft; however, this study was not randomized and may have been influenced by which surgeon was performing the surgery and which techniques were used, as the non–vein graft group was predominantly micropick, whereas the vein-graft group was predominantly KTP and Skeeter drill. Weit et al. compared the hearing results using adipose tissue, fascia, and vein and did not find a statistically significant difference between these three tissue types. There does not seem to be any overwhelming evidence that one method or prosthesis type is superior over all other options in terms of closure of the air-bone gap. The data that we currently have are affected by

variables that are difficult to control for. Likely the most important factor is the surgeon's familiarity and comfort with a particular method and prosthesis.

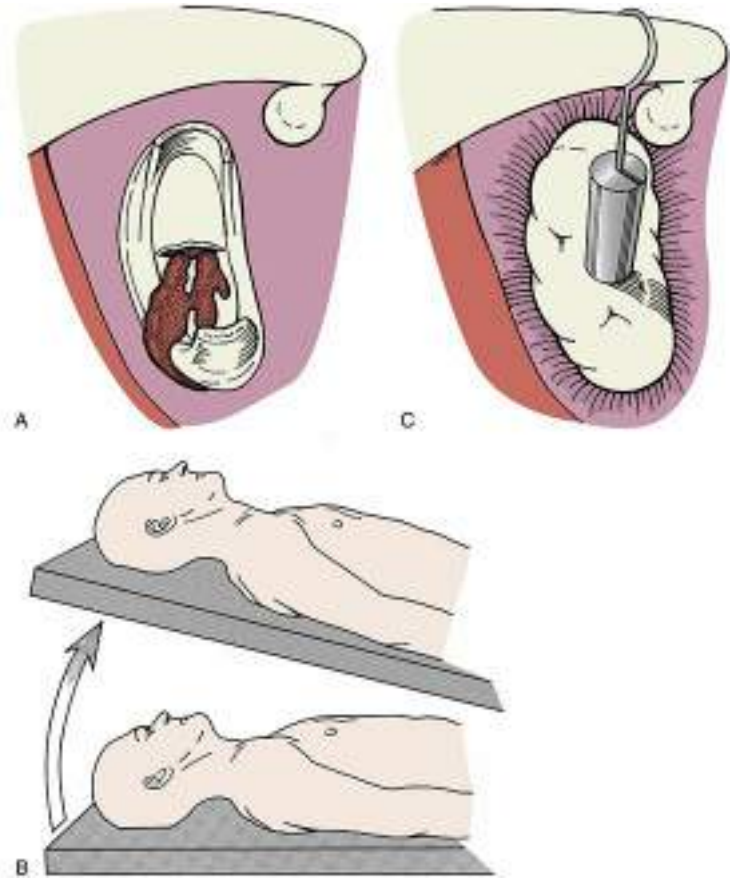

FIG. 133.18 **A,** A gusher of perilymph through the footplate fenestra. **B,** Reverse Trendelenburg position for relief of the perilymphatic gusher. **C,** Use of a piston prosthesis with an adipose tissue graft to seal the perilymphatic gusher.

Editorial Comment

Surgery of the stapes footplate remains the sole domain of the Otolaryngologist. Basic otologic skills must be mastered before proficiency in overcoming footplate fixation is achieved. Facile execution of microscopic bimanual dexterity skills are the foundation for middle ear surgery. During training, residents and fellows typically complete parts of the operative procedure. It is usually not until the surgeon has

full responsibility for the patient that he/she ascends the steep learning curve to achieve enough confidence and expertise to perform the entire procedure.

The use of the laser has been of tremendous benefit in minimizing trauma to the footplate and inner ear. A floating footplate is less likely if laser vaporization can create a fenestration, providing access for a footplate pick. Improvements in footplate drills not having "whip" provides smoother controlled thinning in obliterative otosclerosis.

Each stage in the operation must be accomplished with limited variance to avoid subsequent difficulties in the sequential steps. Inadequate patient positioning, improper design of the flap, trauma to the tympanic membrane, inadequate exposure, excessive bleeding, and a nonsedated patient are a few issues that can cascade into frustrating or unsuccessful surgery. Just as important as the execution of stapes surgery is knowing who the surgery should be offered to and predicting the postoperative anticipated results, which comes with time and experience.

Successful stapedectomy for otosclerosis is one of the most rewarding procedures we can offer. Improved hearing results are noted immediately and hopefully last a lifetime.

Barry Hirsch

Review Questions

1. Landmarks for appropriate exposure during stapedotomy include all of the following, *except*

   a. **Eustachian tube**

   b. Pyramidal eminence

   c. Chorda tympani

   d. Facial nerve

2. The presence of which of these findings is inconsistent with otosclerosis?

   a. **Normal stapedial reflexes**

b. Air-bone gap greater than 20 dB

c. Mixed hearing loss

d. Normal tympanic membrane

3. Which imaging study is a prerequisite to stapedotomy?

a. MRI with and without gadolinium

b. CT without contrast

c. CT with contrast

d. **No imaging study is required**

Mastoid Surgery

Charles B. MacDonald, and Joshua W. Wood

Introduction

The early indications for mastoid surgery involved drainage procedures for acute, life-threatening infections. In current practice, acute coalescent mastoiditis is infrequent and most mastoidectomies are done for chronic infection, usually with cholesteatoma—the focus of this chapter. In the modern era, mastoidectomy is an initial step in neurotologic procedures such as cochlear implantation, surgery of the endolymphatic sac and facial nerve, labyrinthectomy, temporal bone resection, and cranial base approaches to the posterior fossa and petrous apex. For all indications, competent mastoid surgery requires precise surgical sculpting of bone and sequentially identifying and delineating anatomic landmarks. Preoperative planning based on all available information is necessary and yet is usually somewhat open-ended. As disease is exposed, intraoperative decisions must be made. Should the canal wall remain up, down, or reconstructed? Should the cavity be obliterated? Should there be a second-look procedure and/or staged tympanoplasty? What is the best option for ossicular reconstruction?

Subtle variants of normal anatomy and disease extension challenge the surgeon to make appropriate pre- and intraoperative surgical decisions for optimal outcome, which should include the best possible hearing and minimal chance of recurrent/recidivistic disease.[1–4]

Key Operative Learning Points

- In chronic ear surgery, preoperative planning, though essential, may be altered by decisions made based intraoperative findings.
- The status of the contralateral ear will influence the decisions regarding

surgical options for the management of cholesteatoma.

- Skilled use of the operating microscope, otologic drill, otologic endoscopes, and micro instruments are best developed in the temporal bone dissection laboratory.
- Astute awareness of the tegmen, sigmoid sinus, otic capsule, and the vertical segment of the facial nerve must be maintained throughout the procedure.

Preoperative Period

History

1. History of present illness

- Presence and duration of hearing loss, otorrhea, otalgia, dizziness
- Factors associated with onset of symptoms: local trauma, water exposure, barotrauma
- Chronic or recurrent symptoms
- Efficacy of previous medical intervention
- Rapid progression of symptoms may require expedited surgical intervention
- Headache or mental status change may indicate an intracranial complication

2. Past otologic history

- Childhood ear infections or surgery
- Hearing ability prior to the onset of current symptoms
- Occupational or other noise exposure
- Ototoxic medications
- Past radiotherapy with fields including the temporal bones
- Previous mastoid surgery
- Otologic implant: cochlear implant, reconstructed ear canal, stapedectomy prosthesis

- Use of amplification for either ear should be noted.

3. Status of the contralateral ear

- Contralateral middle disease, perforation, Eustachian tube dysfunction
- Bilateral cholesteatoma
- Contralateral hearing loss
- The patient may benefit from contralateral amplification prior to surgery

4. Past medical history

- Conditions involving referred otalgia can complicate postoperative pain control
- Past vestibular symptoms should be considered carefully

5. Medical illness

- Conditions adversely affecting wound healing
- Bleeding disorders
- Conditions posing increased risk for general anesthesia

6. Medications

- Anticoagulants
- Drug allergy

7. Mental and social issues

- Ability to comprehend an informed consent
- Ability to tolerate postoperative otologic instrumentation such as mastoid cavity care
- Compliance with long-term otologic care and likeliness to return following staged surgery

Physical Examination

- A complete otolaryngology examination including the nasopharynx and cranial nerves
- Microscopic examination of the ears with appropriate debridement

- Repeat microscopic examination after treating suppuration may be enlightening
- The ear canal may require canaloplasty for surgical exposure and postoperative care
- The contralateral ear should be carefully examined with an otologic microscope
- Photo documentation of the otologic findings may be helpful
- Rinne and Weber tuning fork tests should be recorded preoperatively
- Postauricular swelling and erythema indicate an abscess and requires emergent intervention
- Acute facial palsy or other local cranial neuropathies require rapid intervention
- Papilledema may indicate an intracranial complication

Audiometry

- Standard bilateral behavioral audiometry is strongly recommended for diagnosis and management
- Children or mentally impaired adults may require auditory evoked brainstem testing to obtain side-specific thresholds.
- Emergent surgery for intracranial complications should not be delayed for audiometry

Imaging

- When planning elective mastoid surgery, imaging is generally obtained to assist in performing safe and expeditious surgery. Nevertheless, imaging is not essential to perform mastoidectomy. For example, if unexpected cholesteatoma is encountered during tympanoplasty, a surgeon may safely proceed with appropriate mastoid surgery without preoperative images.
- Computed tomography (CT) imaging in axial and coronal planes is the standard anatomic study of the temporal bone.

- Axial images demonstrate the extent of mastoid pneumatization and the position of the sigmoid sinus
- Coronal images indicate the contour and level of the tegmen mastoideum and tympani
- CT is excellent in the delineation of congenital ear malformation
- CT demonstrates bone erosion: horizontal semicircular canal, tegmen, Fallopian canal, malleus/incus
- CT cannot usually establish the status of the stapes in the presence of chronic ear disease
- CT may not distinguish cholesteatoma from other soft tissue or fluid, unless bone expansion or erosion of the scutum is identified

- Magnetic resonance imaging (MRI) is the standard study to demonstrate retrocochlear pathology
  - MRI (T2 coronal) will identify an encephalocele, Gadolinium enhancement of tumor, and intracranial complications of mastoiditis
  - MRI (T2 weighted) will identify the membranous labyrinth and nerves in the internal auditory meatus
  - MRI (diffusion weighted imaging) can differentiate cholesteatoma from fluid and thickened mucosa
  - MRI does not demonstrate fine details of the middle ear and mastoid anatomy
- CT and MRI may be required for glomus tumors or lesions of the petrous apex
- CT guided surgical navigation systems may be used in select cases such as lesions of the petrous apex

Indications

- Acute coalescent mastoiditis with or without temporal bone/intracranial complications
- Cholesteatoma involving the epitympanum or mastoid
- Chronic suppurative mastoiditis without cholesteatoma

- Temporal bone resection for malignant disease
- Approach to the facial nerve for tumor, decompression, or cable grafting
- As an initial step in the majority of neurotologic surgical procedures
- Intact canal wall
  - Drainage of acute coalescent mastoiditis
  - Cholesteatoma surgery in which disease is removed or a second look is planned
  - Facial nerve surgery, cochlear implantation.
- Canal wall down (CWD)
  - Limited exposure and underdeveloped pneumatization
  - Unfavorable anatomy with disease affecting the tegmen, sigmoid sinus, and mastoid tip.
  - Cholesteatoma cannot be fully removed, requiring "exteriorization" of disease
  - Risk of surgical complication from repeat procedures is elevated
    - Horizontal canal or other otic capsule fistula
    - In the case of an only hearing ear, CWD mastoidectomy may be wise
    - Cholesteatoma matrix on an eroded footplate or widely dehiscent facial nerve
- Reconstruction of the canal wall may provide excellent exposure without long-term cavity issues. However, this may involve the use of foreign material in a contaminated field. A second look is generally advised.
- Obliteration of the mastoid cavity may make long-term care much easier but have some risk of burying cholesteatoma matrix. If foreign material such as hydroxyapatite cement is used, it will be inserted into a potentially contaminated field.

Contraindications

Patient Factors

- Excessive risk of general anesthesia
- Poor wound healing

Disease Factors

- Mastoidectomy alone is inadequate for cholesteatoma extending beyond the boundaries of the temporal bone
- Auto-epitympanotomy or auto-mastoidectomy may enable adequate exposure for debridement in the office.

Preoperative Preparation

- Control of infection with systemic/topical antibiotics and debridement when possible
- Informed consent includes understanding the chronicity of the disease, risks, and hearing outcomes
- Staged tympanoplasty or second-look procedures should be included in the consent
- The possible role of postoperative amplification should be discussed
- Optimize medical fitness for general anesthesia
- The surgeon should review clinical, audiometric, and imaging data prior to surgery.
- Imaging studies should be available for intraoperative review

Operative Period

Anesthesia

- General: This procedure is performed under general anesthesia. Pharmacologic muscle relaxation should be avoided whether or not facial monitoring is employed.

Positioning

- Positioned supine with the head turned to the contralateral side, protecting the auricle and allowing the surgeon to be seated.
- The neck is in neutral position or slightly flexed to allow better line of sight down the external auditory canal (EAC).
- The facial nerve monitoring electrodes are placed and tested, if employed.
- The patient is strapped to the bed at multiple points, as rotation of the bed is likely during the procedure.
- The surgical assistant and microscope are positioned to facilitate easy access to the field and passing instruments.

Perioperative Antibiotic Prophylaxis

- A first-generation cephalosporin is usually used.
- Patients who are allergic to penicillin derivatives may receive either clindamycin or vancomycin.

Monitoring

- Facial nerve monitoring is often used.

Many surgeons routinely use facial nerve monitoring, although its use does not substitute for knowledge of and respect for the pertinent anatomy.

Instruments and Equipment to Have Available

- Tympanoplasty/mastoidectomy set—most surgeons have favorite preferences
- Otologic drill with various cutting and diamond burs
- Operating microscope, with appropriate lens (usually 225 to 300 mm)

- An otologic endoscope may be useful to view difficult areas

Key Anatomic Landmarks

Key External Landmarks

- MacEwen's triangle
- Linea temporalis
- Spine of Henle
- Cribriform fossa

Key Internal Landmarks

- Tegmen mastoideum
- Sigmoid sinus
- Posterior ear canal wall
- Digastric ridge
- Horizontal semicircular canal (HSC)
- Fossa incudis and incus
- Facial recess

Prerequisite Skills

- The most important skill to have is a detailed three-dimensional knowledge of the anatomy of the temporal bone and common variants.
- The surgeon requires otologic microsurgical skills.
- Most teaching facilities have access to a temporal bone laboratory. Dissection of specimens in the temporal bone laboratory is valuable for the acquisition and maintenance the skills needed to excel in mastoid surgery. The role of computer simulation of temporal bone surgery is evolving.

Operative Risks

- Tympanic membrane (TM) perforation
- Altered taste
  - Stretching or cutting the chorda tympani nerve results in dysgeusia. The symptoms often resolve within a few months.
- Vertigo, sensorineural hearing loss (SNHL)
  - Either, or both, can occur from dislocating the stapes footplate or violating the otic capsule.
  - Touching the incus with the drill can also cause SNHL
- Facial paralysis
  - Caused by direct trauma or thermal injury
  - If facial nerve weakness is identified postoperatively, the surgeon should wait to allow any infiltration of local anesthesia to dissipate.
  - In the case of paresis, the patient should be treated with corticosteroids and closely monitored.
  - In a case of paralysis, if the surgeon is confident that the nerve was spared, corticosteroids and electroneuronography (ENoG) are appropriate.
  - In a case of paralysis in which the integrity of the nerve is in question, then electromyography (EMG) and temporal bone CT are performed.
    - Surgical reexploration should be performed as indicated by EMG or CT scan (see Chapter 138).
- Injury to the tegmen or dura
  - Bony defects that are larger than 1 cm, or any dural injury, should be repaired to prevent the development of a CSF leak or encephalocele.
- Injury to the ossicular chain
  - All of the ossicles are at risk during the procedure, but the incus and stapes are at highest risk.
  - Dissection on the stapes should be from a posterior to anterior

direction to take advantage of stabilization provided by the stapedius tendon.

- Hemorrhage from the sigmoid sinus
  - Hemostasis can often be achieved by applying pressure with Surgicel or Gelfoam soaked in epinephrine.

Surgical Technique

- The operative field, including the ear canal, is prepared with povidone-iodine or other appropriate preparative antibacterial solution.
- The surgical drapes, suction and irrigation tubing, otologic drill, and operating microscope are moved into position.
- The canal and tympanic membrane are examined and fully debrided using the operating microscope, confirming the preoperative findings.
- If a tympanomeatal flap is to be elevated in conjunction with the mastoidectomy, a four-quadrant injection is done using lidocaine with epinephrine. The proper location for this injection is the bony-cartilaginous junction (estimated by the medial-most aspect of the hair-bearing canal skin). A 1.5-inch, 25-gauge needle is used with the bevel aimed toward the bone to ensure the injection is in the proper subperiosteal plane. If the injection is performed properly, the canal skin will blanch down to the tympanic membrane.
- Topical epinephrine (1:1000) on cotton pledgets or Gelfoam can be applied as needed during middle ear and mastoid surgery. If cotton pledgets are used, they should be counted at the termination of surgery.
- If a tympanomeatal flap is to be elevated, an H-shaped vascular strip is established via an endaural approach (Fig. 134.1). The superior (12 o'clock) incision and inferior (6 o'clock) incisions are connected with a vertical incision approximately halfway between the annulus and the bony-cartilaginous junction.
- The postauricular incision is made just superior and posterior to the root of the helix and extends to the mastoid tip and is positioned several millimeters behind the postauricular crease. The incision is

carried down to the loose areolar tissue overlying the temporalis fascia.

- When a mastoidectomy is performed for access for neurotologic surgery, the incision is often placed more posteriorly to give better posterior access.
- In children, the inferior limb of the incision is farther posterior to avoid damage to the facial nerve.

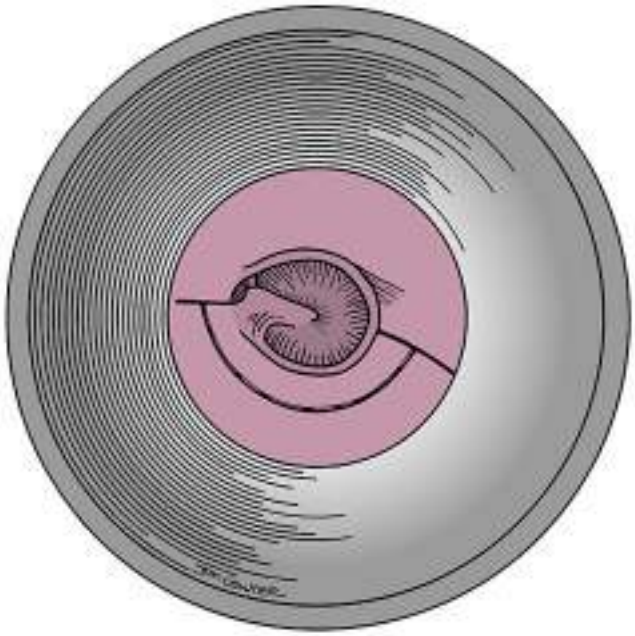

FIG. 134.1 Skin flaps within the external auditory canal.

An H-shaped skin incision creates a laterally based vascular strip-type flap and a medially based tympanomeatal flap.

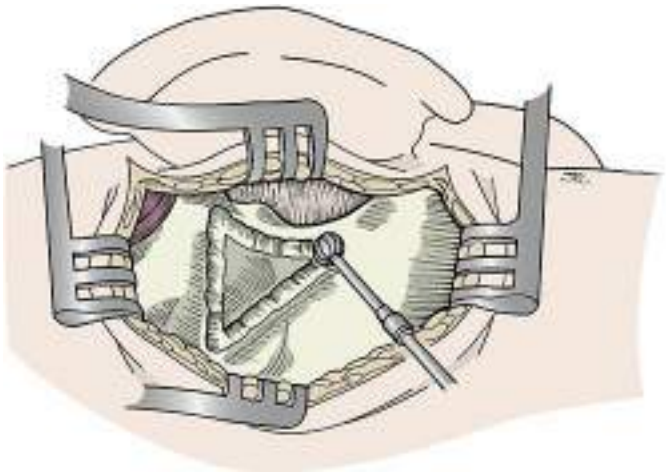

FIG. 134.2 Location and direction of the bone cuts on the mastoid cortex.

The initial bone cuts roughly outline the linea temporalis, posterior external auditory canal, and sigmoid sinus.

- The mastoid cortex is exposed by incising the periosteum along the linea temporalis, and a vertical limb in a "T" or "7" shape. The posterior ear canal is then exposed, and the vascular strip is elevated. The pinna is then retracted anteriorly with a Penrose drain or tracheotomy tape placed through the postauricular incision and brought out through the EAC.
  - The external landmarks including the spine of Henle and cribriform fossa should be identified.
- A temporalis fascia graft can be harvested at this point and set aside.

Intact Canal Wall Mastoidectomy

- The initial drilling on the mastoid cortex should form a triangle, as shown in Fig. 134.2. The cortex is removed and the air cell system is exposed.
- As drilling progresses, the deepest portion should always be over the antrum, which is approximated by MacEwen's triangle. This will ensure that the antrum will be entered before reaching the plane of the facial nerve.

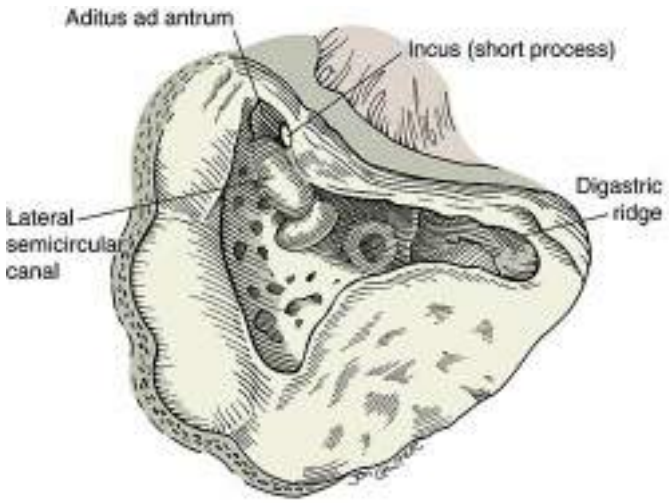

FIG. 134.3 Completed intact canal wall mastoidectomy.

The aditus ad antrum, the short process of the incus, the horizontal semicircular canal, and the digastric ridge are all visible.

- The tegmen will be visible as a pink color change in the bone superiorly in the mastoid cavity, and often small veins indicate close proximity to the dura. The sigmoid sinus likewise will be indicated by a blue color change posteriorly.
- Using the tegmen as the superior landmark and the EAC as the anterior landmark, Koerner's septum is removed and the antrum is entered.
- The bur is downsized and drilling continues toward the root of the zygoma until the HSC and incus within the fossa incudis are seen (Fig. 134.3).
- If a vascular strip was elevated, this should be replaced into the canal, and the canal should be packed with either Telfa or Gelfoam.
- The wound is closed in multiple layers.
  - The mastoid periosteum should be reapproximated to avoid retraction of the skin into the postauricular defect.
  - The deep layer of the skin is closed with 3-0 or 4-0 Vicryl, and the superficial skin is closed with 5-0 fast-absorbing plain gut suture.
  - The incision is then dressed as desired, and a Glasscock cup is applied for 24 hours.

Drilling the Facial Recess

- Defined by the incus buttress, the other boundaries of this potential triangular space are the vertical facial nerve and the chorda tympani nerve. The facial recess allows access into the middle ear via a posterior tympanotomy.
- One must identify the landmarks for the facial nerve, including the HSC, fossa incudis, and the digastric ridge. The short process of the incus points to the second genu of the facial nerve and is in the same plane as the facial nerve. The second genu of the facial nerve is just inferior and medial to the HSC. The cephalic edge of the digastric ridge leads to the stylomastoid foramen.
- Removal of bone proceeds just inferior to the incus buttress by drilling parallel to the course of the facial nerve. Adequate thinning of the posterior wall of the ear canal is an essential element in the facial recess approach. Copious irrigation prevents thermal damage and enhances visualization by removal of bone dust.
- The safest point of entry is the superior aspect of the recess, as it is widest at this point.

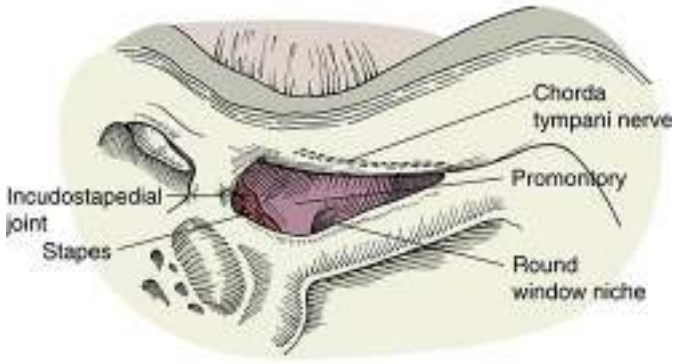

FIG. 134.4 Exposure of middle ear structures through the completed facial recess.

- Once the recess has been entered, drilling can continue medial to the chorda tympani to expand the view into the middle ear. Bone can also be removed as needed from the facial recess.

- The recess can be further expanded to view the middle ear structures including the incudostapedial joint, round window niche, and promontory (Fig. 134.4).
  - Sacrificing the chorda tympani in an extended facial recess approach enables removal of bone as far as the inferior tympanic annulus, exposing the medial surface of the TM and the hypotympanum.

Canal Wall Down Mastoidectomy

- It is especially important to saucerize the bony edges of the mastoidectomy superiorly and posteriorly to reduce the size of the mastoid cavity.
- The bone over the second genu and vertical portion of the facial nerve is thinned.
  - Inadequate removal of bone leads to a high facial ridge, which makes subsequent cleaning of the mastoid cavity difficult.
- The EAC can now be removed, typically with a 4-mm cutting burr, as shown in Fig. 134.5. The area to be drilled can be conceived as the anterior buttress (tympanosquamous suture line and lateral wall of the epitympanum), the posterior buttress (the facial ridge), and the intervening bridge of bone.
- Addressing the incus is an important step.
  - Frequently, the disease requires the incus to be removed. In this case, the incudostapedial joint should be separated before removing the canal wall.
  - If the incus can be left, a thin bridge of bone is left overlying the short process and is removed with a pick or curette.
- Reconstruction of the middle ear space is accomplished by packing the middle ear with Gelfoam.
  - The previously harvested and dried fascia is then placed in an underlay fashion by draping the graft onto the horizontal facial nerve superiorly and onto the facial ridge posteriorly, followed by further packing lateral to the residual TM and graft.

Bondy-Modified Radical Mastoidectomy

- Bondy mastoidectomy refers to the removal of the posterior canal for attic disease, without entering the middle ear space. It is usually used in the presence of attic cholesteatoma, which developed lateral to the ossicular chain without violating the pars tensa of the TM.
- The epitympanic cholesteatoma can be exteriorized through an endaural approach.

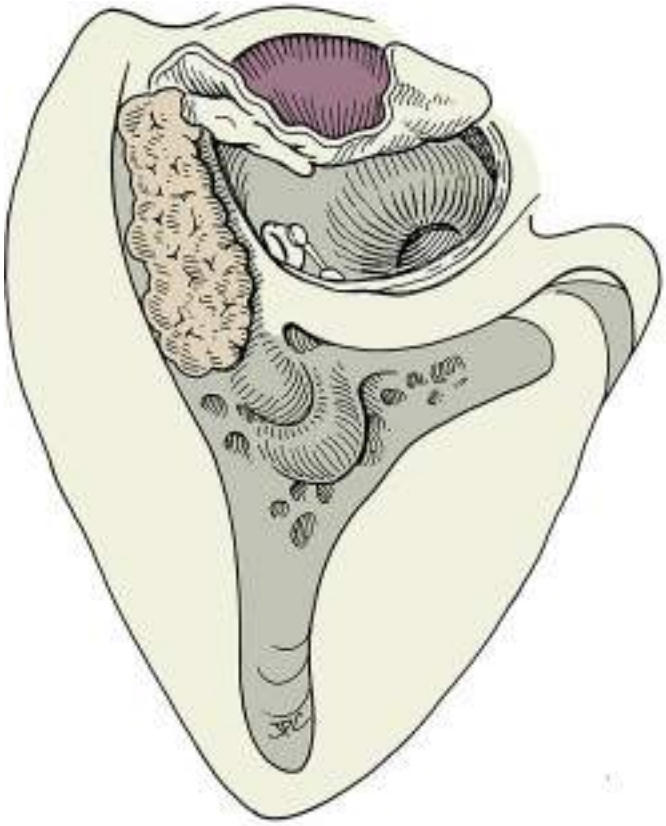

FIG. 134.5 Completed canal wall down mastoidectomy cavity.

- The anterior buttress (as described previously) is removed, and the superior canal wall is lowered to the level of the incus.
- The cholesteatoma matrix is left in place as the epithelial lining of the exteriorized epitympanum.

Radical Mastoidectomy

- This procedure is used in cases where the middle ear disease is irreversible and cannot be fully addressed with a CWD procedure.
- The procedure started with a CWD mastoidectomy
- The malleus, incus, and TM are removed, and reconstruction is not attempted.
- The middle ear mucosa is removed, and the Eustachian tube orifice is obliterated with a soft-tissue graft such as muscle, adipose tissue, or fascia
- The entire middle ear cavity is thus exteriorized into the EAC and mastoid bowl.

Meatoplasty

- This should always be performed when the posterior canal wall is removed, and ensures easy access to the mastoid cavity for in-office cleaning.
- Any meatoplasty will change the orientation of the pinna to some degree and may lead to a cosmetic defect.
  - The meatus should be sized to allow access to the superior, posterior, and inferior portions of the mastoid bowl.
  - Meatoplasty should be made with the expectation of some contracture during wound healing.
- An incisural meatoplasty involves extending the superior radial incision of the vascular strip into the incisura. The conchal bowl can then be pulled posterior and the secured to the postauricular area with 3-0 Vicryl sutures.
  - This technique is limited in that aggressive enlargement of the size of the meatus may create a cupped ear deformity.
- Another technique involves removal of a crescent of conchal bowl cartilage.
  - The conchal cartilage is exposed at its medial aspect from posterior to the pinna, elevated from the anterior overlying skin, incised, and removed.

- The subcutaneous skin of the conchal bowl is then pulled posteriorly, and 3-0 Vicryl sutures are used to secure the posterior meatal skin to the deep periosteal tissue posterior to the mastoidectomy cavity.

- The meatus is then typically stented with a roll of Telfa, a meatal expansile wick, or continuous antibiotic impregnated gauze for 10 to 14 days.

Common Errors in Technique

- Inappropriate choice of drill burs
  - Generally, larger burs are easier to control.
  - If a cutting bur touches bone on more than one side, then it will vibrate and be difficult to control.
  - Cutting burs do not work well at the depth of the mastoid tip.
  - Diamond burs can contact bone on more than one side and can be used at the tip.
  - Diamond burs generate heat rapidly.
- Inadequate saucerization
  - It is important to saucerize the edges of a CWD mastoid cavity to lower the profile of the cavity and provide adequate visualization of deeper structures.
  - In CWD mastoidectomy procedures, inadequate saucerization willprevent the soft tissues from collapsing into the mastoid cavity. This will ultimately lead to a larger mastoid cavity.
- Inadequate meatoplasty
  - This will result in accumulation of debris and contributes to chronic otorrhea.

Postoperative Period

Postoperative Management

- Evaluation of facial nerve, tuning fork tests, and dizziness/nystagmus

in the recovery room area

- Restricted activity levels during the early postoperative period
- Home application of topical antibiotic or lavage with appropriate rinses once packing is removed
- Periodic office debridement

Complications

- Hematoma or bleeding require surgical control. The most common bleeding complication occurs from the sigmoid sinus or jugular bulb and is easily controlled with gentle pressure with Surgicel or Gelfoam in most instances.
- Conductive or SNHL. Conductive hearing loss can occur from damage to the ossicular chain or tympanic membrane, which should be repaired by ossicular chain reconstruction or tympanoplasty. SNHL can occur from damage to any part of the inner ear, including oval and round windows, or semicircular canals. Should the inner ear be violated, the area of injury should be packed with soft tissue to prevent further damage to the inner ear.
- Facial paresis or paralysis. This can occur from direct or indirect damage. The management options are complex and hingers on the integrity of the facial nerve. This complication is discussed in greater detail in the Operative Risks and Evidence-Based Medicine sections of this chapter.
- Injury to the dura creating a CSF leak. Any bony defect that are larger and 1 cm, or any dural injury, should be repaired to prevent the development of a CSF leak or encephalocele.
- Early postoperative infection. This is relatively uncommon but requires aggressive antibiotic therapy to ensure proper healing of the operated field.

Alternative Management Plan

- If surgery for cholesteatoma is deferred, periodic debridement with

home lavage of the ear may control disease. Topical and systemic antibiotics may be required intermittently.

Discussion

Evidence-Based Medicine Question

How can the risk of facial nerve injury be minimized during mastoid surgery?

Damage to the facial nerve is a serious and feared complication of mastoid surgery. Although the risk is quite low, reported as less than 1% for primary cases and 4% to 10% for revision cases, it is nonetheless important for any ear surgeon to understand how to minimize the risks of this potentially devastating complication.[5] Otological surgery represented 17% of all iatrogenic facial nerve injuries, and mastoid surgery was responsible for 82% of these otologic iatrogenic injuries.[6]

The most fundamental technique in mastoid surgery is identification of landmarks. In this regard, the knowledge of the complex anatomy of the temporal bone is the most important protection against facial nerve injury. The major landmarks for identification of the facial nerve include the lateral semicircular canal, the short process of the incus, and the posterior bony external ear canal. The minor landmarks are the digastric ridge, the cochleariform process, and the oval window. The major landmarks should be exposed in each case, and minor landmarks used in selected cases.[7] It is our contention that the stapes/oval window is a major landmark for the facial nerve. The surgeon should also be familiar with the normal variants of the facial nerve.

The surgeon must ensure identification of MacEwen's triangle and drill strictly over this area until the mastoid antrum and lateral semicircular canal are identified. Novice surgeons have a tendency to drill inferiorly and posteriorly to the antrum, which puts the facial nerve at risk. In cases where the antrum is difficult to identify, drilling in an anterior and superior direction is advocated. The second genu of the facial nerve is the most commonly damaged segment during mastoid surgery and is found at the posterior edge of the oval window and medial to the short process of the incus.[7]

Over the past few decades, the use of intraoperative nerve monitoring has become more prevalent. Although monitoring can help with identification of the nerve and give a warning signal, it is not a substitute for anatomical landmarks. A recent publication showed that 49% of respondents felt that facial nerve monitoring should be used as the standard of care in chronic ear surgery. There is a trend among academic faculty and younger surgeons to use nerve monitoring more regularly.[5]

Editorial Comment

Mastoidectomy is the key approach providing initial entry to many otologic procedures. Chronic inflammation of the mastoid and middle ear requires cleaning of the diseased cells and mucosa to achieve removal and provide healthy aeration. Extensive cholesteatoma may require removal of the posterior canal wall to provide access both at the time of the procedure and post operatively for care of the cavity.

Mastoidectomy is the essential procedure needed for placement of a cochlear implant, gaining access to repair a mastoid tegmen defect for encephalocele or CSF leak, facial nerve decompression for lateral trauma, access to the mastoid and hypotympanum for excision of a glomus tumor, endolymphatic sac decompression, labyrinthectomy for vertigo, and resection of vestibular schwannoma via a translabyrinthine approach. The surgeon must appreciate the 3-dimensional anatomy as the dissection proceeds from lateral to medial. Critical structures include the dura, sigmoid sinus, facial nerve, ossicles, and otic capsule. The authors emphasize the benefit achieved with repetitive hands on experience gained in the temporal bone laboratory. In the clinical setting, CT imaging provides the road map for varied anatomy that should be identified in the films and anticipated during the surgery. Repetition of the mastoid procedure builds experience and provides greater comfort with subsequent approaches. However, to avoid complications, focused vigilance must be maintained throughout the procedure.

Review Questions

1. All of the following are common reasons for failed CWD mastoidectomy *except*:

   a. Residual disease left in the epitympanum

   b. **Tympanic membrane perforation**

   c. High facial ridge

   d. Inadequate meatoplasty

2. All of the following statements are accurate regarding a Bondy-modified radical mastoidectomy except;

   a. The posterior ear canal wall is left intact

   b. The epitympanum is cleared with a postauricular approach

   c. **It involves reconstruction of the ossicular chain**

   d. The cholesteatoma matrix is left in place as the epithelial lining of the exteriorized epitympanum

3. What is the relationship of the second genu of the facial nerve to the HSC?

   a. CN VII is lateral and posterior to the HSC

   b. CN VII is medial and posterior to the HSC

   c. CN VII is medial and anterior to the HSC

   d. CN VII is lateral and anterior to the HSC

   e. **CN VII is medial and inferior to the HSC**

Bone-Anchored Hearing Devices

Yael Raz, and Douglas M. Hildrew

Introduction

- Bone-anchored devices conduct sound through bone vibration, bypassing the external and middle ear conductive apparatus
- Useful in patients with conductive or mixed hearing loss who cannot benefit from conventional amplification and are not candidates for surgical correction of their hearing loss
- Also useful in patients with single-sided deafness, as the sound coming to the deafened side can be transmitted by bone vibration to the intact contralateral cochlea with little cross-cranial attenuation
  - Does not provide sound localization but reduces the head shadow effect
- Two general types of devices
  - Percutaneous: sound processor delivers acoustic signal to the osseointegrated implant via direct coupling to an abutment that projects through the skin
    - Consists of three parts: a titanium implant that is osseointegrated into the skull, an abutment that couples the implant to the sound processor, and the sound processor
    - Baha Connect (Cochlear):
      - Baha DermaLock: 6, 8, 10, 12, and 14 mm abutments
        - Cochlear's DermaLock surface technology covers the abutment surface with a hydroxyapatite layer
          - Designed to allow use without thinning of the surrounding soft tissue

        - Cochlear also makes a titanium abutment without a hydroxyapatite covering, offered in 6-, 9-, and 12-mm lengths
    - Ponto (Oticon)
        - Ponto BHX Implant: 6-, 9-, 12-, and 14-mm abutments
- Transcutaneous—skin remains intact. Connection established via magnet
    - Alpha2 MPO (Sophono/Medtronic)
    - Baha Attract (Cochlear)

- Percutaneous strategies have the advantage of direct coupling and therefore better sound transmission.
    - It is estimated that transmission through the skin (transcutaneous) accounts for 10- to 12-dB sound attenuation.[1]
- Percutaneous devices carry a significant risk of soft tissue reaction at the skin–device interface, reportedly as high as 38% to 56%.[2,3]

Key Operative Learning Points

- Successful implantation of a bone-anchored hearing device relies on osseointegration of the implant.
    - Disposable drill bits ensure a sharp bit for each step.
    - Irrigation prevents thermal damage.
    - The implant is inserted with a high-torque drill at slow speed to avoid thermal damage to the surrounding osteocytes.
- Electrocautery to the skin surrounding the percutaneous abutment is minimized to help ensure formation of a healthy skin–abutment interface.
- The deep dermis should be sutured to the periosteum surrounding the abutment to ensure a healthy skin–abutment interface.

Preoperative Period

History

- Radiation, severe osteoporosis, and Paget disease can affect the quality of the bone.
  - Torque applied when the fixture is tightened may have to be adjusted accordingly
- Previous surgical history (mastoidectomy, craniotomy), presence of a ventriculoperitoneal (VP) shunt, or history of a temporal bone fracture will influence device type/location/incision.
- If the patient has ipsilateral intracranial/extracranial pathology that will require magnetic resonance imaging (MRI) for surveillance, the patient and corresponding treatment team should be adequately informed before implantation.
  - MRI performed with an implant magnet in place results in significant artifact that can adversely affect visualization of nearby pathology.
    - Artifact may extend over 11 cm.
  - Baha Attract—internal magnet approved for 1.5 Tesla
  - Alpha 2 (Sophono)—internal magnet approved for 3 Tesla
- Patients who form keloids are particularly prone to develop adverse soft tissue reactions.

Physical Examination

- Check for the presence of scars and/or VP shunt tubing that may impact the placement of the incision or the device.
- In patients with microtia/atresia, if auricular reconstruction is planned, a decision regarding the placement of the device should be made with the planned reconstruction flaps in mind.
  - The device may have to be placed more posteriorly to avoid contacting the anticipated rim of the reconstructed auricle.
    - This prevents disruption of the vascular supply to the temporoparietal skin flap used for its coverage.

Imaging

- Generally not indicated for preoperative planning
  - It should be confirmed that patients undergoing a procedure for the indication of single-sided deafness have been appropriately evaluated for internal auditory canal (IAC)/cerebellar pontine angle (CPA) pathology prior to surgery
- In certain patients where there is concern about the thickness of the bone, CT can be useful.
  - Children with craniofacial anomalies, such as Treacher Collins syndrome or microcephaly, are more likely to have thin cortical bone or a low-hanging middle fossa tegmen.

Indications

- There are two indications for bone-anchored devices:
  - Unilateral profound hearing loss
    - Patient must have excellent hearing in the contralateral ear (air conduction pure tone average [PTA]) ≤ 20 dB).
  - Mixed or conductive hearing loss and patients who are not candidates for conventional amplification/ossiculoplasty (i.e., because of atresia with unfavorable middle ear anatomy, chronic otorrhea after a canal wall down mastoidectomy, history of canal closure as part of lateral temporal bone resection, and/or allergy to ear mold material)
    - Patients with a mixed loss must have a bone line PTA equal to or less than 45 dB to be fitted with the Baha 5 processor, equal to or less than 55 dB for the larger Baha 5 Power processor, and equal to or less than 65 dB sensorineural hearing loss (SNHL) with the SuperPower, which has a behind the ear (BTE) component.
    - Patients with a mixed loss must have a bone line PTA equal to or less than 45 dB to be fitted with the Ponto, Ponto Plus, or Ponto Pro processors and equal to or less than 55 dB for the Ponto Power Plus and Ponto Pro Power processors.

- Patients should experience a benefit with the demonstration device in the office.
  - If the patient is a candidate for a transcutaneous (magnet-based) coupling, the demonstration device should be attached to a soft band during the trial.
    - A soft band more closely approximates the benefit of a transcutaneous device.
  - If the patient is a candidate for a percutaneous (direct-coupling) device, the demonstration device should be attached to a more rigid over-the-head metallic tension band.
    - A tighter metallic headband more closely approximates the benefit of a percutaneous device.
    - Advantages of the percutaneous devices include
      - No dampening of signal at the skin
        - Better sound transmission
      - Less artifact on MRI
        - The large magnets of the transcutaneous devices cause significant scatter and are not well suited for patients who need serial imaging for pathology located near the device.
      - Better retention of the processor
      - Preferable in patients with very thin/frail skin
        - A transcutaneous device may risk skin dehiscence and/or erosion.
    - Advantages of the transcutaneous devices include
      - Good cosmesis
      - No requirements for abutment care
      - Significantly lower rates of skin complications compared with the percutaneous device (infections, skin overgrowth)
      - Easier handling for patients with manual dexterity issues
      - Ability to be converted to a percutaneous device if hearing deteriorates

- If implantation is started with the a percutaneous device, the skin overlying the device would be compromised and it would be difficult to convert to a transcutaneous system.

Contraindications

- Patients who have lived with unilateral profound SNHL may not report much of a benefit compared with those who have recently become deafened.
- Bone-anchored hearing devices are US Food and Drug Administration (FDA)–approved for children 5 years of age or older.
  - Children less than 5 years of age can be fitted with a processor attached to a soft band.
- Caution is advised in patients with reduced hearing and a bone line greater than 55 dB in considering a bone-anchored hearing device.
  - Although the higher-power devices can allow patients with bone lines up to 55 to 65 dB to get benefit, it is helpful to get a sense of the rate of deterioration in hearing.
  - If the hearing is deteriorating rapidly, the patient may quickly lose benefit from the bone-anchored hearing device and a cochlear implant may be more advisable.
- Relative contraindications
  - Radiation, severe osteoporosis, Paget disease, presence of a VP shunt, and patients prone to keloid formation.
  - If the patient has pathology close to the ear that requires monitoring with MRI, a percutaneous device is preferable to a transcutaneous device.
  - Some patients with developmental delay, psychiatric issues, and/or autism spectrum disorders may not be able to perform the hygiene necessary to keep an abutment site healthy.
    - If possible, consider a transcutaneous device.

Preoperative Preparation

- Until approximately age 9, it is recommended that a two-stage approach be used.
  - At the first stage, the implant (fixture) is placed but the abutment or magnet is not attached. Instead, a cover screw is used to maintain patency of the inner threads of the implant.
    - In children, consideration should also be given to insertion of a "sleeper" implant.
      - This is maintained under the skin with a cover screw and serves as a backup in case of failure of osseointegration or secondary trauma with loss of the initial fixture.
  - After allowing for a 3- to 6-month time period for osseointegration, at the second stage the cover screw is removed and the abutment and/or magnet is attached.
- Two-stage surgery should also be considered for adults in the setting of abnormal (irradiated) bone or when insertion of a bone-anchored hearing device is being performed in conjunction with another surgery such as excision of an acoustic neuroma.
- Although in most adults the skull is thick enough to accommodate a 4-mm implant, it is good practice to have a 3-mm countersink and a 3-mm implant available for every case.
- An appointment with an audiologist is typically scheduled prior to surgery so that information regarding the use of the processor and warrantees can be reviewed.
  - The color of the sound processor should also be selected ahead of surgery, since the internal and external components are typically ordered simultaneously

Operative Period

Anesthesia

Usually general, although this can be performed under local anesthesia in adults.

Positioning

Supine, head turned toward the contralateral side

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin IV prior to incision

Monitoring

None necessary

Instruments and Equipment to Have Available

- Surgical instruments
  - Depending on which company and/or system is used, the needs may include a dummy device, raspatorium, dissector, drill, drill indicator, torque wrenches, screwdrivers, and abutment inserter.
  - For the transcutaneous devices, additional instruments that may be needed include the dummy device, soft tissue gauge, bone bed indicator, and implant magnet template.
- Company-specific drill console
- Drilling disposables: ¾-mm conical guide drill, 3- and 4-mm widening (countersink) drill.
  - Additional disposables for the percutaneous devices include a healing cap and a 5-mm biopsy punch.
- Implants (Baha, Ponto) come in multiple variations.
  - Fixture length can be either 3 or 4 mm.
    - This will depend on skull thickness as determined with the guide drill.
  - The implant can come separate, or preattached to the abutment.

- Steps vary depending on the surgeon's choice of a single-stage procedure (preattached) or two-stage procedure.
  - For a two-stage procedure, the implant is covered with a cover screw before skin closure instead of the placing the abutment or magnet.
    - The abutment or magnet may then be placed during a second procedure after full osseointegration has taken place.

- In addition to the company-specific drill console, a conventional otologic drill should be available for the transcutaneous devices.
  - It may be necessary to drill down bone surrounding the implant site so that the magnet lies flush with bone around its entire perimeter.

Key Anatomic Landmarks

- For the percutaneous device, the implant site is typically 50 to 55 mm from the EAC. For the transcutaneous device, the implant site is typically 50 to 70 mm from external auditory canal (EAC).
  - In using the dummy device to mark out the planned implant site, the top of the dummy should line up with the superior aspect of the helix.
  - The procedure may have to be modified depending on patient anatomy—presence of scars, craniotomies/plates/mesh.
  - Particular caution is called for with microtia patients who will be undergoing reconstruction in the future so as not to interfere with vascular supply for planned reconstruction.

Prerequisite Skills

- Experience in otologic surgery.
- The surgeon should be aware that the drills/burrs and other instruments used are specific to each company and to this procedure.

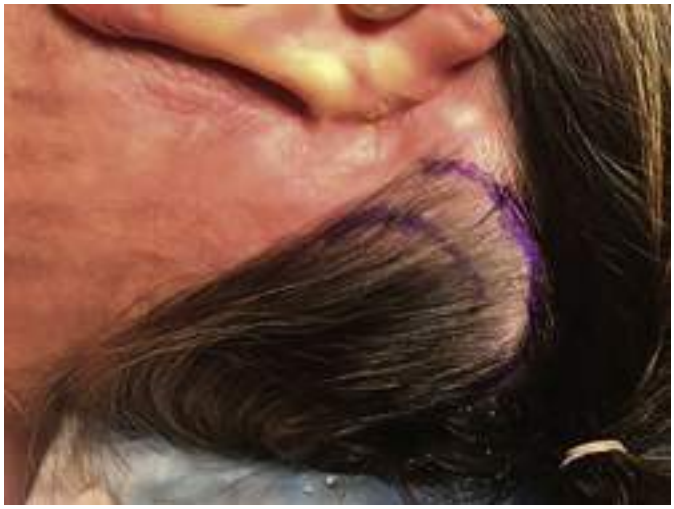

FIG. 135.1 When the Baha transcutaneous device is being implanted, typically a C-shaped incision is made with a posteriorly based flap.

- Trainees will have to familiarize themselves with the company-specific equipment ahead of time, ideally in a Temporal Bone Laboratory.

Operative Risks

- Failure of osseointegration
- Bone, epidural, or sigmoid sinus bleeding
- Cerebrospinal fluid leak
- Percutaneous: adverse soft tissue reaction including overgrowth of skin surrounding the abutment and infection at skin–abutment interface.[3]
- Transcutaneous: numbness of scalp, thinning of skin overlying magnet or exposure of the magnet, discomfort at the site from pressure between the external and internal magnets, higher risk of hematoma since a flap is elevated.

Surgical Technique

- This chapter focuses on technique for the transcutaneous Baha Attract and the percutaneous Baha Connect using a preattached abutment (Baha FAST).

- Baha Attract (transcutaneous).
  - Mark the optimal location of the dummy device.
    - Align the superior aspect of the dummy with the superior aspect of the auricle, 50 to 70 mm from the EAC.
    - The incision should be greater than or equal to 15 mm from the planned magnet location.
    - Typically a C-shaped incision is used with a posteriorly based flap (Fig. 135.1).
      - This allows room for the incision to be extended further posteriorly if the bone at the planned drilling site proves inadequate.
    - An incision that makes a 180-degree arc around the implant site will allow the drilling to be performed in a perpendicular fashion.
    - The incision may have to be modified in patients with previous incisions.
      - Previous postauricular incision can be incorporated as the anterior aspect of the Attract incision, with superior and inferior limbs extending posteriorly at 90-degree angles to the old incision to create a posteriorly based flap.
      - Alternatively, an inferiorly pedicled C-shaped flap can be used to avoid the previous scar.

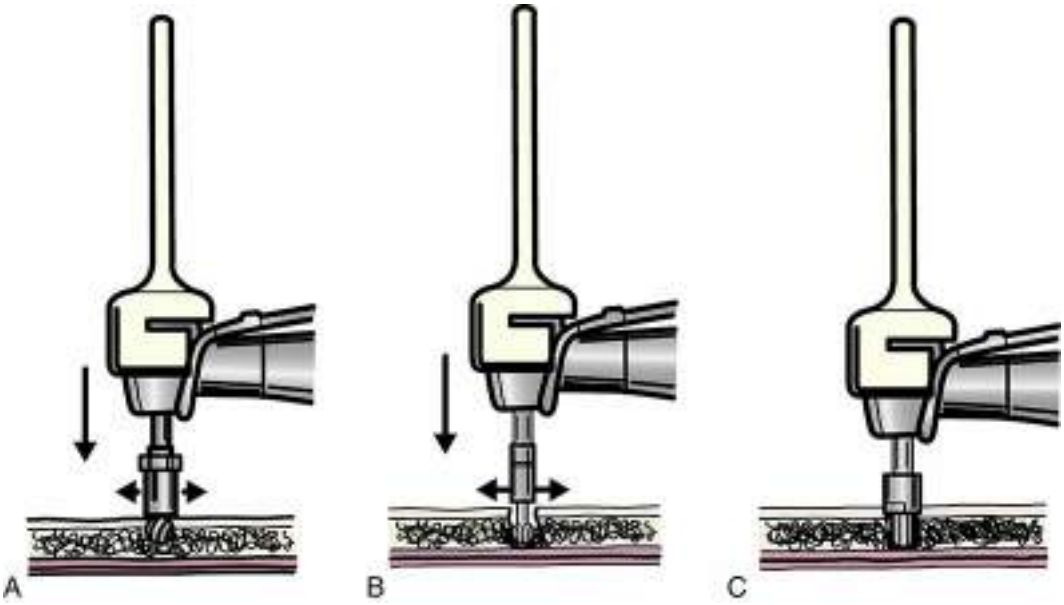

FIG. 135.2 **A,** Drilling begins with the use of the guide drill and a plastic spacer to ensure a depth no greater than 3 mm. **B,** The spacer is then removed and, if cortical bone thickness is sufficient, the guide hole is drilled to a depth of 4 mm. **C,** The appropriately sized countersink is then used.

- It is helpful to mark the bone at the intended implant location with methylene blue.
  - Use a 25-gauge needle on a 1-mL syringe and carefully remove all of the bubbles, making sure that the dye fills the tip of the needle.
    - Keeping the needle tip firmly against the bone, the syringe is then rotated back and forth and a few gentle taps are applied to the plunger.
      - The goal is to mark the bone without coating the soft tissue overlying the bone with excess dye.
- Lidocaine 1% with 1:100,000 epinephrine is injected along the planned C-shaped incision
- The postauricular region is then prepped and draped.
- Incision is carried down to the periosteum, leaving the periosteum intact.
  - Elevation is continued in the plane overlying the periosteum until the planned drilling site is identified (methylene blue is seen).

- Further elevation is necessary in the central region to allow the posterior aspect of the magnet to fit under the skin flap.
    - The implant magnet's template can be used to make sure that the flap has been adequately elevated.
- A cruciate incision is made in the periosteum at the planned drilling site and the periosteal flaps are elevated with a raspatorium.
- The bony contours surrounding the drill site should be carefully inspected at this point.
    - The implant site can be moved a few millimeters if the bone surface is irregular/depressed.
        - Within the topography of the squamosa, it is preferable to place the fixture on a "mountain" rather than in a "valley."
            - The magnet must vibrate freely without contacting surrounding bone.
        - Optimizing placement of the device will save time in later steps of the procedure by maximizing chances that the bone bed indicator will not hit adjacent bone.
- The ¾-mm guide drill is used with the plastic spacer in position under copious irrigation at a drill speed of 2000 rpm (Fig. 135.2).
    - It is vitally important to make sure that this initial drilling is performed perpendicular to the bone. An angled approach at this juncture will affect all the subsequent steps and result in a "tilted" implant.
        - This will require the use of the otologic drill to take down surrounding bone in order to allow the magnet to sit properly without abutting adjacent bone.
    - A drill indicator attachment can be used to facilitate visualization of the drill's trajectory.
    - After use of the guide drill, the dissector is used to determine whether there is bone or dura at the depth of the drill site.
        - Osseointegration may be impaired by the absence of bone at the deep surface of the implant.
        - In most adults, the bone thickness is sufficient to accept a 4-mm

device. This longer fixture is preferable when possible.

- If sufficient bone is encountered with the 3-mm guide drill, the plastic spacer is taken off and drilling is resumed to allow the conical guide drill to reach a 4-mm depth at 2000 rpm under irrigation.
  - If the initial drill site does not have sufficient bone depth, alternate sites can be attempted.
    - If multiple attempts do not reveal bone depth sufficient to handle a 4-mm device, a 3-mm countersink is used and followed by a 3-mm implant.
  - If there is sufficient bone depth, a 4-mm countersink is used under copious irrigation at a drill speed of 2000 rpm.
    - The countersink drill widens the guide hole to an appropriate diameter and creates an even surface for the small flange at the lateral aspect of the implant.
    - If the initial angle of drilling was successfully performed in a trajectory perpendicular to the bone, a 360-degree shallow countersink ring should be apparent at the margin of the drill site.
      - This ensures there is not a step-off when the implant is affixed.
- The appropriate length fixture is opened (3 or 4 mm).
- Very important: the fixture should not be handled directly but rather maintained within the plastic ampule, which is stabilized within the Baha tray.
  - While still seated within the plastic ampoule, the fixture is loaded onto the drill using the implant inserter.
    - Visually aligning the triangular aspect of the inserter with the respective triangle in the head of the implant facilitates this step.
    - A click should be felt when the fixture engages.
- Before the fixture is engaged with bone, the site should be copiously irrigated to eliminate bone dust and remove all bone fragments.
- The fixture is then inserted using a drill speed of 20 to 30 Ncm for soft bone or 40 to 50 Ncm for hard bone.

- No irrigation should be used until the first threads of the implant have engaged (two rotations) to avoid trapping fluid between the bone and the screw.
- Essentially no pressure is necessary at this stage. The drill will stop automatically when the appropriate torque has been reached; it can then be disengaged from the inserted implant.

- The bone bed indicator is then screwed onto the fixture and rotated in a clockwise direction to ensure that there is no adjacent bony prominence that will make contact with the magnet.
  - If the gauge cannot be freely rotated, a conventional otologic drill is used to remove the surrounding prominent bone until the bone bed indicator can be rotated freely and completely.
- The bone bed indicator is then removed and the magnet is screwed into position using the gold-tipped (Unigrip) screwdriver.
  - The magnet is marked with an "up" arrow, which should be pointed superiorly.
  - The magnet should be tightened to a final torque of 25 Ncm using the multiwrench with ISO adapter
- The soft tissue gauge is then used to determine whether the skin flap is appropriate.
  - If over 6 mm thick, it will have to be thinned in order to allow the processor and internal magnet to interact sufficiently.
    - The skin flap should be uniformly thinned to 6 mm, not just overlying the internal magnet.
- Three "tacking" sutures placed midway between the magnet and the incision (at the inferior, anterior, and superior locations) are helpful in closing the dead space between the skin and the periosteum surrounding the magnet (Fig. 135.3).
  - Avoid suturing directly over the magnet.
- The incision is closed with 4-0 Vicryl for the deep layer of the skin followed by a running 5-0 fast-absorbing plain gut.
- Tincture of benzoin, Steri-Strips, a nonadherent gauze dressing, and a compressive dressing (such as a Glasscock cup) are then applied.

- Baha Connect (percutaneous) using DermaLock abutments
  - The technique for the Baha Connect has evolved considerably over the past 15 years.
    - The initial recommendation was to aggressively thin the tissue surrounding the abutment in order to minimize any movement at the device–skin interface and remove the hair follicles surrounding the abutment.
      - This can be performed by hand or using a dermatome attached to the Baha drill.
    - Over time the technique has shifted toward preservation of the tissue surrounding the abutment.
    - Cochlear Corporation has recently discontinued the dermatome attachment, indicating the degree to which the initial approach has been abandoned.
  - Current techniques favor preservation of the surrounding skin.

FIG. 135.3 Several "tacking" sutures are placed between the magnet and the incision to close the dead space between the skin and the periosteum surrounding the magnet.

    - This has led to the development of the Baha DermaLock, in which abutments of varying length with a thin hydroxyapatite

collar are available and the surgeon determines the appropriate abutment length depending on the thickness of the individual patient's skin.

- This is achieved through a linear incision that is in line with the implant site or offset by 1 cm.
  - More recently, some surgeons have eliminated the incision altogether and performed the drilling steps through a biopsy punch method.[4]

- A dummy device is used to mark the planned drilling site, which is 55 mm from the ear canal and in line with the top of the auricle.
- The incision can be placed "in line" (having the abutment emerge through the primary skin incision) or may be "off line" (staggered, so that the abutment emerges through a 5-mm skin biopsy punch posterior to the incision).
  - If the implant is placed off-line (staggered) from the incision, at least 1 cm should separate the two so that a healthy bridge of skin is maintained.
  - The incision should be 2 to 3 cm in length (Fig. 135.4).
- Prior to infiltration with local anesthetic, a needle, hemostat, and ruler are used to gauge the skin thickness in order to choose the appropriate abutment length.
  - For a single-stage procedure, the abutment comes preattached to a 4-mm implant.
  - If there is insufficient bone thickness and the 3-mm implant is used, the abutment must be attached separately if a single-stage procedure is still planned.
  - A 6-mm abutment is used for skin thickness of 3 mm or less, 8-mm abutment for skin thickness of 4 to 5 mm, 10-mm abutment for skin thickness of 6 to 7 mm, 12-mm abutment for skin thickness of 8 to 9 mm, and 14-mm abutment for skin thickness in excess of 11 mm.
    - Skin that is over 11 mm thick will likely need to be thinned.
- Local anesthetic is infiltrated into the planned incision site.

- Methylene blue can be used to mark the planned device site by way of the technique described earlier for the Baha Attract.
- The incision is then made with a knife and carried down to the plane of the periosteum.

FIG. 135.4 A 2- to 3-cm skin incision is used to identify the underlying periosteum. The periosteum is then elevated and drilling proceeds first with the guide drill, then with the countersink drill.

- A cruciate incision is made in the periosteum.
- The periosteum is elevated with a raspatorium and drilling proceeds perpendicular to the bone with the 3-mm guide drill; then, if appropriate, the 4-mm guide drill and the appropriate countersink drill as described for the Baha Attract are used (see Fig. 135.4).
- For insertion of the implant, the abutment inserter bit is used to insert the combined abutment/implant (FAST system).
    - Again, it is important not to touch the fixture. It is retrieved from the plastic ampule using the abutment inserter.

- A click should be felt when the castellated drill bit engages properly with the fixture.

- Before the fixture is engaged with bone, the site should be copiously irrigated so that all bone fragments are removed.
- The fixture is then inserted using a drill speed of 20 to 30 Ncm for soft bone or 40 to 50 Ncm for hard bone.
    - No irrigation should be used until the first threads of the implant have engaged (two rotations) to avoid trapping fluid between the bone and the screw.
    - Essentially no pressure is necessary at this stage. The drill will automatically stop when the appropriate torque has been reached and then can be disengaged from the inserted implant.
    - The drill will stop automatically when the appropriate torque has been reached.
- If the drilling has been performed off line from the incision, a 5-mm biopsy punch can be used to remove skin overlying the abutment. The 5-mm skin opening is then simply advanced over the abutment.
- Wound closure is achieved with a 4-0 Vicryl for the deep layers of the skin, securing it to the periosteum, followed by a running 5-0 fast-absorbing plain gut.

FIG. 135.5 Folded iodine-impregnated gauze is placed between the skin and the healing cap to apply gentle pressure on the skin surrounding the abutment.

    - Tincture of benzoin followed by Steri-Strips placed for a final layer of protection.
- The dressing is then placed over the abutment.
    - A piece of folded iodine-impregnated gauze is positioned over the abutment.
    - A central hole is created within the impregnated gauze so that it surrounds the post of the abutment.
    - Sufficient folds of the gauze are utilized to apply gentle pressure when the healing cap is applied over the gauze. (Fig. 135.5).

Common Errors in Technique

- Failure to drill perpendicular to the bone.
    - This becomes apparent when the countersink step does not yield a

360-degree impression on the bone.

- This error carries through to all the subsequent steps and can result in a sound processor contacting skin rather than vibrating freely (in percutaneous implants) or the need to use the otologic drill to remove some temporal squamosal tissue in order to avoid having the magnet contact bone (in the Baha Attract).
  - If a Ponto device (Oticon) is used, it can be placed as an angled abutment (angled at 10 degrees) to correct this issue.

Postoperative Period

Postoperative Management

- A gentle compressive dressing (Glasscock cup) is applied for 24 hours.
- Pain medication is provided as needed.
- Wound is kept dry for 48 hours.
- Baha Attract: a wound check is performed about a week after surgery.
  - A second visit is often coordinated with the processor fitting, which occurs 1 month out from the surgery.
- Baha Connect (DermaLock): The first postoperative appointment is typically 1 week after surgery. The healing cap is removed and the patient initiates daily hygiene for the abutment using an alcohol-free wet wipe.
  - A second visit several weeks later is helpful in making sure that the skin–device interface appears to be healthy.
  - The sound processor is typically fitted after allowing 3 months for osseointegration.

Complications

- Immediate
  - Pain, bleeding/hematoma, infection, anesthetic complications
  - Exposure or injury to the dura/sigmoid sinus—bone wax can be used

to seal the leak and the drilling performed at a new site.

- If there is good bone thickness, some advocate placement of the device, which will seal/stop the leak or bleeding.
  - Note: A cerebral abscess has been reported with the Baha system, so caution is advised.[5]

- Implant becomes stuck/drill stops before complete insertion has been achieved.
  - If the implant is almost completely engaged, the drill can be reversed to back the implant out by one rotation and then the torque increased slightly (5 Ncm).
  - If the implant is barely engaged and appears to have entered at an inappropriate angle, the drill should be reversed to remove the implant from the site.
    - Check the site to make sure that there is no bone debris in the defect preventing the implant from seating properly.
    - Make sure that the alignment is optimal and attempt reinsertion once.
    - If this is not successful, an alternate site should be chosen.

- Delayed
  - Percutaneous device
    - Adverse skin reaction (overgrowth of skin at the abutment, inflammation/granulation tissue at the skin–device interface).[2,3]
      - The Holger classification system is useful in grading the severity of skin reactions and facilitating comparisons across different manufacturers and techniques.[6]
      - Local wound care is implemented with topical antibiotic ointments, occasional oral antibiotics, silver nitrate chemical cautery of granulation tissue, steroid injection (Triamcinolone), topical steroid application (clobetasol), and rarely surgical revision.[3]
    - Switching to a longer abutment can also help in cases of skin overgrowth.

- If none of these measures is effective, the abutment can be removed, a cover screw placed, and a new abutment placed once the infection has been controlled.

- Baha Attract
  - Discomfort, thinning of skin overlying the magnet, or magnet exposure
  - Persistent pain may be secondary to a loose implant or loose magnet
- Failure of osseointegration—can occur due to poor bone quality or poor surgical technique.
  - Implant loss can also occur with trauma or infection.

Alternative Management Plan

- Conventional amplification
- Contralateral routing of Signal (CROS) aids (for single-sided deafness)
- Cochlear implantation, if criteria are met
- Alternative bone-anchored devices—Ponto (Oticon), and Alpha2 (Sophono/Medtronic)

Discussion

Evidence-Based Medicine Question

- If surrounding skin and soft tissue begins to overgrow the abutment site, what can be done to help reverse this process?
  - Although the incidence of soft tissue skin reactions has been dramatically reduced with the advent of modified surgical techniques and proprietary technology from each of the vendors, these complications do still occur. This topic is not widely discussed within the current literature.
  - A defined treatment algorithm has been proposed to manage soft tissue reactions of progressive severity.[3]

- The first step of the treatment algorithm is that of local wound care. This includes topical antibiotic ointment (Bacitracin, Mupirocen), oral antibiotics (based on wound cultures), application of topical silver nitrate chemical cautery and/or Clobetasol cream (0.5%).
- The second step of the treatment algorithm consists of an intralesional triamcinolone acetonide injection (roughly 40 mg per injection).
- The final step of the treatment algorithm, used only for pronounced overgrowth of skin around the abutment that proves resistant to prior intervention, calls for surgical revision therapy.

Editorial Comment

Bone-anchored hearing devices have been available for over 30 years. The initial product was based on work by Brånemark, implanting titanium into the bone. Tjellström, in 1983, developed a procedure to affix a titanium implant into the mastoid bone. An internally fixed magnet with an external device was the basis for the Xomed Audiant Bone Conductor transcutaneous system, which was withdrawn from the market in the mid-1990s because of limited performance and wound issues. Contemporary percutaneous devices and techniques have been developed that provide excellent hearing results. The indications have included hearing impairment from single-sided deafness as well as conductive and mixed hearing loss. The percutaneous (protruding through the skin) configuration is being supplanted by a transcutaneous (across the skin) connection using magnetic attraction. The impetus for this has been to minimize the wound complications and address cosmetic concerns where the abutment comes through the skin. Soft tissue skin problems include irritation of the skin surrounding the implant, overgrowth of skin over the device, granulation tissue reaction, infection, and, rarely, persistent pain. There have been ongoing successful modifications of the soft tissue approaches to reduce the incidence of these wound complications. This has evolved from creating a split-thickness skin flap with a dermatome for subcutaneous debridement to a C-shaped flap, also with subcutaneous debridement, to placement of the unit 1 cm behind a short vertical incision and, more recently, directly

through a 5-mm skin punch without any soft tissue dissection. Nonetheless, ongoing care of the implant site remains a challenge for some recipients. Current technology now allows for transcutaneous devices to provide sufficient power to offer a real benefit for the appropriate candidates. All three transcutaneous (magnetic attraction) devices (BAHA Attract, Sophono Alpha 2, and BONEBRIDGE) are MRI-compatible, but the field of distortion may interfere with discerning pathology of the ipsilateral temporal lobe.

Another advantage of the transcutaneous devices is the shorter time recommended to load (attach) the processor to the patient. This can be a month, as there is no significant torque applied for attaching or removing the external magnet and processor. The current recommendations for the percutaneous devices remain at 3 months in the United States, although experience in Europe has demonstrated that this can be as short as 2 weeks.

Owing to constraints of space and the desire for brevity, this chapter does not address all of the available products and the specific technical points needed to successfully complete the surgery. The authors have focused on the devices they currently use. Surgeons should be very familiar with the principles and instruments associated with the products they will implant.

Review Questions

1. In placing the fixture into the bony well, no irrigation should be used until the first threads of the implant have engaged (two rotations) to avoid trapping fluid between the bone and the screw.

   a. **True**

   b. False

2. Which of the following is a true statement?

   a. The MRI artifact is less for a transcutaneous device than a percutaneous device.

b. MRI is contraindicated in patients with transcutaneous bone-anchored hearing devices.

c. **The MRI scatter associated with a transcutaneous device may extend up to 11 cm.**

d. All of the transcutaneous bone-anchored hearing devices are FDA-approved for imaging with a 3 Tesla MRI.

3. Which of the following is NOT an indication for a bone-anchored hearing device?

a. Unilateral profound SNHL

b. **Bilateral profound SNHL**

c. Mixed loss and not a candidate for conventional hearing aids

d. Maximal conductive loss and not a candidate for conventional hearing aids

4. Which of the following is a relative contraindication for placing a bone-anchored hearing device?

a. Severe osteoporosis

b. Patients prone to keloid formation

c. Implanting a percutaneous device in a patient with pathology close to an ear that will require monitoring with MRI

d. Inability of patient perform routine cleaning of abutment site

e. **All of the above**

5. The FDA has approved bone-anchored hearing devices for children 5 years of age and older.

a. **True**

b. False

Additional Sources

None necessary

Implantable Middle Ear Devices

Elizabeth Toh, and Jack A. Shohet

Introduction

This chapter is devoted to a review of active middle ear implants that are currently approved by the US food and drug administration (FDA) and are available locally as a surgical rehabilitation option for select hearing impaired individuals. These include the Esteem Implant (Envoy Medical Corporation, Minnesota), the Vibrant Soundbridge Implant System (MED-EL Corporation, Innsbruck, Austria), and the Maxum System (Ototronix, Texas). In the United States, all implantable middle ear devices are currently only approved for sensorineural hearing loss in adults. Each of the above implant systems will be reviewed separately.

All active middle ear implants directly drive the ossicular chain using piezoelectric or electromagnetic transduction. This eliminates the concern for acoustic feedback inherent to conventional acoustic hearing aid technology. With the Esteem and Vibrant Soundbridge systems, there is no concern for ear canal occlusion. The Maxum integrated processor and coil (IPC) worn in the ear canal transmits electromagnetic energy instead of sound, which therefore mitigates the occlusion effect.

Conventional hearing aid technology remains the mainstay for the rehabilitation of hearing loss in patients with favorable external ear anatomy. The primary motivators for the selection of implantable middle ear devices for patients with sensorineural hearing loss include lifestyle considerations (water exposure, convenience, 24/7 continuous use, cosmesis) and limited benefit with conventional amplification in the presence of aidable hearing. Indications also include compromised function or discomfort due to acoustic feedback, sound distortion, occlusion effect, ear canal irritation, abundant cerumen production, or poor fit.

Esteem Implant (Envoy Medical Corporation)

The Esteem Implant is a totally implantable hearing system consisting of three implanted components: a sound processor (SP)/lithium iodine battery placed under the temporoparietal scalp and two piezoelectric transducers (driver and sensor), which are implanted in the mastoid and projected into the middle ear (Fig. 136.1). The Esteem system is activated and adjusted via radio frequency telemetry using an external remote control (Personal Programmer) programmed to customized specifications based on the patient's audiogram.

Mechanical sound vibrations transmitted from the tympanic membrane, malleus, and incus are detected by the sensor, which is coupled to the incus, and converted to electrical signals, which are then transferred to the SP. Amplified and filtered electrical signals are relayed from the SP to the driver, which is attached to the stapes capitulum. The driver converts the electrical signals back to mechanical vibrations, which are delivered through the stapes to the oval window (Fig. 136.2).

Key Operative Learning Points

1. Esteem surgery is technically challenging and demands precise sensor and driver placement for successful hearing outcomes.

2. A well-developed mastoid, normal tympanic membrane, and normal middle ear anatomy are critical for successful placement and function of the Esteem Implant system.

3. The ossicular chain must be permanently disarticulated for Esteem driver placement.

Preoperative Period

History

1. History of present illness

a. Etiology, duration, and stability of hearing loss

b. Hearing aid experience: The patient's reported experience with hearing aids provides good insight into their motivation for pursuing surgery and a starting point for discussing reasonable hearing expectations with the Esteem Implant.

c. Other symptoms suggestive of underlying ear disease, which may contraindicate Esteem surgery, such as dizziness, tinnitus, aural fullness, otalgia, or otorrhea should be identified.

d. Hearing status of the contralateral ear: The patient will not be able to hear in the operated ear for approximately 2 months postoperatively; therefore, it is important to optimize hearing in the nonoperative ear before surgery.

2. Past medical history

a. Prior otologic procedures: Prior myringotomy with or without tube placement, tympanoplasty, ossiculoplasty, or stapes surgery may be contraindications for this procedure.

b. Medical illness: Comorbidities that would impact wound healing, Eustachian tube function, or the need for future magnetic resonance imaging (MRI) scans. History of bleeding disorders is a relative contraindication since extensive soft tissue dissection is required for SP placement, and adherence of the mastoid cement may be challenging.

c. Other surgery: Prior soft tissue surgery in close proximity to the ear to be implanted, ventriculoperitoneal (VP) shunt, or craniotomy surgery may impact the design of the incision and the SP placement.

d. Medications: Anticoagulants, vitamins, and herbal products should be discontinued 1 week prior to surgery.

Physical Examination

1. Ears

Look for a normal ear canal and tympanic membrane and the absence of any obvious tympanic membrane retractions or limited movement, middle ear lesions, or effusions. Inspect the postauricular scalp to ensure the absence of any skin pathology.

Audiogram

1. Pure tone audiogram: air and bone conduction thresholds

2. Speech audiogram: speech reception thresholds (SRTs), unaided word recognition scores

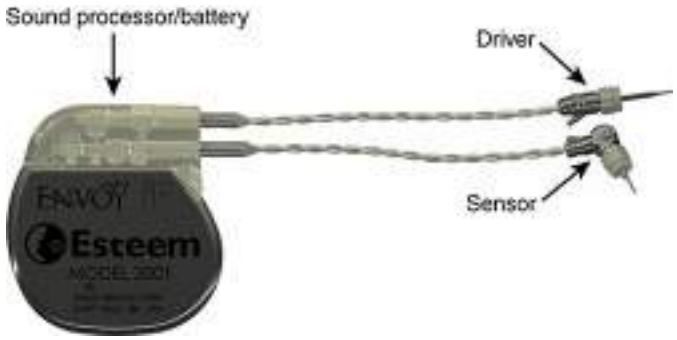

FIG. 136.1 The Esteem Implant.

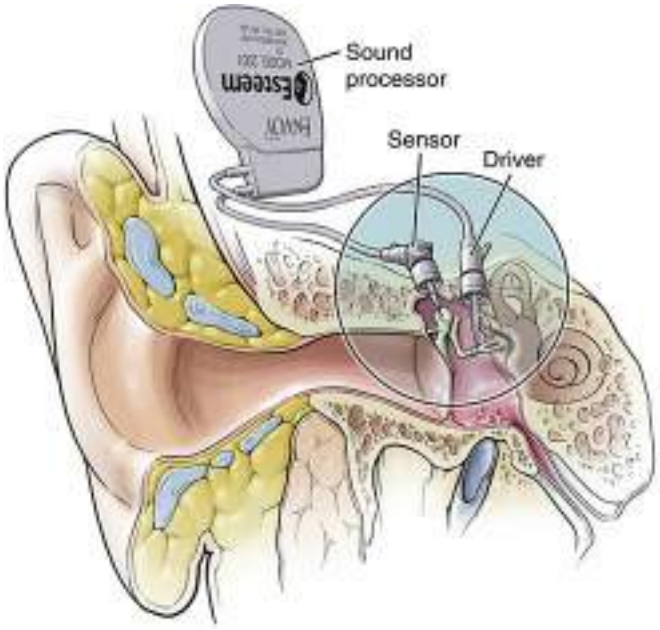

FIG. 136.2 Placement and function of the Esteem Implant.

3. Sound field testing: aided thresholds, word recognition at 50 dB HL and at comfortable suprathreshold levels

4. Tympanograms

Imaging

1. Temporal bone computed tomography (CT) scan

This is obtained preoperatively to ensure adequate space for the placement of transducers (minimum of 22 mm between sigmoid sinus and stapes capitulum and 2.5 mm between incudomalleal joint and tegmen tympani). If hearing is symmetric, the mastoid with larger dimensions is preferable for ease of implantation.

2. MRI brain with gadolinium*

Not routinely required. This is obtained preoperatively to screen for retrocochlear pathology ONLY if hearing loss is asymmetric.

Indications

1. Adults 18 years or older with stable bilateral moderate to severe sensorineural hearing loss (PTA 40 to 90 dB)

2. Unaided word recognition scores greater than or equal to 40%

3. Normal Eustachian tube function

4. Normal tympanic membrane

5. Normal middle ear anatomy

6. Adequate mastoid and middle ear space for implant placement determined on temporal bone CT scan

7. Minimum of 30 days' experience with appropriately fitted hearing aids

8. Realistic hearing expectations

In general, *experienced hearing aid users* meeting indications 1 to 6 who desire the Esteem device for lifestyle, comfort, convenience, or cosmetic reasons and who have realistic expectations for comparable or more natural hearing relative to conventional hearing aids are ideal candidates.

Contraindications

1. History of significant Eustachian tube dysfunction, active chronic middle ear disease, or cholesteatoma

2. Prior ossiculoplasty or stapes surgery

3. Meniere disease or other inner ear diseases associated with fluctuating hearing loss

4. Retrocochlear pathology

5. Disabling tinnitus

6. Anticipated need for MRI in the future

Preoperative Preparation

1. Choice of ear to be implanted:
   a. Poorer hearing ear
   b. Larger mastoid dimensions
   c. Poorer hearing aid fit
2. Discontinue any anticoagulants 10 to 14 days prior to surgery.

Operative Period

Anesthesia

General: Esteem surgery is always performed under general anesthesia.

Positioning

Supine: Patient is positioned supine with the body firmly secured to the operating table and the head turned away from the surgeon. The operating room table is turned 180 degrees.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin for patients who are not allergic to

penicillin or cephalosporin

Clindamycin for penicillin-allergic patients

Monitoring

Facial nerve monitoring

Intraoperative system analyzer (ISA) testing is performed by field clinical engineer (FCE).

Instruments and Equipment to Have Available

1. Standard mastoid set

2. Additional middle ear instrumentation*: includes TABB double-edged flap knives, curved Rosen needle

3. SP and transducer templates*

4. High-speed drill for mastoid surgery

5. Bipolar electrocautery: to be used for hemostasis after the implant is placed

6. Diode,* argon, CO_2, or KTP laser

7. Laser Doppler vibrometer and reflective tape*

8. Sterile ear microphone*

9. Esteem ISA*: used to test Esteem Implant function intraoperatively. Both equipment and engineer are provided by the manufacturer.

10. Second microscope fitted with laser Doppler vibrometer*

11. Hydroxyapatite cement and glass ionomer cement*

12. Deionized water

An FCE is provided by Envoy Medical for every initial and revision Esteem surgery to perform intraoperative functional and device testing.

Key Anatomic Landmarks

1. Incus: identified in the epitympanum anterolateral to the lateral semicircular canal. This provides an indicator for the approximate level of the facial recess along the posterior ear canal.

2. Facial nerve: The mastoid segment is the medial boundary of the facial recess.

3. Chorda tympani nerve: This is the lateral boundary of the facial recess and is often sacrificed in Esteem surgery for driver placement. The fibrous annulus of the tympanic membrane lies lateral to the chorda.

4. Tegmen tympani and mastoideum: the floor of the middle fossa and superior boundary of the mastoid and epitympanic dissection

Prerequisite Skills

1. Mastoidectomy and facial recess exposure

2. Ossiculoplasty surgery

3. Otologic laser certification

4. Otologic cement application

Operative Risks

Risks of mastoidectomy surgery, including injury to the sigmoid sinus, tegmen, dura, posterior ear canal, lateral semicircular canal, facial nerve, and ossicular chain are discussed elsewhere in this book. Those listed below highlight the additional risks incurred for placement of the Esteem Implant.

1. Injury to the facial nerve

The facial nerve may be injured while opening the facial recess as a result of direct trauma or heat injury. The facial nerve also may be injured when using the diode laser to section the long process of the incus. The vertical segment of the nerve should be protected by placing a finger in the mastoid cavity while screwing the stabilizer bars to prevent inadvertent slipping of the screwdriver into the mastoid. The tympanic

segment of the nerve should be well covered with moist Gelfoam while using the diode laser.

2. Trauma to the ossicles

Drill trauma to the malleus and incus may occur as the epitympanum is being opened to expose the incudomalleal joint. The stapes is at risk for dislocation and fracture when separating the incudostapedial joint and removing mucosa from the capitulum. The incus is at risk for dislocation when creating a neojoint between the sensor and incus body. Trauma to the ossicles is best avoided with gentle manipulation of the mobile ossicular chain during surgery and gentle stabilization of the ossicle with a suction or other atraumatic micro-instrumentation.

FIG. 136.3 The recommended Esteem sound processor (SP) placement and surgical incision.

3. Injury to or transection of the chorda tympani nerve

Transection of the chorda tympani nerve is necessary in most cases to provide adequate surgical exposure for driver placement and cement application between the driver tip and stapes capitulum.

4. Tympanic membrane perforation

This may occur when widening the facial recess after the chorda tympani nerve has been sacrificed. Once the fibrous annulus is identified, no further drilling should be performed on the lateral aspect of the facial recess. The tympanic membrane is also at risk with the use of the diode

laser. Care should be taken to direct the laser away from the tympanic membrane and pause to allow heat dissipation between laser exposures.

Surgical Technique

- Mark position for SP placement (Fig. 136.3) on a relatively flat part of the skull posterosuperior to the anticipated mastoid cavity. Mark a lazy S incision behind ear to accommodate placement of the SP at least 1.5 cm away from the anterior border of the SP. Perform small strip shave and inject incision site with local anesthetic containing 1:100,000 epinephrine solution.
- Place facial nerve monitoring electrodes in ipsilateral orbicularis oculi and orbicularis oris muscles and appropriate ground and stimulating electrodes. A separate ground electrode for the intraoperative implant testing is placed in the midline forehead.
- Prepare and drape the ear in usual sterile fashion.
- Insert the microphone into the sterile ear canal and secure the pinna forward with watertight adhesive dressing once the functionality of the microphone has been confirmed by the FCE.
- Make a postauricular incision down to the avascular plane superficial to the temporalis fascia layer and elevate the anterior and posterior skin flaps.
- Incise the temporalis fascial layer and periosteum in a vertical, stepped fashion anterior to the skin incision. Elevate the periosteum anteriorly and posteriorly. The spine of Henle and posterior-superior bony ear canal should be exposed anteriorly. Posterior exposure permits SP placement.
- Drill an SP bed in the previously identified SP location behind the anticipated mastoid cavity and a shallow electrode trough to accommodate the SP header and electrodes. Suture tying down of the holes on either side of the SP bed may be considered to secure the SP.[1]
- Perform a cortical mastoidectomy with skeletonization of the mastoid tip, sigmoid sinus, posterior fossa plate, tegmen, and posterior ear canal. Open the epitympanic recess for clear exposure of the body of the incus and incudomalleal joint. This wide exposure is necessary for

placement and visualization of the driver and the sensor, as well as the application of cement.

- Place a small saline-soaked Gelfoam pledget over the proximal body of the incus (sensor neojoint location) to keep the mucosa moistened through the remainder of the procedure until the placement of the sensor.
- Open the facial recess, keeping the incus buttress intact and skeletonizing the facial nerve. Unless the facial recess is unusually wide, the chorda tympani nerve is sacrificed, and the fibrous annulus of the tympanic membrane forms the lateral boundary of surgical exposure in these cases.
- Sharply remove any visible ossicular chain adhesions. Place small strips of reflective tape on the stapes and incus body (remove the Gelfoam for this purpose). Obtain intact chain measurements using the laser Doppler vibrometry (FCE). If the ossicular chain is hypomobile, do not proceed with Esteem implantation.[2]
- If ossicular chain mobility is within the normal range, proceed to incise the mucosa of the incudostapedial joint with a #59 beaver blade, and elevate the stapes capitulum mucosa medially toward crura, then separate the incudostapedial joint.
- Place the saline-soaked Gelfoam medial and lateral to the incus in the middle ear to protect the tympanic facial nerve and tympanic membrane.
- Amputate the distal 3 to 4 mm of the long process of the incus long using a laser (for diode laser, use 5 to 8 watts, single pulse mode, pulse duration 100 to 200 ms). Then remove the Gelfoam from the middle ear.
- Paint the stapes capitulum with methylene blue-soaked Gelfoam.
- Remove any methylene blue-stained mucosa over the stapes capitulum and dry the capitulum with the laser (for diode laser use 2 watts, single pulse mode, 100 to 200 ms pulse duration). This is a critical step for reliable bonding of the ionomeric cement used to couple the Esteem driver tip to the stapes capitulum.
- Precoat the stapes capitulum with ionomeric cement and allow to cure

for 10 minutes.

- Screw on the Glasscock stabilizer bars to the posterior cortical margin of the mastoid cavity, and attach the driver and the sensor.
- Test capacitance of the driver and sensor with the provided cables (FCE).
- Position the sensor in the mastoid with the tip over incus body adjacent to incudomalleal joint. Then place the driver in the mastoid with the tip over the cement-coated stapes capitulum, bellows parallel to the footplate, avoiding bony contact within the facial recess (Fig. 136.4).
- Carefully place small saline-soaked Gelfoam pledgets in the mastoid cavity medial and adjacent to the sensor and driver transducer bellows, creating a physical barrier to prevent anterior migration of the hydroxyapatite cement.
- Rotate the patient toward the surgeon, and apply hydroxyapatite cement completely around transducer bodies proximal to their silicone shields. After 3 minutes, inspect the driver and sensor tips for migration as the cement cures. This can be controlled early in the cement curing process by applying gentle pressure on the stabilizer bars or bellows using micro-instrumentation. Allow the cement to cure for 15 to 20 minutes. Ensure there is no undo pressure on the transducer leads, which can displace the transducer tips.

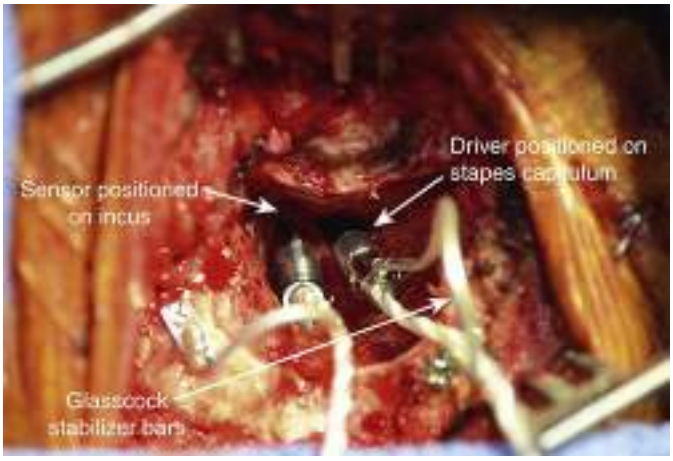

FIG. 136.4 The positioning of Esteem driver and sensor.

- The Gelfoam is carefully removed from the mastoid 5 to 10 minutes

after the application of cement.

- Apply ionomeric cement around the driver tip onto the stapes capitulum cement precoat, and allow it to cure for 10 minutes.
- Apply ionomeric cement to the sensor tip, and allow it to cure for 5 minutes. Then create a neojoint by incising the incus mucosa around cement-ossicle interface, separating the cement cap with the sensor tip from the incus. A sharp, gently curved pick and TABB knife are useful for this step.
- Irrigate the mastoid and middle ear with antibiotic solution.
- Test the sensor and driver placement and function using laser Doppler vibrometry (FCE). If either one is not functioning within the parameters defined by prior intact chain measurement, transducer placement must be revised and the testing repeated until acceptable measures are obtained.
- Clean the proximal sensor and driver leads with deionized water and dry.
- Insert the sensor and driver leads into the SP header, and secure the SP in the bony seat. Perform system testing (FCE).
- Remove stabilizer bars.
- Perform layered wound closure (2-0 Vicryl muscle/periosteum, 3-0 Vicryl subcutaneous, and 4-0 Vicryl subcuticular, and apply Steri-Strips).
- Remove the microphone, and inspect the ear canal and tympanic membrane.
- Place a pressure dressing over the ear for 24 hours.[1]

Common Errors in Technique

1. Inadequate mastoid and middle ear exposure

Wide mastoid cavity saucerization and a wide facial recess with attention to removing the superior-lateral corner at the root of the zygoma are all helpful to maximize visualization and cement application around the driver tip.

2. SP placement too far posterior

Ideal location for the SP is the posterosuperior to the mastoid cavity (behind superior limb of lazy S incision) for easy access during surgery for future battery changes.

3. Driver misalignment

The driver bellow should be positioned parallel to the plane of the stapes footplate and must not be in contact with the facial nerve in the facial recess.

4. Incomplete cement coverage over the driver tip

This is deficient most commonly along the anterior interface. It is best to draw cement over the anterior joint interface early in the cement application process for ease of visualization and access. Care should be taken to ensure that cement does not contact the incus remnant or tympanic membrane.

5. Driver and sensor migration

Expect marginal volume expansion of the hydroxyapatite cement during the curing process. This may cause slight shifts in positioning of the sensor and driver tips. Monitor the position of the sensor and driver tips during the first 5 minutes after cement application, and control tip migration with direct pressure on the bellows.

6. Hydroxyapatite cement desiccation and fracture

This can be avoided by placing moist Gelfoam over the cement as it cures. Any fracture lines through the cement must be reinforced with additional cement.

Battery Change Technique

- Average battery life of the Esteem Implant is 5 years.
- Since the Esteem battery is integral to the SP unit, battery changes afford the patient any interval technology updates for the implant system.
- Battery change is usually performed under local anesthesia unless otherwise indicated by patient preference/tolerance.

- Only bipolar electrocautery should be used for battery change, and avoidance of any electrocautery is preferred.
- Prior to the procedure, the new SP is programmed using the patient's existing SP parameters, and the Personal Programmer is linked to the new SP.
- Tape the surgical ear forward.
- After sterile preparation and draping, the original postauricular incision anterior to the SP component is infiltrated with local anesthetic with 1:100,000 epinephrine solution buffered with sodium bicarbonate solution.
- The initial skin incision is made with a scalpel. Thereafter, blunt and sharp dissection are used to isolate the proximal driver and sensor leads adjacent to the SP header and expose the fibrous capsule encasing the SP.
- Incise fibrous capsule, and remove SP from soft tissue pocket. Remove the driver and sensor leads from the SP header.
- Perform capacitance testing with the cable provided by the FCE.
- Inspect leads for surgical trauma. If the electrical component of either lead is violated during the procedure, the wound should be closed and the patient returned to the OR electively for a formal revision to replace the damaged transducer.
- Irrigate the SP pocket with bacitracin or other antibiotic solution.
- Clean the leads with sterile deionized water, and dry with instrument wipes.
- Insert the driver and sensor leads fully into appropriate header slots in the new SP.
- Confirm hearing restoration, and perform volume testing to confirm functionality of the new SP. The implant is active from the time of surgery.
- Close the wound in layers.
- Apply a pressure dressing over the ear for 24 hours.

Postoperative Period

Postoperative Management

1. Wound care: Expect mild soft tissue edema around the incision and implant. Keep a light pressure dressing over the ear for 24 hours.

2. Activate and program the SP 8 weeks after surgery. This allows adequate time for the resolution of retained blood within the middle ear, thus avoiding the possibility of mechanical feedback.

3. One or two additional programming visits may be helpful to optimize hearing outcomes within the first year.

Complications

1. Wound infection

All wound infections should be treated aggressively with broad-spectrum skin flora coverage.

2. Wound dehiscence

If primary wound closure without tension is not possible, a local soft tissue flap with or without skin grafting may be required to cover the SP. Prophylactic antibiotic coverage for skin flora should be prescribed.

3. Mastoid and/or middle ear scar tissue/adhesion formation

Adhesions restricting mobility of the sensor or driver may limit gain and cause feedback. Functional testing with or without temporal bone CT imaging may help to localize involvement to the sensor or driver. A transmastoid approach for revision surgery is generally recommended unless functional testing localizes scar tissue formation between the driver tip and incus remnant or tympanic membrane.

4. Driver detachment

This can be diagnosed on functional testing of the implant. A transcanal approach may be used to replace or augment ionomeric cement over the driver tip.

5. Poor functional gain with implant

If hearing benefit with the Esteem Implant remains poor (significantly worse than the preoperative aided condition), revision surgery and transducer repositioning may improve function. Alternatively, the implant may be removed and hearing reconstructed with a partial ossicular replacement prosthesis, a Kraus K-Helix Crown prosthesis (Grace Medical), or ionomeric cement.

6. Facial paralysis

Treat with 7- to 10-day oral steroid taper.

7. Dysgeusia

Long-term dysgeusia is expected in 5% to 7% when the chorda tympani nerve is sacrificed.

Alternative Management Plan

For patients desiring the benefits afforded by the Esteem Implant System (24/7 function, limited water exposure, cosmesis, convenience) at a lesser cost or risk, deep insert extended-wear hearing aids (Lyric) may be considered. The average battery life on the Lyric hearing aid is 2 to 3 months.

Discussion

Evidence-Based Medicine Question

Besides advantages in lifestyle with a totally implanted hearing system, are there any audiometric advantages with the Esteem Implant compared to conventional hearing aids?

A prospective, nonrandomized, multicenter, subject-as-own-control, FDA clinical trial demonstrated an improvement in SRT from 41.2 dB with the hearing aid to 29.4 dB with the Esteem Implant. Word recognition score at 50 dB HL (WRS50) improved from 46.3% with the subjects' hearing aids to 68.9% with the Esteem. A pure tone average (PTA) improvement of 27 ± 1 dB was seen.[1]

Editorial Comment

The Esteem Totally Implantable Hearing System

Eric M. Kraus, Douglas A. Chen

Overview: Postmarket approval experience has been gained during the last 7 years. Careful patient selection is paramount. Patients report improved sound fidelity and clarity as compared to hearing aids secondary to low distortion system characteristics and an unobstructed ear canal. Long-term results have shown stable hearing without deterioration in bone conduction thresholds compared to the contralateral ear. Better audiometric tests to quantitate fidelity are needed. The system is capable of 55 dB of acoustic gain, which is better in low than high frequencies. Such gain levels are capable of creating temporal bone vibrations that can be detected by the sensor and may result in mechanical feedback. Expert programming is essential. However, patients enjoy the freedom of not having to wear external hardware. The necessity to replace the battery every 3 to 5 years remains problematic secondary to skin thinning, compromised blood supply, and fibrosis. A rechargeable option would markedly decrease potential surgical risks, time, and cost.

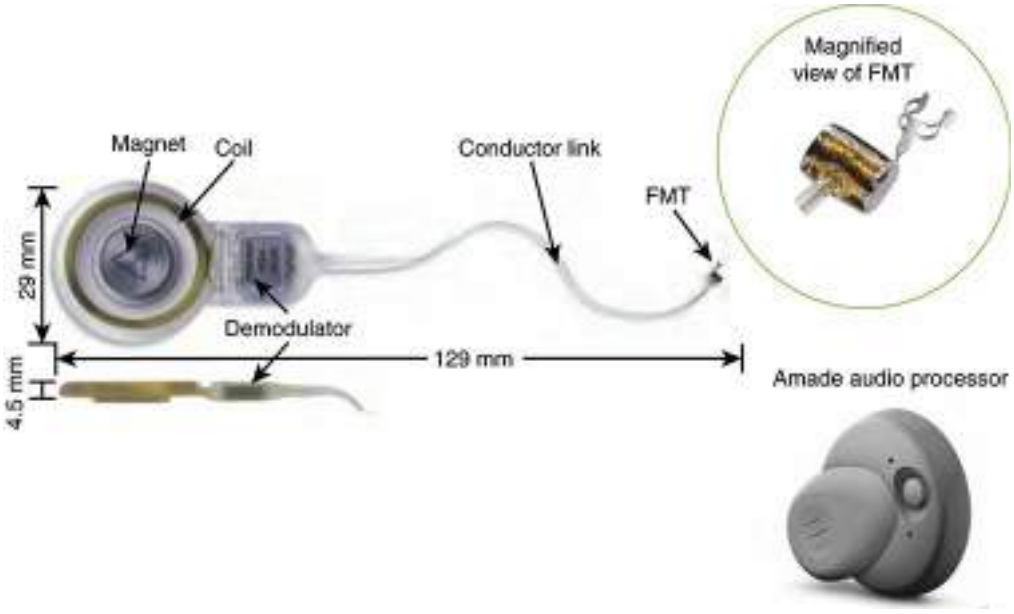

FIG. 136.5 Vibrant Soundbridge implant with external audio processor and internal vibrating ossicular prosthesis with magnified view of floating mass transducer (FMT).

Surgical considerations: The operative procedure is challenging due to three-dimensional considerations during implantation of the transducers. The surgical learning curve requires approximately 20 procedures to acquire the necessary skill set. The facial recess must be opened widely to its anatomic limits. The chorda tympani nerve is sacrificed in approximately 70% of cases. Stable fixation of the SP is critical to prevent anterior migration. After 13 years of follow-up, some patients have required explantation and ossicular reconstruction due to late effect fibrosis, bone bridging, or the inability to achieve enough gain without mechanical feedback. Explantation and effective ossicular reconstruction are possible with hearing restoration back to baseline levels.

Eric M. Kraus

Vibrant Soundbridge Device (Med-El Corporation)

Vibrant Soundbridge is a partially implantable active middle ear device that uses electromagnetic energy to mechanically drive the ossicular chain. The system has two components (Fig. 136.5):

1. An externally worn audio processor secured magnetically to the scalp

2. A surgically implanted vibrating ossicular prosthesis (VORP) attached to a floating mass transducer (FMT). The FMT is coupled to the ossicular chain with an attachment clip to serve as an electromagnet transducer. It comprises a miniature magnet encased in a hermetically sealed titanium casing wrapped with electromagnetic coils.

Sound detected by the audio processor microphone is processed and relayed across the skin to the internal receiver of the VORP. Electrical signals are then relayed from the VORP to the FMT, which in turn generates vibrations from the oscillating magnet within an electromagnetic field to drive the ossicular chain (Fig. 136.6). The use of Vibrant Soundbridge for surgical rehabilitation of conductive and mixed hearing loss by placing the FMT directly on the round window membrane remains investigational in the United States at the time of this publication. The current Vibrant Soundbridge implant system available in the United States is not MRI compatible.

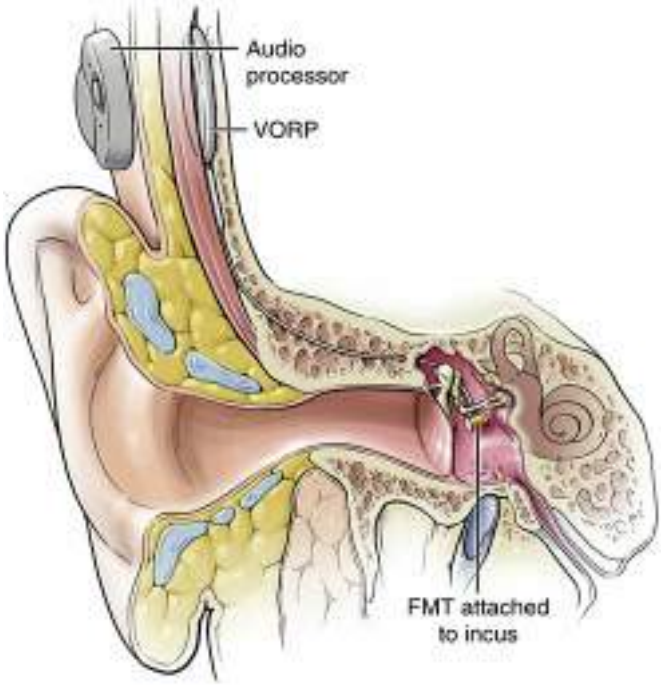

FIG. 136.6 Placement of Vibrant Soundbridge implant. *VORP*, Vibrating ossicular prosthesis; *FMT*, floating mass transducer.

Key Operative Learning Points

1. The ossicular chain integrity is maintained during placement of this direct drive active middle ear implant.

2. A wide facial recess is necessary for placement of the FMT.

3. Adequate crimping of the attachment clip is necessary to ensure the function of this implant.

Preoperative Period

History and Physical Examination

As for the previously described Esteem Implant

Audiogram

1. Pure tone audiogram: air and bone conduction thresholds

2. Speech audiogram: SRTs, unaided word recognition scores

3. Sound field testing: aided thresholds, aided word recognition with headphones at the most comfortable level and with hearing aids at 65 dB SPL

4. Tympanograms

5. Acoustic reflex thresholds

Imaging

1. Temporal bone CT scan

This is generally recommended for the preoperative mapping of the mastoid and facial nerve anatomy.

2. MRI brain with gadolinium*

Not routinely required. This is obtained preoperatively to screen for retrocochlear pathology if the hearing loss is asymmetric.

Indications

1. Adults 18 years or older with stable moderate to severe sensorineural hearing loss who desire an alternative to a conventional acoustic hearing aid

2. Word recognition scores of 50% or better at most comfortable level using headphones or with hearing aids at 65 dB SPL

3. Intact tympanic membrane and ossicular chain with normal middle ear function

4. Prior hearing aid experience is strongly recommended

5. Realistic hearing expectations

Contraindications

As for the Esteem Implant

Preoperative Preparation

As for the Esteem Implant

Operative Period

Anesthesia

General

Positioning

Supine: The patient is positioned supine with the body firmly secured to the operating table and the head turned away from the surgeon. The operating room table is turned 180 degrees.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin for patients without allergy to penicillin or cephalosporin

Clindamycin for penicillin-allergic patients

Monitoring

Facial nerve monitoring

Instruments and Equipment to Have Available

1. Standard mastoid set

2. High-speed drill for mastoid surgery

3. MED-EL Surgical Accessory Kit*: includes three VORP templates, forming forceps, and a skin flap 7 mm gauge

4. Bipolar electrocautery: to be used for hemostasis after the implant is placed

Key Anatomic Landmarks

1. Incus: identified in the epitympanum anterolateral to the lateral semicircular canal. This provides an indicator for the approximate level of the facial recess along the posterior ear canal.

2. Facial nerve: The mastoid segment is the medial boundary of the facial recess.

3. Chorda tympani nerve: This is the lateral boundary of the facial recess and may need to be sacrificed if the facial recess is too narrow to accommodate the FMT. If the chorda tympani nerve is sacrificed, the fibrous annulus of the tympanic membrane forms the lateral boundary of the facial recess.

Prerequisite Skills

1. Mastoidectomy and facial recess exposure

2. Middle ear/ossiculoplasty surgery

Operative Risks

In addition to the standard risks of mastoidectomy and facial recess surgery, the following are risks incurred for Vibrant Soundbridge Implant surgery.

1. Injury to the facial nerve/chorda tympani

A very wide facial recess is necessary to pass the FMT and forming forceps into the middle ear. Heat trauma to the facial nerve can be avoided by ensuring continuous irrigation while skeletonizing the facial nerve in this location. If the chorda tympani nerve must be sacrificed for access, it should be sharply divided at its take-off from the mastoid segment of the facial nerve.

2. Trauma to the ossicles

This may be incurred to the incus or stapes while positioning and crimping the FMT attachment clip onto the incus. This is best avoided using an atraumatic surgical technique. If the attachment clip cannot be tightened safely through the facial recess, this may be accomplished in the middle ear through a transcanal approach.

Surgical Technique[3]

- Mark the position of the VORP posterosuperior to the intended mastoidectomy cavity, then mark out a lazy S incision with the superior limb at least 1.5 cm anterior to the VORP. Perform a small strip shave, and inject the incision site using local anesthetic with 1:100,000 epinephrine solution.
- Place facial nerve monitoring electrodes, and confirm the functionality of the monitor.
- Prepare and drape the ear in the usual sterile fashion.
- Make the postauricular incision down to the avascular plane above the temporalis fascia, and elevate the anterior and posterior skin flaps.
- Elevate an anteriorly based pericranial flap to expose the mastoid cortex. If a bony recess for the VORP demodulator is planned, the pericranial flap should extend posterosuperior to the intended mastoid cavity for bony access.
- Mark the outline of the VORP demodulator position with the VORP template, and drill a shallow bony recess. Place drill tie-down holes on either side of the bony recess to secure the VORP.
- *The slim profile of the current VORP offers the option for temporalis pocket placement without drilling a bony recess or placing tie-down sutures. This can be done by incising the periosteum along linea temporalis and bluntly dissecting a pericranial pocket between the temporoparietal suture line anteriorly and the lambdoid suture posteriorly. Size the pocket with the VORP template.*
- Drill a bony electrode trough extending from the bony recess or temporalis pocket to the posterior margin of the mastoid cavity.
- Ensure that the skin flap over the receiver coil and magnet is 7 mm or

less using a skin flap gauge.

- Perform a mastoidectomy, leaving cortical bone overhanging the cavity along the superior and posterior margins to secure the conductor link. Identify and expose the incus body in the epitympanum.
- Open the facial recess within the boundaries of the chorda tympani nerve and facial nerve. The recess must be able to accommodate a 2.5- to 3-mm diamond bur in order to provide adequate access for the FMT and forming forceps. The chorda tympani nerve may need to be sacrificed if the recess is narrow. Preserve the incus buttress to maintain the integrity of the ligament that secures the short process of the incus.
- Place and secure the VORP in the bony recess or within the temporalis pocket.
- Prebend the distal conductor link a few millimeters from the FMT so that once the FMT is secured to the ossicular chain, the conductor link does not contact the walls of the facial recess.
- Advance the FMT through the facial recess, and position it parallel to the axis of motion of the stapes, with the FMT up against the incudostapedial joint and the clip as far superior on the incus long process as possible (Fig. 136.7).
- Tighten the clip around the incus long process using the forming forceps.
- Tuck the excess conductor link under the superior or posterior mastoid cortical overhang.

FIG. 136.7 Floating mass transducer attached to incus.

- Reapproximate the pericranial flap, and close the wound in the usual layered fashion. Any wound hemostasis after placement of the VORP should be performed using bipolar electrocautery only.
- Place a pressure dressing over the ear for 24 hours.

Common Errors in Technique

1. Thick skin flap

Impairs magnetization of the audio processor and proper implant function postoperatively. Use the skin gauge to ensure that the skin flap over the VORP magnet is less than 7 mm thick.

2. VORP placement

If the patient wears eyeglasses or head gear, the VORP should be positioned such that the external SP location does not interfere with use of either.

3. Conductor link contact with facial recess walls

This will impede movement of the FMT and can be avoided by creating a pre-bend in the conductor link before placement of the FMT.

4. FMT contact with surrounding structures

FMT contact with the promontory, pyramidal eminence, or tympanic membrane will impede movement of the FMT and should be avoided during placement.

5. FMT damage

Avoid repeated manipulation of the FMT attachment clip, and avoid grasping the FMT at its junction with the conductor link.

6. Suboptimal attachment clip fixation

If the facial recess is narrow, an additional transcanal exposure may be needed to securely crimp the attachment clip in place.

Postoperative Period

Postoperative Management

As for the Esteem Implant. The audio processor is activated 8 weeks after implant placement. A baseline hearing test is also obtained for the implanted ear.

Complications

1. Wound infection

All wound infections should be treated aggressively with broad spectrum skin flora coverage

2. Facial paralysis

Related to facial recess drilling. Treat with 7- to 10-day oral steroid taper

3. Dysgeusia

May occur if the chorda tympani nerve sacrificed

4. Hearing degradation

May result from incus long process erosion at the attachment clip site, clip detachment, or scar tissue formation and may necessitate revision surgery

Alternative Management Plan

As for the Esteem Implant

Discussion

Evidence-Based Medicine Question

Does mass loading of the ossicular chain with the FMT have any measurable impact on air-conduction thresholds in implanted ears?

Several studies have reported the absence of any change in air-conduction thresholds in implanted ears. However, bone conduction thresholds at 0.5 and 1 kHz improved, suggesting improved hearing via bone conduction due to an additional mass on the middle ear structures.[4]

Editorial Comment

Surgery for the Vibrant Soundbridge requires extensive facial recess exposure to ensure adequate access for positioning and crimping of the clip. Glass ionomer cement has been used to further facilitate fixation of the clip, but it must be used conservatively to not fixate the FMT.

Douglas A. Chen

Maxum Hearing Implant System (Ototronix, Texas)

The Maxum is a semi-implantable electromagnetic hearing system comprised of:

1. Internally implanted component: titanium-encased magnet with a nitinol (nickel/titanium alloy) split attachment coil used to couple the implant to the ossicular chain at the incudostapedial joint

2. Externally worn component: This is deeply inserted in-the-canal digital sound processer with an integrated electromagnetic induction coil (IPC; Fig. 136.8).

The fundamental technology of the Maxum system was developed from the SOUNDTEC Direct Drive Hearing System, which required the use of a behind-the-ear IPC. Sound detected by the IPC microphone is amplified, processed, and delivered as electrical signals to the

electromagnetic coil. The latter generates an electromagnetic field, within which the implanted magnet coupled to the ossicular chain vibrates. These vibrations are transferred from the stapes to the inner ear.

Key Operative Learning Points

1. The ossicular chain does not need to be disarticulated for placement of the implant magnet.

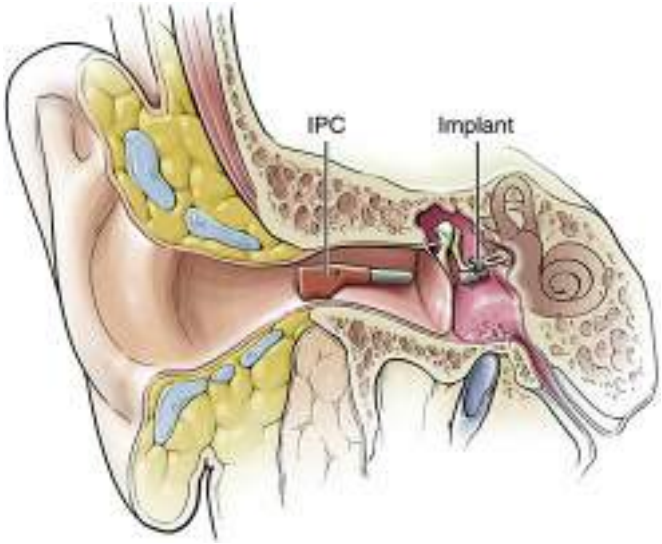

FIG. 136.8 Placement of Maxum deep insert sound processor with integrated electromagnetic induction coil and implant. *IPC*, Integrated processor and coil.

2. Precise alignment of the implant magnet with the external ear canal is critical for optimal implant function and hearing benefit.

Preoperative Period

History

As for the Esteem Implant with the exception of 2c, since a transcanal approach is used

Physical Examination

1. Ears

Assess the ear canal dimensions. Minimum anatomic dimensions for IPC fitting include a canal length 20 mm from the meatus to the tympanic membrane and a width of 4 mm at the meatus and 3 mm from the second bend to the tympanic membrane.[1] Look for normal tympanic membranes and the absence of any obvious middle ear lesions or effusions. A deep earmold impression of the entire external ear canal to the tympanic membrane is made and then analyzed by the manufacturer to ensure an IPC can be constructed to accommodate the anatomy.

Audiogram

1. Pure tone and speech audiogram

2. Tympanograms

Imaging

1. Temporal bone CT scan

Not routinely required. This is indicated only if the ear exam or audiogram is suggestive of middle ear pathology.

2. MRI brain with gadolinium*

Not routinely required. This is indicated only for retrocochlear screening if sensorineural hearing loss is asymmetric.

Indications

1. Adults 18 years or older with stable moderate to severe sensorineural hearing loss who desire an alternative to a conventional acoustic hearing aid

2. Unaided word recognition score of 60% or better in implanted ear

3. Intact tympanic membrane and ossicular chain with normal middle ear function

4. Prior hearing aid experience is strongly recommended

5. Realistic hearing expectations

Contraindications

1. All contraindications for the Esteem Implant apply to the Maxum implant

2. A narrow ear canal

3. Any other external ear canal condition that would preclude or interfere with wearing a completely-in-the-canal IPC

Preoperative Preparation

1. Choice of ear to be implanted:
   a. Poorer hearing ear
   b. Non-telephone ear
2. Discontinue any anticoagulants 10 to 14 days prior to surgery.

Operative Period

Anesthesia

Local with or without intravenous sedation: This is recommended for most patients. The procedure may be performed under general anesthesia if the patient prefers.

Positioning

Supine: The patient is positioned supine with the head turned away from the surgeon.

Perioperative Antibiotic Prophylaxis

None necessary

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Nonmagnetic cylinder-holding forceps*
2. Diode, KTP, argon, or CO_2 laser
3. Glass ionomer cement*
4. Image capture capability on surgical microscope

Key Anatomic Landmarks

1. Incudostapedial joint

Prerequisite Skills

1. Middle ear/ossiculoplasty surgery
2. Otologic laser certification
3. Otologic cement application

Operative Risks

1. Tympanic membrane perforation

This may occur when elevating the tympanomeatal flap and attempting to enter the middle ear without visualizing and elevating the fibrous annulus.

2. Injury to chorda tympani nerve

This can be avoided by careful dissection when elevating tympanic

membrane to expose the posterior mesotympanum. Care must be taken to avoid the chorda during laser crimping.

3. Ossicular trauma

The positioning of the magnet cylinder may be modified by adjusting the attachment clip angle. This should be done before crimping the attachment coil to minimize ossicular trauma. Manual crimping is avoided for the same reason.

Surgical Technique

- The patient's ear is prepped and draped in the usual sterile fashion.[5]
- The ear canal is injected circumferentially with local anesthetic containing 1:100,000 epinephrine solution, including the posterior vascular strip.
- A tympanomeatal flap is elevated, and the middle ear is entered posteroinferiorly while carefully separating the chorda tympani nerve from the tympanic membrane.

FIG. 136.9 Ideal positioning of Maxum implant cylinder eliciting "full moon" pattern of light reflection.

- The posterosuperior ear canal is curetted until the incudostapedial joint, pyramidal eminence, and tympanic facial nerve are all visible.
- The integrity and mobility of the ossicular chain are then confirmed.
- A moist piece of Gelfoam is positioned over the promontory as a cushion for the implant and to facilitate manipulation and positioning.
- The implant cylinder is picked up with a nonferromagnetic grasper and positioned inferior to the incudostapedial joint with the C-clip around the incudostapedial joint.
- The implant is positioned using the Gelfoam and nonferromagnetic instruments so that the lateral portion of the magnet is perpendicular to the axis of the ear canal. This will elicit a "full moon" pattern of light reflection from the microscope's light (Fig. 136.9).
- The C-shaped clip should be visualized almost circumferentially around the incudostapedial joint before heating with the laser at the lowest power setting.
- A glass ionomeric cement is reconstituted and applied to the C-clip around the incudostapedial joint to further fixate it and prevent movement.
- A photo of the implant cylinder in place is taken and given to the manufacturer to facilitate IPC manufacturing.
- Return the tympanomeatal flap to its native position, and pack the ear canal with antibiotic-soaked Gelfoam.

Common Errors in Technique

1. Suboptimal alignment of implant cylinder

A "full moon" pattern must be seen from the lateral surface of the magnet prior to fixing it in place. The magnet must also be clear of the promontory or tympanic membrane to ensure proper vibratory freedom.

2. Inadequate or inadvertent cement placement

Only a very small amount of cement is required to fixate the magnet. Excess can cause fixation to other structures and impair implant mobility. If not completely fixated with cement, the magnet can move when the

IPC is not being worn, which causes a disturbing rattling sensation in the ear.

Postoperative Period

Postoperative Management

1. Avoid water exposure to the implanted ear for 3 to 4 weeks.

2. An ototopical solution may be used daily for 3 weeks.

3. Remove any residual ear canal packing 3 weeks after surgery.

4. Activate the implant 3 to 4 weeks after surgery.

5. Two or more additional fitting/programming visits may be necessary to optimize the fit and function of the IPC after activation.

Complications

1. Tympanic membrane perforation/trauma

Persistent perforations incurred from surgery may require myringoplasty if spontaneous closure does not occur 3 to 6 months after surgery. Tympanic membrane trauma from the IPC coil early in the fitting process can occur, but it is rare.

2. Dysgeusia

This may occur even without obvious trauma to the chorda tympani nerve. This should be managed expectantly.

3. Sensorineural hearing loss

Excessive or aggressive manipulation of the ossicular chain when securing the attachment clip may cause sensorineural hearing loss.

4. Loose implant magnet

This usually manifests as reduced hearing benefit or audible rattling with implant magnet vibration when not wearing the IPC. Revision surgery may be required to further fixate the implant.

Alternative Management Plan

As for the Esteem Implant

Discussion

Evidence-Based Medicine Question

Does the Maxum offer any hearing benefit over and above optimally fitted conventional hearing aids?

Several comparative outcomes studies using the SOUNDTEC device have demonstrated average functional gains of up to 10 dB over preoperative best aided conditions, and up to 5% average improvement in speech discrimination scores.[6,7]

Editorial Comment

The Maxum Implant

Overview: As with all hearing implants, careful patient selection is important. Specifically, the patient's ear canal must be straight enough to accommodate the deep insertion tip of the electromagnetic SP (IPC). If the canal is stenotic or angled, a staged, pre-implant canalplasty may be required prior to performing an ear canal mold impression, which is used to create a custom IPC. The implant is capable of up to 60 dB of functional gain from 125 to 12,000 Hz. It is particularly good at amplifying high frequencies. Patients whose PB Max word recognition scores are better than their word recognition scores when tested at 40 dB above SRTs, or at maximum comfort levels, have been found to be good candidates. Direct stapedial and cochlear vibration lead to increased fidelity due to low distortion characteristics of the implant. IPC adjustments may require some trial and error. Most patients adapt to the deep insertion IPC within 3 weeks. Bilateral implants are possible. Scratching sounds sometimes reported with first-generation implants have been eliminated by second-generation design enhancements.

Surgical considerations: The operative procedure is performed through a straightforward, outpatient, transcanal tympanotomy under

local or general anesthesia. Adequate visualization of the incus and stapedius tendon is necessary. The Nitinol split ring connector is right- or left-ear specific. During implantation, nonmagnetic, Maxum middle ear instruments are used to prevent the implant from attracting to the standard surgical instruments. Carefully placing the split ring around the lenticular process and heat shrinking the ring requires a gentle learning curve. Once heat crimped, the stapedius tendon stabilizes the ring during fine adjustments prior to applying cement. Intraoperative photographs are taken to help facilitate the postoperative IPC tip adjustment.

Review questions

1. In patients with the Esteem Implant, development of acute eustachian tube dysfunction can result in all of the following, except

   a. Decreased hearing

   b. Ear pain

   c. Feedback

   d. **Vertigo**

2. Which of the following is a contraindication for hearing rehabilitation with an Esteem Implant?

   a. **Meniere disease**

   b. Prior history of herpes zoster oticus

   c. External canal exostoses

   d. Tinnitus

3. Hearing benefit with the Vibrant Soundbridge implant may be impacted by all of the following, except

   a. Cementing the FMT attachment clip to the incus

   b. Thick scalp flap

   c. Marginal contact between the FMT and the promontory

d. **Mild eustachian tube dysfunction**

4. Risks of Vibrant Soundbridge implant surgery include:

   a. Alopecia

   b. **Dysgeusia**

   c. Facial hypoesthesia

   d. Tympanic membrane perforation

5. What is the most likely cause of rattling in an ear implanted with the Maxum device?

   a. Incorrect placement of the implant magnet

   b. Contact between the magnet cylinder and the promontory

   c. Contact between the magnet cylinder and the tympanic membrane

   d. **Inadequate fixation of implant magnet on the ossicular chain**

6. When implanting the Maxum, the chorda tympani nerve is at risk for injury except when:

   a. Elevating the tympanomeatal flap

   b. Curetting the posterosuperior ear canal

   c. **Palpating the ossicular chain**

   d. Laser crimping the attachment clip

Cochlear Implantation in Adults

Jonathan L. McJunkin, and Craig Buchman

Introduction

A cochlear implant is an implanted medical device that restores the ability to perceive sound. The two patient populations that have benefited most from cochlear implants are children with congenital or early-onset profound hearing loss and postlingual adults who no longer benefit from amplification.

Key Operative Learning Points

- The middle ear is accessed via mastoidectomy through a facial recess approach between the facial and chorda tympani nerves.
- The round window is located inferior to the incudostapedial joint and is the key landmark for insertion of the electrode array.
- The receiver-stimulator portion of the cochlear implant is positioned 2 cm posterior to the mastoidectomy cavity.
- Slow insertion of the electrode is thought to minimize trauma to the inner ear and potentially preserve hearing.

Preoperative Period

History

History of Present Illness

- Details of hearing loss: When did the hearing loss begin? Has its

progression been gradual, rapid, or sudden? Is there a known cause for the hearing loss—hereditary, noise-related, ototoxic medications, meningitis? Which ear is the better-hearing ear?

- Amplification history: How long has the patient used amplification in each ear? If/when did the patient stop wearing a hearing aid on either side?
- Current communication ability: How much lip-reading ability does the patient have? Which environments are problematic? Is the patient socially isolated?

Past Medical History

- Prior treatment: Sudden hearing loss, chronic ear disease, previous ear infections, radiation therapy
- Medical illness: Any conditions precluding 3 hours of general anesthesia? Cardiac, pulmonary status?
- Surgery: Prior implants? Stapes surgery? Chronic ear surgery? Craniotomy?
- Medications: Surgery on patients using anticoagulants: nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin, rivaroxaban. Inquire about oral narcotic with acetaminophen abuse.

Physical Examination

- General appearance: Ability to communicate in office setting? Eye contact? Syndromic features?
- Ear: Postauricular skin characteristics? Previous surgical scars? Ear canal and tympanic membrane intact, free of infection? Otorrhea?
- Vestibular: Nystagmus? Gait?
- Cranial nerves: Facial nerve function? Weber and Rinne tests?

Imaging

- Standard preoperative computed tomography (CT) imaging to assess

temporal bone anatomy. Check for abnormal cochlear morphology (ossification in setting of meningitis); enlarged vestibular aqueduct; and characteristics of the facial nerve, sigmoid sinus, and tegmen.

- Magnetic resonance imaging (MRI) may be used in patients where there is concern for cochlear nerve aplasia in order to visualize the nerve within the internal auditory canal. It may also help in assessing the patency of the cochlea.

Indications

- Children with prelingual deafness
  - Children 1 to 2 years of age: Pure tone average (PTA) >90 dB in bilateral condition
  - Children above 2 years of age: Pure tone average (PTA) >0 dB in bilateral condition or failure to progress with auditory amplification
- Adults with postlingual deafness
  - Bilateral moderate to profound sensorineural hearing loss no longer benefiting from amplification
  - Open set sentence bilateral testing less than 60% in best-aided condition, less than 50% in the better ear (non-Medicare)
  - Hybrid cochlear implant
    - Normal to moderate hearing loss in low frequencies and severe to profound loss in the middle to high frequencies
    - Consonant-nucleus-consonant (CNC) word score between 10% and 60% in the ear to be implanted in the preoperative aided condition and the other ear equal or better but not above 80%
    - Previous suitable hearing aid trial if not already using amplification

Contraindications

- Cochlear nerve aplasia
- Cochlear aplasia

- Active middle ear infection

Preoperative Preparation

- Chlorhexidine scrub in the 24-hour period before surgery
- Pneumococcal vaccinations (Pneumovax 23 and Prevnar 13)
- Cessation of anticoagulants

Operative Period

Anesthesia

- General

Positioning

- Supine with the head turned away from the operative side

Preoperative Antibiotic Prophylaxis

- First-generation cephalosporin

Monitoring

- Facial nerve monitor

Instruments and Equipment to Have Available

- Operating microscope
- Standard mastoidectomy equipment
- Cochlear implant insertion instruments set
- Smooth jeweler's forceps

- 5910 Beaver ophthalmic blade for round window incision

Key Anatomic Landmarks

- Incudostapedial joint/oval window: The stapedial tendon is often the first landmark visualized upon entering the middle ear through a facial recess approach. The tendon originates from the pyramidal process and attaches to the stapes, which is located in the oval window. The round window niche can be identified directly inferior to the oval window.
- Round window: The round window overlies the scala tympani of the basal turn of the cochlea.
- Facial nerve: The middle ear space is accessed from the mastoid by posterior tympanotomy (facial recess) between the facial nerve and chorda tympani nerve.

Prerequisite Skills

- Complete mastoidectomy
- Fine motor skills are necessary to insert the electrode

Operative Risks

- Improper insertion of the cochlear implant:

  The electrode array can be placed into a hypotympanic air cell, missing the cochlea entirely. This risk can be minimized by obtaining adequate exposure through the facial recess approach and carefully removing the lip of bone overlying the round window. There is frequently a layer of fibrous tissue that obscures the round window; this should be removed as well.
- Injury to the facial nerve
- Injury to the chorda tympani nerve
- Violation of the annulus, entry into the medial external auditory canal
- Injury to a low-lying mastoid tegmen, leak of cerebrospinal fluid (CSF)

Surgical Technique

- Timeout to confirm that the correct side is being performed
- The operative ear is prepped and draped.
- The skin incision is marked 1 cm posterior to the postauricular crease superior to the mastoid tip to the level of the superior temporal line (Fig. 137.1).
- The postauricular incision site is injected with 1% lidocaine with 1:100,000 epinephrine.
- Soft tissue dissection is carried down to the level of the periosteum. The edges of the incision are undercut to gain exposure toward the mastoid tip and zygomatic root.
- The periosteum of the mastoid is incised to create an anteriorly based periosteal flap that is elevated anteriorly to the level of the spine of Henle. The posterior aspect of the external auditory canal is identified without elevating the soft tissue medially along the canal.

FIG. 137.1 Skin incision marked for cochlear implant on the right side.

FIG. 137.2 Facial recess approach view of right ear. *Orange arrow:* Lateral process of incus. *Blue arrow:* Lateral semicircular canal. *White arrow:* Incudostapedial joint. *Black arrow:* Round window niche. *Asterisk:* Cochleostomy site located anteroinferior to round window.

- Complete mastoidectomy is performed. The bony posterior canal wall is thinned. A facial recess approach is performed.
- The incudostapedial (IS) joint in the middle ear space is identified.
- The round window niche 2 mm inferior to the IS joint is identified (Fig.137.2).
- Carefully remove the lip of bone superior to the round window using the drill. Remove any fibrous tissue that obscures a clear view of the round window membrane (Fig. 137.3).
- Cochleostomy can be performed anteroinferior to the round window by drilling the bone until it is eggshell thin. The last layer is ideally removed with either a pick or rasp to minimize damage to intracochlear structures.

FIG. 137.3 Magnified view of right ear facial recess. *White arrow:* incudostapedial joint. *Black arrow:* Round window after niche has been opened. *Asterisk:* Cochleostomy site anteroinferior to round window.

- Sodium hyaluronate or another lubricating solution may be applied over the cochleostomy site.
- Once the approach to the cochlea is complete, the site for the receiver-stimulator is prepared.
- A subperiosteal pocket is developed posterosuperior to the edge of the mastoidectomy.
- The implant mockups are used to determine when an adequate pocket has been elevated. The device is typically placed at a 30- to 45-degree angle superiorly from the temporal line.
- The well for the implant is drilled at a minimum of 2 cm posterior to the mastoidectomy site to make sure that the anterior edge of the receiver-stimulator will not abut the external portion of the processor.
- A channel is drilled from the well to the mastoidectomy for the electrode array. The silicone mockup is used to check that the device can easily be placed into the prepared site.
- The wound is copiously irrigated to remove any bone dust. The monopolar cautery is taken off the field.

- The implant is placed into the subperiosteal pocket and drilled well with the Weitlaner retractor, which is already in place, to avoid damaging the implant.
- The orientation of the stimulating electrodes is visualized with the microscope. The electrodes should be oriented superiorly to face the cochlear modiolus upon insertion (Fig. 137.4).
- The electrode array is inserted into the cochlea slowly, using smooth forceps to grasp the array just proximal to the contacts.
- The insertion technique will vary depending on the design of the electrode array. Certain arrays are placed with the advanced off-stylet technique: The array is initially inserted partially with a stylet in place. It is then advanced slowly and smoothly into the cochlea while the stylet is held steady. Once the array has been fully inserted, the stylet is removed while the array is held in place. If there is initial difficulty with insertion, the array can be gently rotated or backed out slightly before attempting to readvance it. The array is inserted to the marker rings as indicated by the manufacturer.

FIG. 137.4 Cochlear Implant electrode array insertion in a right ear. Note that the contacts of the electrode array are oriented superiorly toward the modiolus. *White arrow:* Electrode array at round window with contacts oriented superiorly. *Green arrow:* Incus.

- A small piece of soft tissue (fascia or periosteum) is placed at the cochleostomy adjacent to the array to seal the site. Another piece of fascia can be placed in the facial recess.

- If there is excess length to the electrode array, it is carefully coiled in the mastoid cavity to avoid pulling the array from the cochlea.
- The grounding electrode (if present) is placed under the temporalis muscle superiorly.
- The periosteum is closed to cover the electrode array. The soft tissue is closed in three layers. A mastoid dressing is applied.

Common Errors in Technique

- Inadequate facial recess:

  A narrow facial recess makes identification of the round window more difficult. Insertion of the electrode array is also more challenging if there is inadequate anteroposterior space to release the array from the inserting forceps.

- Anterior placement of receiver stimulator:

  While minimizing the length of the postauricular incision is cosmetically appealing, the implant must be placed an adequate distance posteriorly to allow space for the external portion of the device. Smaller incisions make it more difficult to visualize tissue elevation posteriorly while also controlling bleeding.

- Rapid insertion of the electrode array:

  Slower insertion of the electrode array minimizes damage to intracochlear structures.[1]

Postoperative Period

Postoperative Management

- The mastoid dressing should be worn for 24 hours. The patient can shower without scrubbing the wound after 48 hours.
- Pain medication: Mild pain is expected after cochlear implant surgery.
- Anticoagulants can be restarted on postoperative day 1.

Complications

- Hematoma: The patient should be counseled to monitor for unusual swelling or color change of the incision site. Any significant edema or bleeding from the incision is atypical and requires evaluation. If a hematoma develops, the patient should be taken back to the operating room for evacuation of the hematoma and control of bleeding.
- Infection: Any purulent drainage from the wound or overlying skin edema and erythema are concerning for infection. Antibiotics should be started promptly. If infectious signs do not improve rapidly, limited incision and drainage without device removal is often effective.[2]
- Injury to the chorda tympani nerve: The patient may report taste dysfunction (metallic sensation) on the affected side if the chorda tympani nerve is injured. This can last for months before gradually resolving.
- Injury to the facial nerve: Facial paralysis in the immediate postoperative period warrants careful reflection by the surgeon on the mechanism and site of injury. Possibilities include heat transfer from the drill shaft while exposing the round window through the facial recess approach or direct injury to the mastoid segment. If there is concern for direct injury, the patient should be returned to the operating room for exploration. Delayed or partial facial weakness should be managed conservatively.
- Meningitis: The overall risk of meningitis is slightly higher in cochlear implant recipients compared with the general population.[3]

Alternative Management Plan

- Auditory amplification
- Sign language and lip reading

Discussion

Evidence-Based Medicine Question

Do cochlear implant recipients achieve better open set word recognition than in the best-aided preoperative condition?

Yes. One study demonstrated an average improvement from 16% preoperative HINT score to 61% CNC score in the implanted ear.[4]

Editorial Comment

Cochlear implant technology has evolved over the past 30 years. The properly screened patient can be offered an implant with the assurance that he or she will achieve significant benefit not experienced with a hearing aid. The indications for candidacy have been lifted from people only with profound hearing loss to those with normal hearing in the low frequencies and severe to profound loss in the high frequencies. If low-frequency hearing is not preserved with a hybrid device (electric acoustic stimulation), the outcome has still been shown to be better than with the use of a hearing aid alone.

Bilateral implants should enhance sound localization and the ability to understand conversations in the presence of background noise. Most third-party providers support implantation of a second device. It is thought that central processing is augmented with input from both ears. In our experience, most adult patients are satisfied with one cochlear implant and use of a hearing aid in the opposite ear.

Testing for candidacy has been modified to allow people with less severe hearing loss to become candidates. Previous tests were done using hearing in noise test (HINT) tests without competing sound. AzBio sentence testing adds a more difficult dimension to the method of testing. Currently, background sound can be instilled into the testing paradigm to create an environment similar to that of the real world. Presentation levels with a signal-to-noise level of +5dB make it harder for people with hearing aids to function. A cochlear implant can be offered with the assurance that it can reliably improve the ability to hear speech.

For many recipients a cochlear implant is a life-changing event. They are no longer isolated from employment, family, and friends. This is a remarkable technology that brings back one of the critical special senses: the hearing of sound and speech.

Review questions

1. Where in the cochlea is the electrode array placed?

   a. **Scala tympani**

   b. Scala media

   c. Scala vestibuli

   d. Scala olympi

2. Cochlear implants are contraindicated for patients with profound sensorineural hearing loss and

   a. Mondini malformation

   b. History of meningitis

   c. Age above 85 years

   d. **Active middle ear infection**

3. The most frequently used landmarks in the middle ear to identify the round window niche include the following, except the

   a. Stapes tendon

   b. Oval window

   c. Facial nerve

   d. **Eustachian tube**

4. What is the key landmark for positioning the cochleostomy?

   a. Oval window

   b. Cochleariform process

   c. Pyramidal process

   d. **Round window**

Facial Nerve Decompression

J. Seth McAfee

Introduction

The facial nerve is afflicted by paralysis more frequently than any other nerve in the body, most commonly in its peripheral segment as it courses through the temporal bone. The functional and cosmetic implications of facial paralysis carry the potential to significantly impact a patient's life, with resulting psychologic damage. There are many sources of otologic facial paralysis (Table 138.1), and managing facial paralysis is inevitable in the career of physicians managing otologic pathology. This chapter focuses on the role of facial nerve decompression in managing facial paralysis.

The facial nerve is composed of an estimated 10,000 fibers.[1] Seventy percent are myelinated motor axons innervating the muscles of facial expression, and the remaining 3000 fibers are spread amongst general visceral efferents (salivation and lacrimation), general sensory afferents (cutaneous sensation), and special visceral afferents (taste). The extent to which facial animation is compromised is directly correlated to the fraction of injured motor fibers. The anatomy of the facial nerve is organized by distinct layers, including the endoneurium, perineurium, and epineurium (Fig. 138.1). The endoneurium surrounds each nerve fiber, closely adherent to the Schwann cell layer of each axon. Individual fibers are then grouped into fascicles, and each fascicle is surrounded by perineurium. The epineurium is the outermost layer, where the vasa vasorum and lymphatics deliver oxygen and nutrients to the nerve. Sunderland[2] described a classification system for stratifying the severity of seventh nerve injury, as outlined in Fig. 138.2. First-degree injury is termed neuropraxia, describing a physiologic conduction block due to intraneural edema, with intact neural structure. Relief of compressive forces facilitates resolution of injury and return of function. Second-

degree injury results from failure to relieve compressive forces, termed axonotmesis, resulting in injury to axons without violation of the endoneurial sheath. With relief of the pathologic process, complete recovery is anticipated. Third-degree injury indicates disruption of the endoneural tubules. Disruption of endoneurial tubules allows disorganized axonal regeneration, as each axon can enter any open endoneurial tube. This pattern of disorganized, faulty regeneration accounts for synkinesis, and recovery is anticipated to be incomplete. Fourth-degree injury is characterized by violation of the perineurium in addition to axons, myelin sheaths, and endoneurium. Attempts at regeneration are even more disorganized, with axons aberrantly entering the wrong fascicles. Fifth-degree injury is characterized by complete laceration or transection of the nerve, to include the epineurium. Recovery after fourth- and fifth-degree injury is uniformly poor. Neurotmesis includes third through fifth degree injuries.

Key Operative Learning Points

1. The decision as to whether facial decompression is advantageous is based upon the etiology of paralysis, duration of paralysis, and outcome of electrodiagnostic testing.

2. Electrodiagnostic testing is necessary only in cases of complete paralysis, as the prognosis for cases of incomplete paralysis is uniformly good.

3. Evoked electromyography (EEMG) may underestimate the extent of recovery in a regenerating nerve and should be followed by electromyography (EMG) to survey for voluntary motor unit action potentials (VUMAPs), prior to consideration of decompression.

4. There is no consensus in the literature to support facial decompression in acute otitis media (AOM).

5. Facial paralysis in context of chronic otitis media (COM) with cholesteatoma should be addressed operatively without delay, with goals of exploring the facial nerve and eliminating disease.

6. Surgical decompression for Bell's palsy must address the meatal foramen. This can be accomplished by middle fossa or translabyrinthine approaches.

Preoperative Period

History

1. History of present illness
   a. How long has the paralysis been present?
   b. Was the paralysis abrupt or gradual in onset?
   c. Has this occurred previously (ipsilateral or contralateral)?
   d. Does the patient have hearing loss?
   e. Does the patient have ear pain or drainage?
   f. Is the patient dizzy?
   g. Was there associated trauma to the head?
2. Past medical history
   a. Does the patient have a history of chronic ear disease?
   b. Has the patient been previously diagnosed with Bell's palsy?
3. Surgical history
   a. Has the patient had prior otologic surgery?
4. Medications
   a. Is the patient anticoagulated?

Physical Examination

1. Facial examination
   a. Which branches of the facial nerve are affected?
   b. What is the extent of the weakness?
   c. What is the House-Brackmann score? (Table 138.2)
   d. Is there involvement of other cranial nerves?
   e. Is there or has there been a vesicular rash?
2. Otologic examination

a. Is there suppurative drainage or cholesteatoma?

b. Is there trauma to the ear canal or tympanic membrane?

Imaging

The decision as to whether imaging is necessary is guided by the etiology of the paralysis. A radiographic evaluation generally provides little information for a diagnosis of Bell's palsy. However, a surgeon considering middle fossa decompression may obtain computed tomography (CT) to assist in identifying surgical landmarks or to facilitate intraoperative image guidance. Facial paralysis in combination with suppurative ear disease warrants imaging to evaluate the course of the facial nerve, survey for additional intratemporal or intracranial complications, and to facilitate preoperative planning and counseling.

Paralysis exceeding 6 months duration, facial twitching, slow progression of weakness over a period of weeks to months, and recurrent episodes should prompt a radiographic evaluation for neoplastic disease.

1. Electrodiagnostic testing

Electrodiagnostic testing represents the primary diagnostic modality by which the severity of neural injury is assessed, facilitating estimations of prognosis. A finding of facial paralysis is not specific with respect to the extent of injury, as a patient with neuropraxia may demonstrate paralysis of similar severity to the patient with a transected nerve. In turn, the goal of electrodiagnostic testing is to identify the patient population sustaining injury of such severity that the chance of satisfactory, spontaneous recovery is low. This information is gathered by way of facial EMG and EEMG. Electrodiagnostic testing is necessary only in cases of complete paralysis, as the prognosis for cases of incomplete paralysis is uniformly favorable.

Data modified from Mary M: Differential diagnosis by history, physical findings and laboratory results. In May M (ed): The Facial Nerve. New York, Thieme-Stratton, 1986.

a. Evoked electromyography

EEMG assesses the functional capacity of the nerve by measuring the amplitude and latency of a compound muscle action potential (CMAP) after neural stimulation. This is accomplished with the use of surface electrodes placed at the stylomastoid foramen for stimulation and the nasolabial fold for measurement. The CMAP of the injured side is comparatively expressed as a percentage of the normal side, that percentage representing the number of electrically excitable fibers. Because the applied stimulus cannot propagate through degenerated axons, the CMAP represents the collective stimulus of intact (neuropraxic) fibers. It should be noted that a transected facial nerve may generate a CMAP of normal amplitude until Wallerian degeneration and sufficient axonal loss have progressed beyond the intratemporal segment, past the point of the applied stimulus. This process occurs over a period of 48 to 72 hours, during which EEMG provides limited useful information. EEMG should then be performed on an every other day basis to survey for progressive axonal degeneration (Fig. 138.3). Reliability of EEMG fades after a period of 2 to 3 weeks, as regenerating fibers and fibers recovering from neuropraxia fire asynchronously, yielding a disorganized, diminished response.

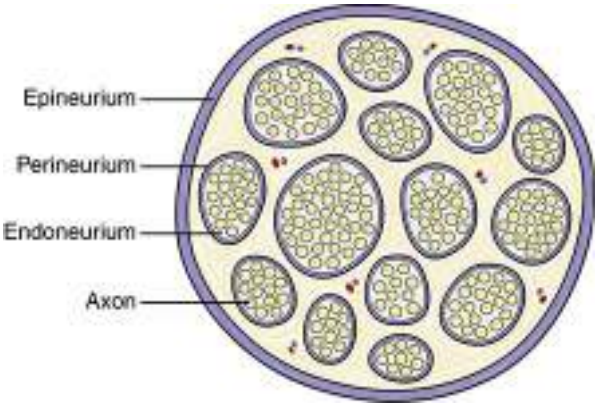

FIG. 138.1 Cross-section schematic of nerve demonstrating endoneurium, perineurium, and epineurium.

b. Facial nerve electromyography

In contrast to EEMG, EMG measures responses that are volitional in nature. Needle electrodes are inserted into facial musculature for analysis of resulting electrical activity during insertion, rest, and volitional movement. EMG is capable of detecting VUMAPs when no facial mobility is visually evident.[3] This feature renders EMG helpful in the setting of postoperative paralysis. If the nerve is transected, EMG will immediately show loss of VMUAP. However, loss of VMUAP is not specific to nerve transection, as neuropraxia may generate identical findings.[4] Therefore, demonstration of VMUAP is helpful to the surgeon in that it indicates the nerve is intact. Loss of VMUAP in this setting is less helpful, given the lack of specificity in regards to severity of injury. While EMG is capable of identifying a nerve as intact in the acute period, it is incapable of confirming degeneration in this time frame. Contrarily, EMG does provide utility in detecting muscle denervation 2 to 3 weeks out from injury, as destabilized resting potentials of the muscle membrane appear graphically as fibrillation potentials. This 2- to 3-week period represents the time in which Wallerian degeneration ensues. Polyphasic action potentials n this time frame indicate muscle re-innervation. Finally, when EEMG results have progressed to thresholds indicating need for decompression, EMG should be performed to survey for early VMUAPs, which project a favorable prognosis in absence of surgical intervention. This is necessary because with early reversal of a conduction blockade, dys-synchrony of nerve firing may result in failure to generate a CMAP,

yielding a false-positive result on EEMG.

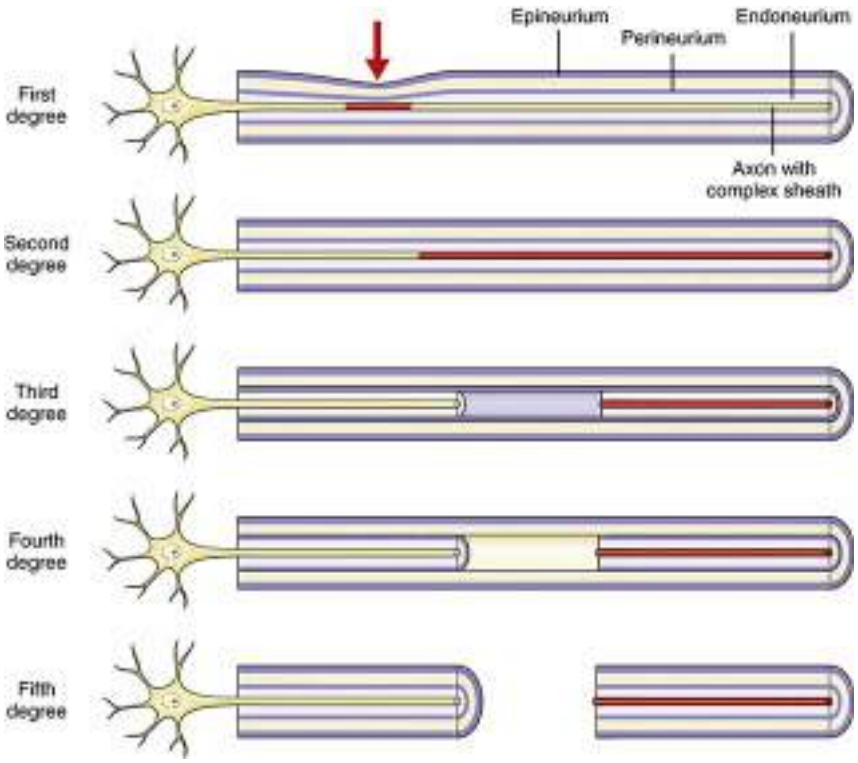

FIG. 138.2 Classification of Degrees of Neural Injury (From Sunderland): First degree—Compression (arrow) without loss of structure; recovery is normal. Second degree—Axon degeneration: regeneration is appropriate, and recovery is satisfactory. Third degree—Loss of endoneural tubes; recovery is incomplete with synkinesis. Fourth degree—Disruption of perineurium; recovery is very poor. Fifth degree—Complete disruption; no recovery.

TABLE 138.2

House-Brackmann Facial Nerve Grading System

Grade 1	Normal	Normal function in all areas
Grade 2	Mild dysfunction	Slight weakness noticeable on close inspection
Grade 3	Moderate dysfunction	Noticeable but not disfiguring weakness. Complete eye closure with effort. Mild synkinesis

Grade 4	Moderately severe dysfunction	Obvious weakness and/or disfiguring asymmetry. Incomplete eye closure. Normal symmetry/tone at rest
Grade 5	Severe dysfunction	Barely perceptible motion. Disfiguring asymmetry at rest
Grade 6	Total Paralysis	No movement

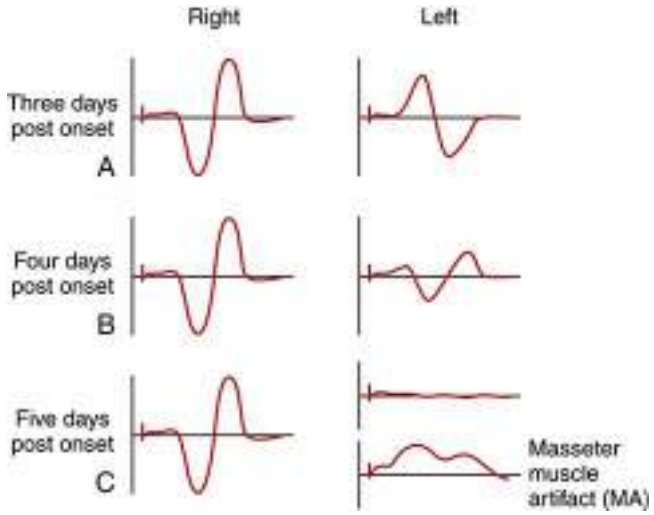

FIG. 138.3 Compound muscle action potential comparison of evoked electromyography. Progressive loss of response on the left as a result of axonal degeneration. **A,** Three days post onset. **B,** Four days post onset. **C,** Five days post onset. Masseter muscle artifact may be confused with a small evoked potential. The masseter is stimulated when high voltages are used. It can be best identified by its very short latency.

2. Audiogram

Defining auditory function will assist in reaching a diagnosis. For those patients requiring facial nerve decompression, the status of hearing is a key consideration in choosing a surgical approach.

Indications

1. Bell's palsy

Bell's palsy is a diagnosis of exclusion, presenting as an acute hemifacial weakness in the absence of further symptomatology. Weakness is global in distribution, and sparing of the forehead suggests a central etiology. Bell's palsy is by far the most common of the acute facial palsies, accounting for 75% of cases, at an estimated incidence of 30 to 40 cases per 100,000 people annually. Reviews of the natural history demonstrate satisfactory recovery in greater than 80%, and 85% of patients will demonstrate improvement within 3 weeks of onset.[5] Timing to onset of recovery and completeness of the palsy are the two most significant prognostic indicators.

Electrodiagnostic studies have localized the conduction blockade in Bell's palsy to the meatal foramen,[6] which is the entry location of the facial nerve into the temporal bone, forming the labyrinthine segment. This is the narrowest segment of the canal, estimated at 0.68 mm in diameter. The anatomy of the meatal foramen is characterized by a confluence of Bill's Bar and the falciform (transverse) crest with dense periotic bone laterally in the internal auditory canal (IAC). The nerve is devoid of epineurium, and is instead ensheathed by a band of periosteum that seals the entry site into the fallopian canal, resulting in potential for entrapment in situations of neurogenic edema (Fig. 138.4).

The mainstay of the patient's evaluation in Bell's palsy is electrodiagnostic testing. Audiometry demonstrates symmetric function, with the exception of an absent acoustic reflex on the involved side, and routine use of imaging is unnecessary. Facial nerve decompression is indicated for patients demonstrating CMAP reduction of 90% or greater, with confirmed lack of motor activity on voluntary facial EMG.[7,8] These criteria are based upon the observation that approximately one half of this patient population will sustain permanent, unsatisfactory recovery in the absence of decompression. If 90% degeneration is not documented within 2 weeks of onset, further electrodiagnostic testing is unnecessary, and prognosis for recovery is good.

Review of the literature demonstrates that pharmacologic treatment of Bell's palsy is a subject of considerable debate. However, guidelines support the use of combined systemic steroid (prednisone 1 mg/kg per day + taper) and antiviral therapy (valacyclovir 500 mg tid × 10 days) in patients presenting within 3 days of onset of paralysis,[9] and common practice supports initiation of therapy in patients presenting within 7

days.

2. Chronic otitis media

Paralysis of the facial nerve due to COM is a known complication of advanced disease, generally related to the effects of chronic suppuration and cholesteatoma. Authors have proposed various mechanisms, including chronic osteitis, bone erosion, nerve edema and inflammation, neural compression, and ischemia. Disruption of the nerve is most common in its horizontal course. Onset of facial palsy in COM may be abrupt or gradual. A palsy of abrupt onset is commonly due to acute infection superimposed on the presence of cholesteatoma. Such an occurrence should serve as a reminder that not all paralysis of acute onset is due to Bell's palsy. There is little controversy regarding treatment for facial paralysis associated with COM. Careful management with early surgical intervention has proven its efficacy in supporting neural recovery, and antibiotics and steroids are considered important adjunctive measures. The timing of surgery in relation to the onset of facial palsy is paramount. Patients should be taken to the operating room without delay, regardless of the extent of paralysis or the duration of time since onset. The goals of surgery are to eradicate all cholesteatoma and infection and to explore the facial nerve, which may require facial decompression. No consensus has been reached regarding the necessary extent of decompression at the time of surgery. Regardless of the specifics of surgical methodology, complete eradication of disease in a single procedure should be the operative goal for patients with facial paralysis due to COM.

3. Iatrogenic facial nerve injury

Factors which predispose a patient to iatrogenic injury can challenge even the most accomplished of surgeons, include variable landmarks and distorted tissue planes in revision surgery, inflammatory disease altering the course of the nerve, congenital structural anomalies, and errors in microsurgical technique. Second to hearing loss, facial paralysis is the most common reason for malpractice lawsuits in otologic surgery today.[10] If upon the patient's waking the surgeon is confronted with an immediate, complete paralysis, several issues deserve consideration. Use of a local anesthetic is a known source of temporary paralysis. If the surgeon identified the nerve and is confident of its integrity, patience should be all that is necessary for return of facial function. Similarly, use

of packing material may inflict undue stress and compression of the facial nerve. Consideration of more invasive management options begins when palsy persists despite removal of packing, and the waning effects of local anesthesia have passed. If the status of the facial nerve is unknown or if it was aggressively instrumented, one should proceed with exploration. However, if the surgeon is confident the nerve is intact despite gentle manipulation, observation may be appropriate.

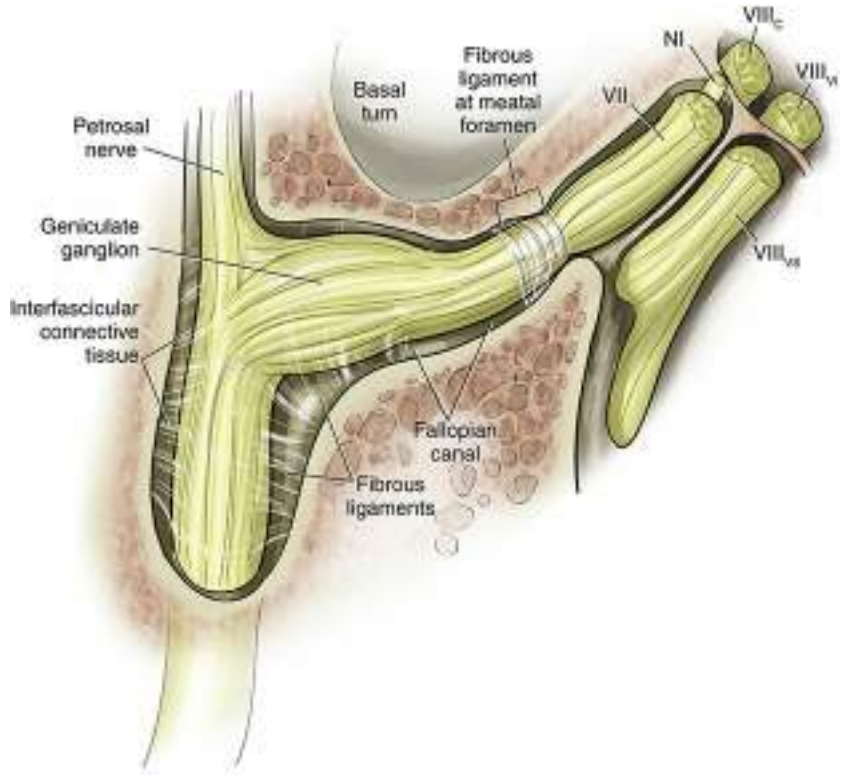

FIG. 138.4 Surgical anatomy of the lateral internal auditory canal, meatal foramen, and first genu of the facial nerve. Left ear, superior view.

As previously discussed, EMG may serve as a diagnostic adjunct in the acute setting for aiding in the decision to explore or observe. Demonstration of VMUAP indicates that the nerve is intact, eliminating the immediate need for exploration. Loss of VMUAP in this setting is less helpful, as this may indicate injury as mild as neuropraxia or as advanced as transection. If palsy is complete and early exploration is deferred, serial electrodiagnostic testing with EEMG is indicated after 48 to 72 hours have passed. Reduction in the

EEMG response to less than 10% of the normal side within 5 days of injury is indicative of severe injury and potentially transection. EMG should then be utilized to survey for VMUAP's. If no volitional activity is noted on EMG, the patient should be taken for re-exploration. The quality of the outcome declines dramatically when surgery is delayed beyond 30 days post injury, and when repair is delayed past 1 year, results are uniformly poor. Patients with delayed onset facial palsy, even when it progresses to a complete palsy, generally achieve satisfactory recovery.

Facial paralysis associated with noniatrogenic trauma may merit decompression, which is discussed in Chapter 145.

Contraindications

1. Herpes zoster oticus/Ramsay Hunt

The symptomatic combination of otalgia and a herpetic, vesicular eruption of the ear and face is known as herpes zoster oticus. The addition of facial paralysis is referred to as Ramsay Hunt syndrome. Symptoms result from reactivation of varicella zoster virus, previously quiescent in the geniculate ganglion. The frequency of complete paralysis is significantly higher, and the likelihood of satisfactory recovery is substantially reduced. Symptoms are generally more severe, and the patient may demonstrate involvement of multiple cranial nerves. Accompanying auditory and vestibular symptoms confer an even worse prognosis. Radiographic workup is of limited utility, and in contrast to Bell's palsy, electrodiagnostic testing has proven unreliable. Early administration of combined systemic steroid and antiviral therapy is paramount, and the role of surgical decompression is limited.

2. Facial paralysis associated with acute otitis media

The advent of antibiotics has dramatically reduced rates of peripheral facial palsy complicating AOM. Facial paralysis in this setting is a phenomenon observed nearly exclusively in children. The care of these patients should be considered urgent, and include myringotomy and aggressive use of topical and systemic antimicrobials. Tympanostomy tube placement permits ongoing egress of inflammatory fluid as well as established access to the middle ear for administration of topical

medication. Mastoidectomy is indicated in the case of associated coalescing mastoiditis or intracranial extension, but facial nerve decompression cannot be recommended for facial paralysis due to AOM.

3. Facial paralysis in the only hearing ear

4. Unfit for general anesthesia due to overall health status.

Preoperative Preparation

1. Review the history and assumed source of facial paralysis.

2. Review the audiogram to assess the hearing status of the ipsilateral and contralateral ears.

3. Review imaging, if obtained.

4. In cases where electric diagnostic testing was performed review the EEMG and EMG.

Operative Period, Middle Fossa Decompression

Anesthesia

General

Positioning

The patient is placed supine with head turned and the operative ear facing upward. For a middle fossa approach, the surgeon is positioned at the head of the bed. If the surgeon elects to use an image guidance system, a Mayfield clamp should be used to secure the head.

Preoperative Antibiotic Prophylaxis

1. First-generation cephalosporin

   a. Additional medications

1) Dexamethasone

2) Mannitol (0.5 mg/kg) administered at the time of skin incision for brain relaxation, easing temporal lobe retraction

3) Hyperventilation to CO_2 partial pressure of 25 mm Hg

Monitoring

Somatosensory evoked potentials as well as the seventh and eighth nerves are monitored intraoperatively. Request should be made of anesthesia to avoid muscle relaxants beyond what is necessary for induction

Instruments and Equipment to Have Available

1. Operative microscope
2. Otologic drill
3. Assortment of otologic burrs
4. Surgeon's preferred, fine otologic instrumentation
5. Craniotomy set
6. Middle fossa retractor
7. Facial nerve monitor and stimulator

Key Anatomic Landmarks

1. Arcuate eminence/superior semicircular canal (SSCC)

The arcuate eminence is commonly the first landmark identified on the floor of the middle fossa to assist the surgeon in locating the facial nerve. The labyrinthine segment courses just anterior to the ampullated end of the superior semicircular canal.

2. Greater superficial petrosal nerve

The greater superficial petrosal nerve (GSPN) courses anteriorly across

the floor of the middle cranial fossa. It location can be confirmed by retrograde stimulation of the facial nerve by passing current with the facial nerve stimulator. The angle between the GSPN and the superior semicircular canal is approximately 120 degrees, bisected by the IAC.

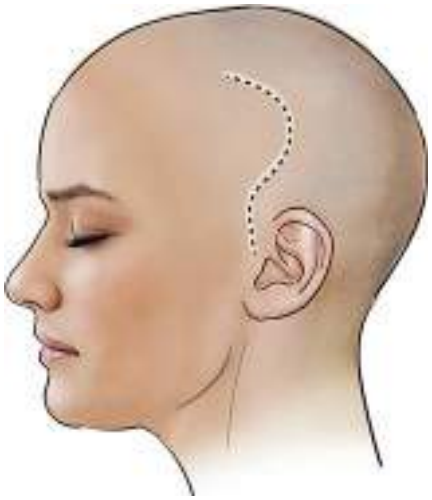

FIG. 138.5 The incision for middle fossa exposure of the facial nerve begins slightly anterior to the tragus and extends superiorly approximately 10 to 12 cm.

3. Middle ear

Structures of the middle ear, including the head of the malleus and body of the incus, are additional landmarks by which the facial nerve can be identified. Identification of the tympanic segment of the facial nerve proximal to the second genu facilitates retrograde dissection of the geniculate ganglion and identification of the labyrinthine segment.

Prerequisite Skills

1. Knowledge of the anatomy of the middle fossa
2. Fine microscopic surgical techniques
3. Knowledge and experience with intracranial surgery

Operative Risks

1. Sensorineural hearing loss

2. Cerebrospinal fluid (CSF) leak

3. Dizziness

4. Persisting facial weakness

5. Temporal lobe injury

6. Epidural hematoma

7. Cerebrovascular accident

Middle Fossa Surgical Technique

1. Skin incision/soft tissue dissection

The skin incision is placed in the pretragal area, extending superiorly past the helical root before gently curving posteriorly and then anteriorly (Fig. 138.5). An anteriorly based U-shaped muscle flap is designed such that innervation and blood supply are preserved. Skin and muscle flaps are covered with hydrating sponges and mobilized out of the field with a self-retaining retractor.

2. Craniotomy

Otologic burrs or a craniotome is used to create a craniotomy measuring 5 cm from anterior to posterior and 4 cm from superior to inferior (Fig. 138.6). Given the anterior angulation of the petrous pyramid, it should be designed such that 2⁄3 of the craniotomy opening is anterior to the external auditory canal. The root of the zygomatic serves as a reliable landmark for the floor of the middle fossa, and flush positioning of the craniotomy in this regard minimizes the extent of temporal lobe retraction. Special care should be taken when designing the craniotomy so that the vertical incisions are parallel, providing a precise fit for the middle fossa retractor. Too wide a craniotomy may exceed the reach of the retractor, precluding its use and severely compromising exposure. Dura is carefully elevated away from the bone flap, which is removed and placed on the back table for later use. Branches of the middle meningeal artery may be positioned on the surface of the dura or medial side of the bone flap, and bleeding can be controlled with judicious use of an irrigating bipolar cautery. A sized

Kerrison or surgical drill is used to lower the inferior margin of the craniotomy if necessary.

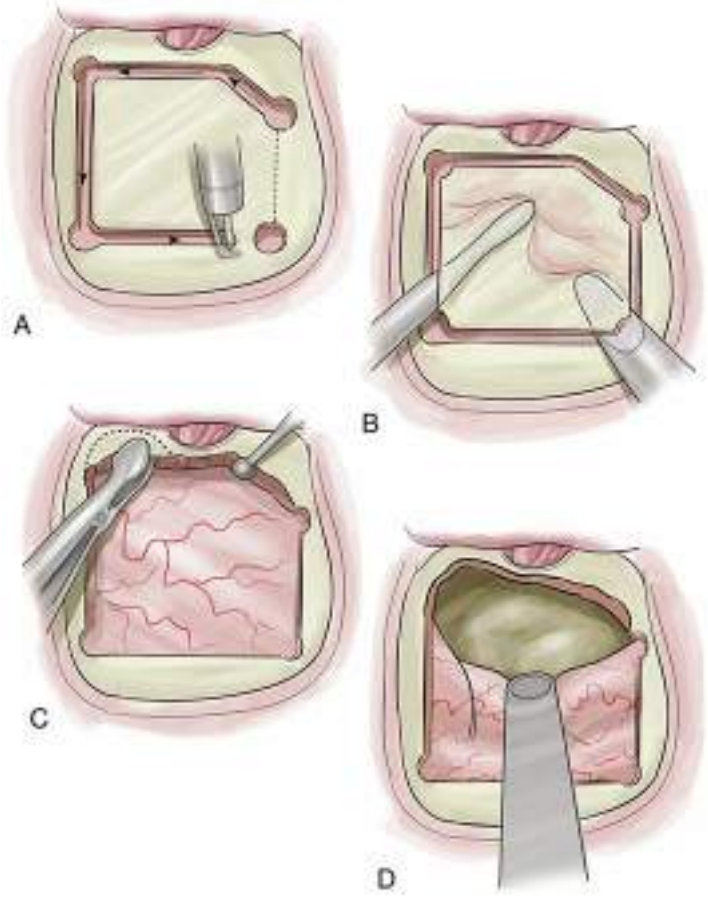

FIG. 138.6 Anatomic drawings courtesy of Jackler's Atlas of Skull Base Surgery. **A,** Use of craniotome or otologic burrs to create the craniotomy opening. **B,** Separation of the bony flap from underlying dura. **C,** Lowering of the inferior margin of the craniotomy to the middle flossa floor to optimize exposure and reduce temporal lobe retraction. **D,** Posterior to anterior dural elevation.

3. Elevation of the dura

The dura is elevated in a posterior to anterior direction. This technique protects against elevation of the GSPN and subsequent violation of a potentially dehiscent geniculate ganglion. Identification of the middle meningeal artery marks the anterior extent of the dissection. This area commonly bleeds from the pterygoid plexus and is controlled with

oxidized cellulose or Surgifoam. Care is taken to identify the superior petrosal sinus along the petrous ridge, such that retractor placement is atraumatic.

4. Identification of the arcuate eminence

Evaluation of the floor of the middle fossa is commonly unyielding of clear anatomic landmarks. However, the perpendicular trajectory of the superior semicircular canal to the petrous ridge is a reliable anatomic relationship. The arcuate eminence marks the position of the superior semicircular canal, which discloses the position of the IAC. However, the arcuate eminence commonly is not readily identifiable, and an elevation of bone may not represent the true location of the underlying superior canal. This situation requires methodical removal of bone with a larger diamond burr and copious irrigation, layer by layer, in the anticipated region of the superior canal. Appreciation of the dense, yellow bone that is characteristic of the otic capsule further directs drilling to uncover the blue-lined SCC. The position of the IAC can be estimated 60 degrees anterior to the position of the superior canal (Fig. 138.7A).

5. Facial nerve identification and decompression

The facial nerve can be identified by one of several methods. Drilling medially near the porous allows for safe blue-lining of the IAC (Fig. 138.7A). This area is free of the anatomic hazards common to the ampullated end, where the cochlea and labyrinth are positioned. Once the position of the IAC is confirmed, bone is removed laterally to identify Bill's bar. The labyrinthine segment is identified anterior to Bill's bar. Alternatively, the labyrinthine segment can be identified by opening the tegmen tympani, identifying the facial nerve at the first genu, and following it to the geniculate ganglion (Fig. 138.7B). Once identified, attention is directed at relieving the constriction imposed by the meatal foramen (Fig. 138.7B). The nerve is decompressed using a 1-mm diamond burr. Copious irrigation should be used to avoid transfer of thermal energy, which may further injure the nerve. Special care should be taken while thinning bone over the labyrinthine segment in identifying a potential blue line anterior or posterior to the nerve, as the cochlea and superior semicircular canal are positioned in these locations respectively. Fine picks are used to remove the final layer of bone overlying the labyrinthine segment and geniculate ganglion. Removal of the bone and sharp opening of the periosteal sheath in this location is done in an effort

to relieve the constriction imposed by the meatal foramen.

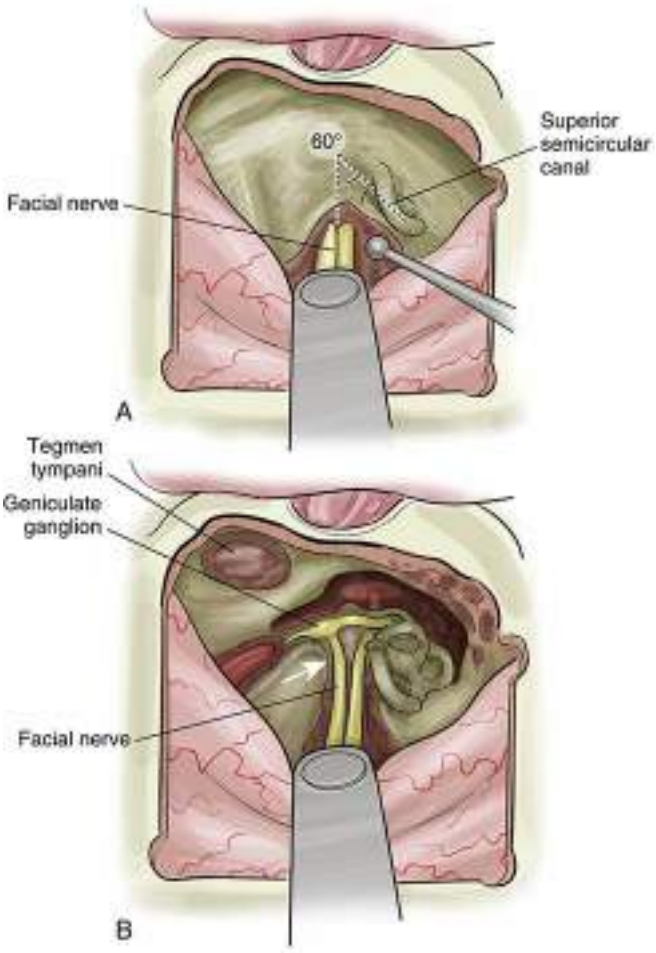

FIG. 138.7 Anatomic illustrations courtesy of Jackler's Atlas of Skull Base Surgery. **A,** Identification of the facial nerve at the porus acousticus of the internal auditory canal (IAC), estimated at 60 degrees anterior to the position of the superior semicircular canal. **B,** Alternative method of identifying the facial nerve by opening tegmen tympani, identifying the horizontal segment, and dissecting it retrograde to the geniculate ganglion and labyrinthine segment. Arrow marks the position of the meatal foramen as the nerve exits the fundus of the IAC.

6. Closure

After completing the decompression, opened air cells of the petrous apex are waxed, a graft of temporalis muscle is placed over the IAC, and

temporalis fascia is positioned over the middle fossa floor. The retractor is removed, the temporalis flap is closed, and the temporal bone flap is replaced and secured. A multilayer, watertight skin closure is performed with deep absorbable suture and nylon superficially in the skin.

Common Errors in Technique

1. Malposition or inadequate size of the craniotomy approach

2. Failure to lower the inferior aspect of the craniotomy to the floor of the middle fossa

3. Injury to the GSPN and geniculate ganglion if they are uncovered and exposed

4. Violation of the cochlea or superior semicircular canal

5. Unrecognized injury to the integrity of the dura

6. Development of a hematoma if inadequate hemostasis is not obtained

Postoperative Period

Decompression by the middle fossa approach requires observation of the patient in the ICU overnight. Narcotic analgesics are initially used judiciously, given their propensity to mask intracranial complications. The following day the patient is transferred to the floor, where he or she is encouraged to ambulate and resume a normal diet. The drain is removed when collection is less than 20 cc. Discharge routinely occurs 3 to 6 days following surgery.

Complications

1. Hearing loss

Inadvertent fenestration of the cochlea or labyrinth may result in sensorineural hearing loss and vertigo. Should fenestration occur, the site should be immediately occluded with bone wax. Contact of the drill with the ossicular chain may also generate sensory neural hearing loss.

2. Cerebrospinal fluid leak

Trauma to middle fossa dura may result in a CSF leak. It is important to use the proper sized burr, watch all edges of the burr while drilling, and use diamond burrs when in tight areas or around exposed dura. If the dura is violated, repair with fascia, muscle, or homograft dura/pericardium is necessary.

3. Temporal lobe edema/contusion

Temporal lobe injury may occur during the craniotomy or due to temporal lobe retraction. If injury to the temporal lobe is suspected, a CT scan of the head should be performed, and a neurosurgeon should be consulted.

4. Epidural hematoma

While uncommon, epidural hematoma can occur following middle fossa craniotomy. Treatment involves urgent craniotomy for evacuation of the hematoma.

Alternative Management Plan

1. Transmastoid decompression: Indicated when facial nerve injury is limited to the tympanic and mastoid segments of the facial nerve

2. Translabyrinthine decompression: Affords access to the entire course of the facial nerve. This approach should be reserved for cases when hearing preservation is not a priority.

Discussion

Evidence-Based Medicine Question

For patients with Bell's palsy who exhibit electrophysiologic features associated with poor outcomes, does facial nerve decompression result in improved outcomes compared to nonsurgical treatment?

1. Gantz et al.[7] reported a prospective study in which results of surgical decompression were compared to nonsurgical controls treated with steroids. Surgical decompression was offered to patients exhibiting 90% degeneration on ENoG (EEMG) and a lack of voluntary motor unit action

potential on EMG within 14 days of onset. Nineteen patients underwent surgical decompression compared to 11 nonsurgical controls. Of those undergoing decompression, 18 (95%) had a good outcome (defined as return to HB 1 or 2), half of which recovered to normal function. One patient (5%) recovered to a HB 3 and none to a HB 4 or 5. Among nonsurgical controls, 66% demonstrated a poor outcome. Among the 33% with a good outcome, none recovered to normal function. Among patients decompressed after 14 days of onset, results were similar to nonsurgical controls.

2. Patients exhibiting 90% degeneration on ENoG and a lack of voluntary motor unit action potential on EMG within 14 days of onset can expect to have at least a 50% chance of poor recovery of facial nerve function.[7]

Editorial Comment

There is evidence supporting timely surgical intervention for specific indications in facial paralysis can improve outcomes compared to medical therapy alone. There are challenges that must be met by the surgeon and his/her team who offer management of acute facial paralysis. They can be considered to be independent. The first is knowing the appropriate electrical tests that can provide pertinent information as to the inferred status of the facial nerve. One must know the indications for each test, when they should be obtained, and interpretation of the results. This information allows the physician to decide whether surgical exploration or decompression is a reasonable option. The next challenge is having the ability to surgically intervene. In particular, decompression of the labyrinthine segment of the facial nerve via a middle fossa approach requires knowledge and experience beyond that necessary for routine otologic procedures.

Hearing is unaffected in Bell's palsy yet the cochlea and superior semicircular canal are in immediate danger should the dissection stray from the exact location of the nerve.

Transmastoid surgery of the facial nerve is also indicated in patients with acute paralysis secondary to COM with cholesteatoma. CT imaging often identifies the site of pathology and the route in which intervention should be directed. Electrical testing is not necessary given the immediate urgency needed for intervention.

Traumatic injury to the facial nerve also requires electrical testing to help determine the status of the integrity of the nerve. This is addressed in Chapter 145, Temporal Bone Trauma.

Review Questions

1. Which of the following is true regarding facial electromyography (EMG)?

   a. Facial EMG is effective in identifying muscle denervation in the acute period by demonstration of fibrillation potentials.

   b. The lack of volitional motor unit action potentials in the immediate postoperative setting indicates neuropraxia of the facial nerve.

   c. **The presence of volitional motor unit action potentials in the immediate postoperative setting indicates neuropraxia of the facial nerve.**

   d. Facial EMG has no application in the immediate postoperative period but is more effectively implemented to identify denervation after Wallerian degeneration occurs.

2. For which of the following etiologies of facial paralysis is decompression generally not indicated?

   a. Chronic otitis media (COM) with cholesteatoma

   b. Bell's palsy

   c. Latrogenic injury

   d. Acute otitis media

   e. Ramsay Hunt

   f. a and c

   g. **d and e**

3. Which of the below statements is not true of the meatal foramen?

   a. The meatal foramen represents the site of entry of the facial nerve into the fallopian canal.

b. The meatal foramen is formed by a confluence of bony partitions and dense periotic bone at the fundus of the internal auditory canal (IAC).

c. The facial nerve is devoid of epineurium at the meatal foramen, instead ensheathed by dense periosteum that seals the entrance into the fallopian canal.

d. **Facial paralysis in context of Bell's palsy requires decompression at the meatal foramen and second genu.**

Tumors of the Facial Nerve

Howard S. Moskowitz

Introduction

Disorders of the facial nerve most commonly develop because of a variety of infectious and inflammatory processes. Involvement of the facial nerve can occur anywhere along its course ranging from the posterior fossa, temporal bone, to parotid gland either by primary or secondary involvement of the facial nerve. Tumors of the facial nerve represent a much less common etiology in patients presenting with facial nerve dysfunction. Consideration for neoplastic involvement of the facial nerve should be routinely considered, particularly in circumstances of slow progressive loss of motor function of the facial nerve or recurrent episodes of paresis or paralysis. The most common tumor involving the facial nerve is the schwannoma. Many other neoplastic processes that can involve the facial nerve have been reported including hemangiomas, paragangliomas, and granular cell tumors. Furthermore, many types of cancer have the capability to metastasize to the temporal bone and may involve the facial nerve.

Schwannomas of the facial nerve arise from Schwann cells that are the myelin-producing cells peripheral to the axon. The histologic appearance of Antoni A (dense array of cells), Antoni B (areas of loose stroma), or combined patterns is identified on histologic examination. A schwannoma can arise anywhere along the course of the facial nerve (Fig. 139.1). These tumors can also exhibit multiple discrete intraneural connections between distant portions of the facial nerve.1 Hemangiomas of the facial nerve typically occur at the geniculate ganglion, generally believed to arise from the extensive capillary plexus that surrounds the facial nerve at this location. The facial nerve can also become involved with a glomus jugulare or tympanicum, and there have been reports of paragangliomas developing primarily from the Fallopian canal and

invading the facial nerve.

Patients with tumors of the facial nerve commonly present with a facial nerve paresis or paralysis that fails to improve with medication, therapy, or time. However, up to 50% of patients with a primary schwannoma of the facial nerve do not present with signs or symptoms of facial nerve dysfunction. Other common symptoms at presentation include hearing loss, tinnitus, or vestibular dysfunction. The diagnosis is typically made after radiologic studies are obtained.

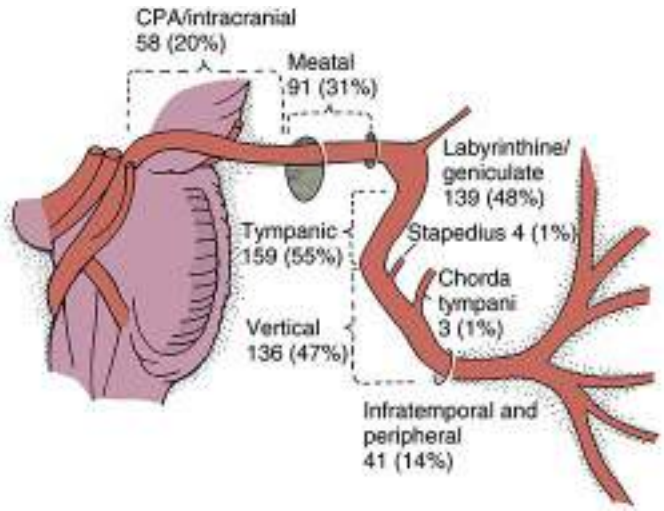

FIG. 139.1 Segmental distribution and frequency of facial schwannomas.

These tumors may involve multiple segments of the facial nerve.

A fundamental consideration regarding management concerns the extent of facial nerve weakness and the prospects for recovery, as the risk of facial nerve injury can be high with surgical management of these tumors.2 In some patients, consideration for stereotactic radiosurgery (SRS) may play a role in the treatment paradigm.

Key Operative Learning Points

1. Consideration for facial nerve function should play a key role in the decision as to whether or not to proceed with surgery.

- The fundamental goal is to preserve facial nerve function for the longest duration possible.

2. Surgical management of tumors that are intimately associated with the nerve will often result in complete facial nerve paralysis.

- Need to compare current facial nerve function with the best conceivable surgical result with optimal reconstruction

3. It is essential to consider the hearing status in the affected ear and the contralateral ear.

4. Schwannomas of the facial nerve exhibit a tendency to involve portions of the facial nerve beyond the extent of the visible tumor.

- Intraoperative frozen section should be obtained to ensure clear surgical margins.
- Prepare to use different surgical approaches if additional exposure is required for tumor resection and repair.

5. SRS may be an effective treatment option for control of tumors of the facial nerve and should be considered in patients with higher surgical risks, good facial function, or only one hearing ear.

Preoperative Period

History

The history should include comprehensive details regarding facial nerve function. Patients commonly present with a progressive facial nerve weakness. A patient who exhibits slowly progressive facial weakness over several months suggests a tumor. The paralysis may also be "recurrent," although it may never recover completely between episodes. A significant number of patients may have no weakness on initial presentation. The patient may complain of facial twitching or fasciculations and may complain of eye symptoms due to inability to blink or close the eye.

Patients may present with normal hearing or some degree of hearing loss. In some cases, patients may not report significant hearing loss but may only complain of tinnitus. Sensorineural hearing loss may result

from tumors that compress the cochlear nerve or invade the otic capsule. Patients may also have conductive hearing loss if the tumor involves the tympanic portion of the facial nerve and impacts the ossicular chain. Patients may report vestibular dysfunction owing to compression of the vestibular nerve or possible erosion into the labyrinth. Patients do not typically complain of pain, but when present, the pain may be indicative of a malignant tumor.

The past medical and surgical history should be thoroughly reviewed. A determination of the patients' medical status and comorbidities will play a key role in determining which of the potential treatment options would be most suitable for the patient.

Physical Examination

1. Neurologic examination
   a. Facial nerve examination
      1) Assess extent of weakness of gross and fine motor function.
      2) Attention to signs of synkinesis and mass motion
      3) Categorize the extent of facial nerve function using the House-Brackmann scale (Table 139.1).
      4) Keep photographs and video documentation to illustrate any progression of facial weakness over time.
   b. Hearing examination
      1) Weber and Rinne tuning fork testing to ascertain the type of hearing loss
         - Negative Rinne may result when ossicular chain movement is impeded by the tumor.
      2) Formal audiogram
         - Acoustic reflexes—This can give insight into compromise of facial nerve function with ipsilateral and contralateral stimulation.
   c. Full cranial nerve examination
      1) Trigeminal nerve

- Dysfunction can be evaluated by testing of the corneal reflex.

2) Lower cranial nerves

- Close attention to voice, cough, swallow, and vocal cord function

TABLE 139.1

House-Brackmann Facial Nerve Grading System

Grade	Description	Characteristics
I	Normal	Normal facial function in all areas
II	Mild dysfunction	*Gross:* Slight weakness noticeable on close inspection; may have very slight synkinesis *At rest:* Normal symmetry and tone *Motion:* Forehead—moderate to good function; eye—complete closure with minimal effort; mouth—slight asymmetry
III	Moderate dysfunction	*Gross:* Obvious but not disfiguring difference between the two sides; noticeable but not severe synkinesis, contracture, or hemifacial spasm *At rest:* Normal symmetry and tone *Motion:* Forehead—slight to moderate movement; eye—complete closure with effort; mouth—slightly weak with maximal effort
IV	Moderately severe dysfunction	*Gross:* Obvious weakness and/or disfiguring asymmetry *At rest:* Normal symmetry and tone *Motion:* Forehead—none; eye—incomplete closure; mouth—asymmetrical with maximal effort
V	Severe dysfunction	*Gross:* Only barely perceptible motion *At rest:* Asymmetry *Motion:* Forehead—none; eye—incomplete closure; mouth—slight movement
VI	Total paralysis	No movement

d. Clinical examination of the vestibular system to ascertain underlying balance disorders

1) Electronystagmography or videonystagmography may be useful in determining the extent of vestibular dysfunction.

2) Fistula testing in cases in which the integrity of the labyrinth is suspect

2. Otoscopic examination

a. Essential, but generally normal

b. If the tumor involves the tympanic segment of the facial nerve, then

a retrotympanic mass may be visualized.

c. May present as a swelling in the external auditory canal if the descending or mastoid segment of the facial nerve is involved

3. Head and neck examination

a. The parotid gland and neck should be examined to search for evidence of tumor or cervical lymphadenopathy.

4. Ophthalmologic examination

a. Essential to assess corneal protection

b. If the patient demonstrates a poor Bell's phenomenon and is unable to adequately protect the cornea, then the patient may need a gold or platinum eyelid weight.

c. If ectropion is present the patient may need a lower lid-tightening procedure.

5. Electrophysiologic facial nerve tests

a. May be useful in some cases

b. Electroneuronography may show a reduction in amplitude that supports the compromise of neural integrity.

c. Facial electromyography prototypically shows simultaneous denervation (fibrillation potentials) and re-innervation (polyphasic voluntary motor unit potentials).

- This combination of potentials is more commonly encountered in slowly progressive pathologic processes.

Imaging

1. High-resolution computed tomography (CT) and magnetic resonance imaging (MRI) should be used to demonstrate the presence and extent of a facial nerve tumor.

2. Imaging characteristics of selected tumor types:

a. Facial nerve schwannomas

1) MRI

- Typically enhance with administration of contrast
- Solitary lesions or may have skip lesions with intervening segments of normal appearing facial nerve ("beads on a string")3

2) CT

- May exhibit widening of the Fallopian canal

b. Hemangiomas

1) Found predominantly at the geniculate ganglion4

2) MRI

- Heterogeneous hyperintensity on T2-weighted sequences with punctate foci of hypointense signal

3) CT

- Irregular borders with remodeling of surrounding bone or evidence of intratumor bony spicules

c. Paragangliomas

1) MRI

- Salt and pepper appearance on T1-weighted sequences with contrast as well as hyperintensity on T2-weighted sequences

Indications

Treatment is typically reserved for patients who exhibit evidence of progressive tumor size and/or neurologic sequelae. Some tumors may appear stable from a radiologic perspective, but they can result in worsening facial function, hearing loss, vestibular dysfunction, or other neurologic changes. Before undertaking surgery, it is essential to consider the site and the extent of the lesion and the hearing status of both ears. It is generally difficult to recommend treatment if the patient exhibits normal facial movement or only subtle weakness. However, patients may require active management in cases of hearing loss, unrelenting pain, pulsatile tinnitus, or atypical vestibular complaints.

1. Facial nerve weakness

a. Surgery is typically not undertaken until facial nerve function has

worsened to greater than House-Brackmann grade 3.

- If resection of the facial nerve tumor results in loss of facial nerve continuity, the best facial nerve result attainable with reconstruction is a House-Brackmann grade 3.

b. Residual facial nerve function

- Patients with long-standing facial nerve paralysis may have worse results after facial nerve repair.

2. Hearing status

a. Good contralateral hearing

- Full complement of surgical options is available

b. Poor contralateral hearing

1) In patients with normal hearing, attempted removal of tumor should generally be avoided if injury to the ipsilateral cochlear nerve or otic capsule is likely.

2) Tumor decompression should be considered unless the size or location of the tumor presents no other options.

Contraindications

1. Surgery should not be performed in patients with severe underlying medical conditions that preclude their ability to undergo a surgical procedure. SRS may be an option for these patients.

2. Patients with small tumors or with little or no neurologic sequelae should be strongly considered for watchful waiting with serial clinical and radiologic examinations.

3. Surgical intervention should be avoided in patients with facial nerve tumors in an only hearing ear.

Preoperative Preparation

1. Medical clearance should be obtained prior to surgery. Standard avoidance of medications or supplements that may promote bleeding and inhibit coagulation should be stressed to the patient.

2. Coordination with electrophysiology monitoring services should be arranged in advance of the procedure date.

3. Review the diagnostic imaging studies and audiometric findings of both ears.

4. If facial nerve repair is to be performed by another service, reconfirm their planned participation.

Operative Period

Anesthesia

1. All standard surgical techniques require general anesthesia.

2. Careful coordination and discussion with the anesthesia service regarding the extent of usage of paralytic medications.

Positioning

1. Most surgical procedures for treatment of tumors of the facial nerve can be performed with supine positioning with the head turned to the contralateral side.

2. Patient position should be made to permit access to the abdomen if abdominal adipose tissue is needed for reconstruction as well to the neck (greater auricular nerve) or leg (sural nerve) if a nerve graft is required to repair the facial nerve.

Perioperative Antibiotic Prophylaxis

1. A first-generation cephalosporin is generally sufficient for cases of exclusive transmastoid surgery.

- In cases of documented allergy to penicillins, clindamycin can be used.

2. For more extensive surgical cases where the antibiotic is desired to penetrate the central nervous system, ceftriaxone may be a better option.

- In cases of documented allergy vancomycin can be used.

3. A dose of antibiotics is given prior to the incision and then maintained for a total of 24 hours.

Monitoring

1. Routine anesthesia monitoring
2. Electrophysiologic monitoring
   a. Facial nerve function should be monitored with real-time monitoring with the opportunity for direct stimulation of the facial nerve.
   b. Auditory brainstem responses, direct cochlear nerve recordings, somatosensory evoked potentials, and other testing modalities may serve a role in the surgical management based on surgeon preference.

Instruments and Equipment to Have Available

1. Standard mastoidectomy and middle ear dissection set
2. Soft tissue set for harvesting abdominal adipose tissue or nerve graft
3. Microsurgical set for facial nerve grafting
4. Facial nerve stimulating probe compatible with facial nerve monitoring system
5. Middle fossa retractor
6. Retractor system for sigmoid sinus and posterior fossa dura
7. Operating microscope

Key Anatomic Landmarks

Course of intratemporal facial nerve

1. After leaving the brainstem, the facial nerve enters the internal auditory canal (IAC). The course of the facial nerve is divided into

several segments:

a. Meatal segment—within the IAC

b. Labyrinthine segment—fundus of IAC to facial hiatus and geniculate ganglion

c. Tympanic segment—geniculate ganglion to pyramidal eminence (second genu)

d. Mastoid segment—pyramidal eminence to stylomastoid foramen

2. There are several key anatomic associations:

a. Within the IAC, the facial nerve courses anteriorly and superiorly as it approaches the geniculate ganglion and middle ear.

1) The facial nerve passes superior to the falciform (transverse) crest in the lateral aspect of the canal.

2) The facial nerve passes anterior to the vertical crest of bone known as Bill's bar.

b. As the facial nerve courses posteriorly through the middle ear, it is usually well covered in the bone of the fallopian canal and courses superior to the cochleariform process and the oval window.

c. The facial nerve gives off the chorda tympani nerve branch as it descends through the mastoid segment.

Prerequisite Skills

1. Extensive expertise with all approaches for lateral skull base surgery and middle ear surgery including reconstruction of the ossicular chain.

2. Must be prepared for the possibility that tumor has infiltrated the facial nerve and will require resection with re-anastomosis or nerve grafting

Operative Risks

1. Facial nerve paralysis

2. Hearing loss

3. Vestibular dysfunction

4. Vascular injury

5. Intracranial complications

Surgical Technique

There are a variety of surgical options for the management of tumors of the facial nerve including decompression, debulking, and resection with possible primary re-anastomosis or interposition graft if the integrity of the facial nerve is lost. Radiographic size, location, degree of hearing loss, and involvement of adjacent structures will dictate the most advantageous surgical approach. The surgeon should individualize these criteria to the needs of the patient.

1. Decompression

   a. Involves removal of the bone overlying the Fallopian canal, which allows room for more tumor growth

      - May reduce potential effects of nerve compression and should permit axonal flow for neuronal transmission

   b. Tumor will likely continue to grow, but decompression may provide a longer period before a final decision must be made regarding potential facial nerve sacrifice

2. Debulking

   a. More controversial approach that has been used for management of facial nerve schwannomas

   b. Several reports from different centers have used this approach to manage tumors while preserving facial function.

   c. Given that there can be histologic evidence of normal nerve fibers running through the tumor, there is often concern for potential complete damage to facial nerve function.

3. Resection with possible primary re-anastomosis or interposition graft if the integrity of the facial nerve is compromised

Techniques

1. Transmastoid approach

- Tumors confined to the horizontal or vertical fallopian canal

2. Middle fossa approach

- Tumors of the IAC, labyrinthine segment, and geniculate ganglion region if hearing preservation is attempted
- Patients older than 65 do not typically tolerate this approach due to fragility of the dura and effects of temporal lobe retraction.

3. Middle fossa and transmastoid approaches can be combined.

- Larger tumors centered at the geniculate ganglion
- There is a need for access to proximal and distal nerve stumps for repair in cases where hearing is attempted to be preserved.

4. Translabyrinthine approach

- If hearing is worse than the 50/50 rule (pure tone average greater than 50 dB and speech discrimination less than 50%), hearing conservation surgery should not be attempted.
- Permits direct access to the tumor and facilitates repair

5. Retrosigmoid approach

- Uncommon approach for facial nerve tumors (not covered in this chapter)

Transmastoid Approach

1. Standard postauricular approach 1 cm posterior to postauricular sulcus through skin, subcutaneous tissue, and fibroperiosteal layer over mastoid cortex

2. Wide cortical mastoidectomy with identification of horizontal semicircular canal, delineation of sinodural angle, and appropriate thinning of the bone of the posterior ear canal

3. Identify the short process of the incus, and, depending on tumor location, open the facial recess widely.

4. Progressively thin the bone overlying the facial nerve until translucent.

5. The incus will need to be removed for access to the tympanic segment (Fig. 139.2).

6. Removal of the head of the malleus will permit exposure of the proximal tympanic segment.

7. May need to sacrifice the chorda tympani nerve with extension of facial recess inferiorly if tumor extends toward the distal aspect of the vertical segment

8. If the tumor cannot be separated from the nerve, sharply transect the nerve, remove the tumor, and evaluate the margins with frozen sections.

9. Repair the nerve with an interposition graft from the greater auricular nerve.

- Position without tension between remaining segments of the facial nerve.
- May use fascia or fibrin glue to minimize mobility

10. Ossicular reconstruction if ossicular chain has been disrupted

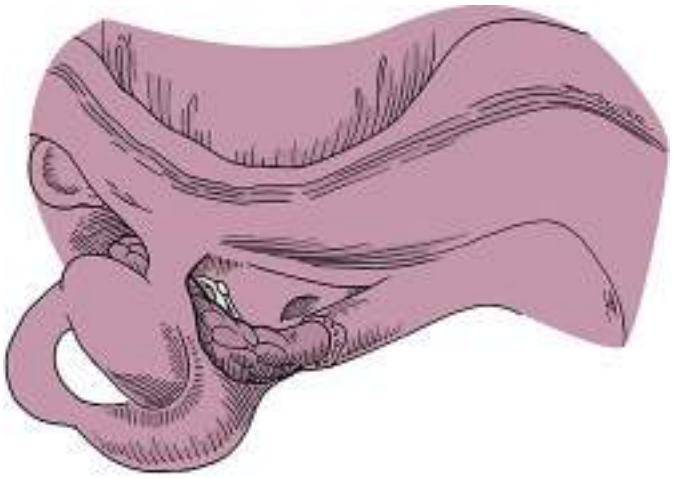

FIG. 139.2 A complete mastoidectomy via a facial recess approach provides exposure of the epitympanum and the vertical segment of the facial nerve. The incus has been removed to reveal the tumor. The head of the malleus is intact.

Middle Fossa Approach

1. Consider the use of intraoperative mannitol, furosemide, and a single dose of corticosteroid.

2. Incision in the pretragal area is extended superiorly with a gentle curve

3. Inferiorly based U-shaped flap of temporalis muscle and fascia is retracted inferiorly

4. A 5 × 5-cm craniotomy should be made 2/3 anterior and 1/3 posterior to the external auditory canal.

   a. Based on root of zygoma as close to floor of middle fossa as possible

   b. Perform with high-speed drill either by outlining entire flap or by exposing four corners (burr holes) and delineate with footplate drill

   c. Bone flap is set aside for later replacement

5. Elevate the dura from the floor of the middle fossa.

   a. Identify the middle meningeal artery (anterior limit).

   b. Elevate posterior to anterior to avoid injury to dehiscent geniculate ganglion.

   c. Identify the greater superficial petrosal nerve and arcuate eminence.

   d. Middle fossa retractor should be placed to support the temporal lobe

6. Identify the superior semicircular canal with a high-speed drill and copious irrigation.

7. Remove bone from the medial aspect of the petrous ridge at the bisection of angle formed by the greater superficial petrosal nerve and superior semicircular canal

   a. IAC is identified in the medial aspect of the meatal plane and traced laterally

   b. Circumference of the porus acusticus is exposed 270 degrees

   c. Dissection proceeds from medial to lateral

   d. Need to narrow exposure laterally to 90 degrees to avoid injury to the cochlea and superior semicircular canal

8. Dura of the IAC is divided along its posterior aspect

9. Tumors that arise eccentrically from the nerve may be excised while

maintaining continuity of the nerve, but if the facial nerve integrity is lost, a graft is required (Figs. 139.3 and 139.4).

10. May use a small piece of temporalis fascia or adipose tissue to fill the defect in the IAC

11. Retractor is removed, and the temporal lobe can re-expand

12. Replace the craniotomy flap and secure with miniplates.

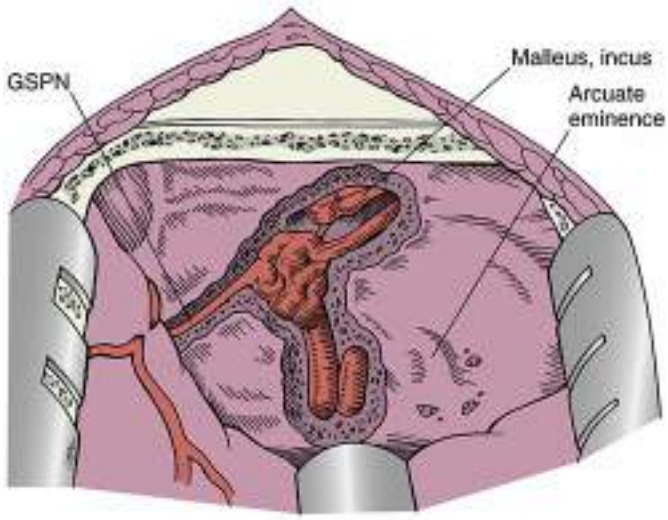

FIG. 139.3 Middle fossa approach to a tumor of the facial nerve located at the geniculate ganglion.

The labyrinthine and proximal horizontal segments are exposed. *GSPN*, Greater superficial petrosal nerve.

Combined Middle Fossa and Transmastoid Approach

1. Enables full dissection of the intratemporal course of the facial nerve

2. Particularly useful for lesions at the geniculate ganglion with extension proximally and distally

3. May permit preservation of inner ear function

4. Uses the same postauricular incision

   a. Superior limb extends beyond the root of the helix to the preauricular area, parallel to the hairline toward the temporal area

b. The incision courses superiorly and curves posteriorly parallel to the superior temporal line (Fig. 139.5).

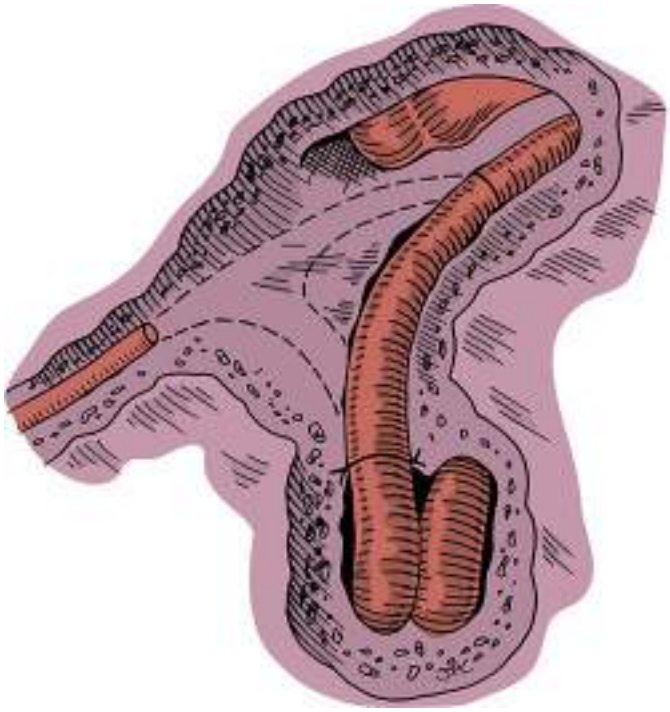

FIG. 139.4 Interposition cable graft repair from the facial nerve in the distal internal auditory canal to the horizontal segment.

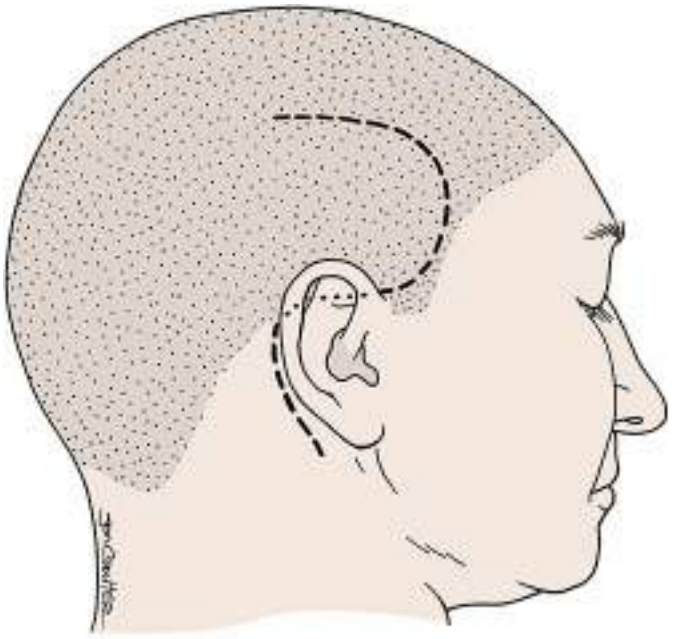

FIG. 139.5 Incision for a combined middle fossa–transmastoid approach.

5. Tegmen tympani is removed to expose the tumor and course of facial nerve that can be repaired with bone taken from the middle fossa craniotomy plate

Translabyrinthine Approach

1. Standard postauricular curvilinear approach 3 to 4 cm posterior to postauricular sulcus

- The superior and inferior limbs are extended to allow anterior retraction of the pinna.

2. Create the initial skin incision superficial to the temporalis fascia and mastoid periosteum.

- Stagger the offset medial incision in the deeper layer anterior to the skin incision to assist with the watertight closure.

3. Perform a complete mastoidectomy (▮ Video 139.1).

- Remove bone 2 cm posterior to the sigmoid sinus to expose the dura of the posterior cranial fossa.

4. Identify the facial nerve in its descending portion and skeletonize it

just proximal to the stylomastoid foramen.

5. Remove the tegmen bone over the middle fossa dura adjacent to the sinodural angle and over the posterior fossa dura.

6. Perform a standard labyrinthectomy.

7. The bone posterior to the IAC is removed.

8. Bone remains at an eggshell thickness over the dura of the IAC until all bony dissection is completed.

9. Bone is removed around the IAC superiorly and inferiorly to provide 270 degrees of exposure.

10. Once the facial nerve is identified, the dura of the posterior fossa and midportion of the IAC are opened sharply.

11. The tumor is removed using microsurgical technique (Fig. 139.6) (Video 139.2).

12. Nerve repair depends on length resected

a. Small—requires primary repair by mobilizing residual nerve segments from the fallopian canal, supporting nerve segments with Gelfoam, and may also re-approximate with one 9-0 or 10-0 nylon suture if possible (Fig. 139.7)

b. Large—requires interposition nerve graft (Fig. 139.8) (Videos 139.3 and 139.4)

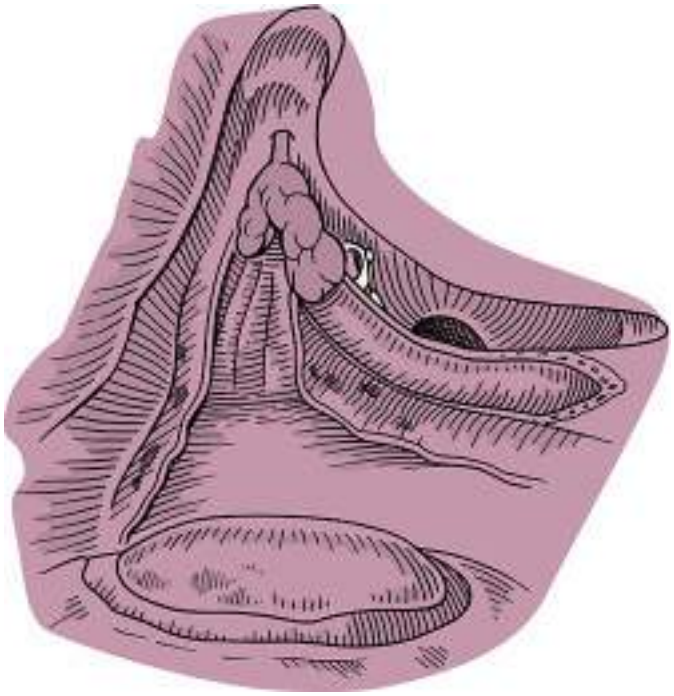

FIG. 139.6 Translabyrinthine approach to a tumor of the facial nerve proximal to the geniculate ganglion. An island of bone remains over the sigmoid sinus. The dura of the internal auditory canal is intact. The tumor extends from the fundus to the second genu.

13. Harvest abdominal adipose tissue.

   a. Use separate instruments and change gloves.

   b. Adipose tissue should soak in bacitracin solution and the wound copiously irrigated with bacitracin solution.

14. Fill the cavity with adipose tissue and provide support to the nerve anastomosis.

Greater Auricular Nerve Graft

1. Supplies sensation to the pinna and preauricular area

- Sacrifice of nerve generally leaves only a small area of anesthesia

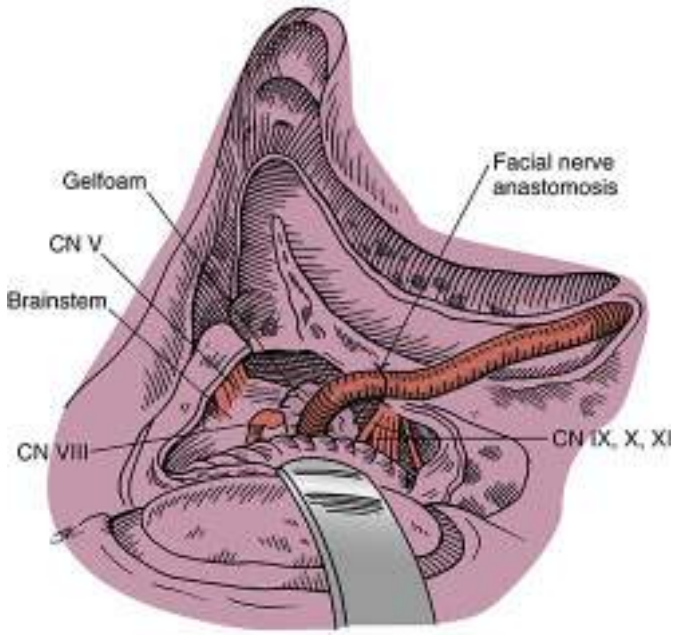

FIG. 139.7 Horizontal and vertical segments of the facial nerve mobilized to permit primary repair of the facial nerve (cranial nerve [CN] VII). The brainstem, trigeminal nerve (CN V), cochleovestibular nerves (CN VIII), and lower cranial nerves (CN IX, X, XI) are demonstrated. Gelfoam supports the proximal nerve for suturing.

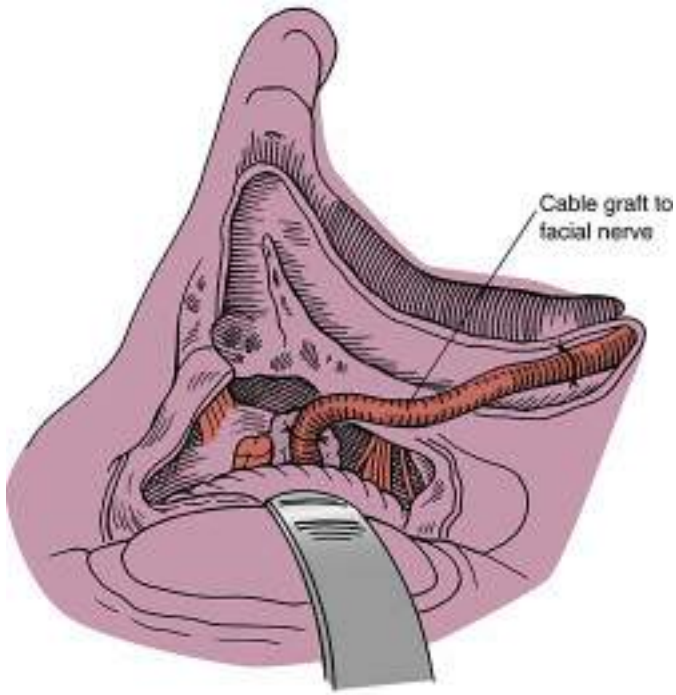

FIG. 139.8 Greater auricular nerve interposition cable graft to the facial nerve from the porus to the distal vertical segment.

2. Anatomy of nerve is relatively constant

3. Two methods to localize (Fig. 139.9)

   a. Divide the sternocleidomastoid (SCM) muscle into thirds and identify at posterior border of SCM between upper and middle thirds.

   b. The nerve is located midway along a line connecting the mastoid tip and the angle of the mandible.

4. Incision in skin crease taken through subcutaneous tissue

- Retrograde dissection along the nerve by retracting the SCM anteriorly permits more proximal harvesting of the nerve from its origin in the cervical plexus.

Common Errors in Technique

1. Essential to weigh the risks and benefits of complete tumor extirpation versus the potential development of facial nerve paralysis

2. Need to ensure that surgical margins at both ends of the resected tumor are clear of microscopic tumor

- Frozen sections should be taken to confirm that the margins are clear of tumor since visual inspection is not sufficient for this purpose.

Postoperative Period

Postoperative Management

1. The patient should be admitted to the intensive care unit for the first day following more extensive surgical procedures.

2. Patients should be placed on strict eye precautions.

- Lubricating ointment, artificial tears, moisture chamber

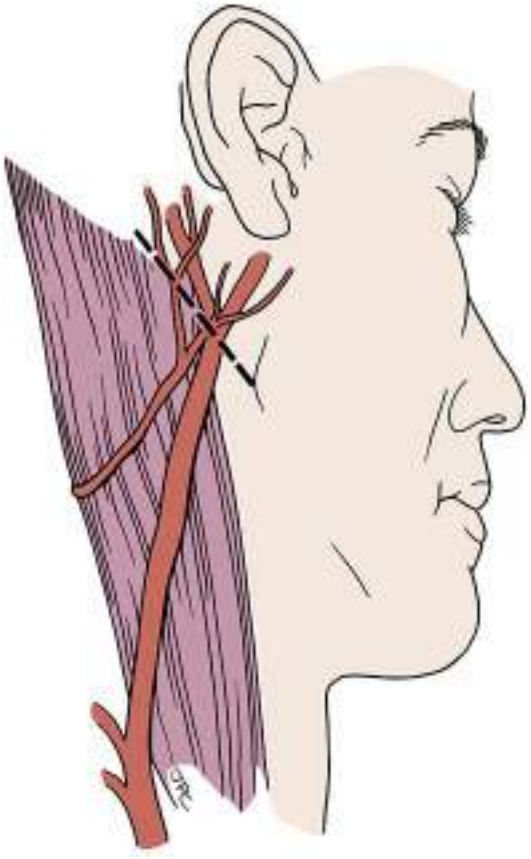

FIG. 139.9 Methods for identifying the greater auricular nerve with pertinent anatomic landmarks. The greater auricular nerve exits posterior to the sternocleidomastoid muscle at the junction of its upper and middle thirds. The greater auricular nerve can also be found midway between the angle of the mandible and the mastoid tip.

3. Neurologic symptoms are closely monitored for the first 24 hours.

4. Compression dressing over the surgical site should remain in place for 3 to 5 days.

5. Consultation for physical therapy should be made, and the use of a walker may be helpful for early rehabilitation should vestibular function be compromised.

6. Sutures or staples should be removed 7 to 10 days after surgery.

Complications

1. Facial nerve paresis or paralysis

a. Frequently present preoperatively but may worsen postoperatively even if facial nerve integrity is maintained

b. Critical attention to protect cornea

- If corneal protection is compromised a gold or platinum weight can be inserted into the upper eyelid.

2. Cerebrospinal fluid leak

a. Look for clear otorrhea, rhinorrhea, or skin fistula

b. Patients should avoid straining or sneezing with closed mouth.

c. If a cerebrospinal fluid (CSF) leak develops, treatment should be started to prevent meningitis.

1) Consider bed rest with lumbar drain

2) Re-explore wound with possible obliteration of the Eustachian tube

3. Hearing loss and loss of balance function

a. Surgery may disrupt cochlear nerve function or violate the cochlea, particularly with surgical procedures that involve the IAC (excludes translabyrinthine procedures).

b. Essential to be aware that these tumors can erode into the adjacent otic capsule to produce a fistula to the cochlea or the labyrinth

- Fistulas can be asymptomatic and may not be evident on preoperative imaging.

c. Patients should undergo a formal postoperative audiogram.

4. Vascular injury

a. Intraoperative venous bleeding generally responds to local compression.

b. Injury of the carotid is not usually an issue unless eroded by tumor.

c. Posterior fossa approaches should include identification and protection of the anterior inferior cerebellar artery.

Alternative Management Plan

Based on aspects of tumor size, location, and associated signs and symptoms, there are other options for facial nerve tumors:

1. Watchful waiting with serial clinical examinations and imaging

2. SRS

If facial nerve function is insufficient after surgery despite apparent maintenance of facial nerve continuity or seemingly appropriate facial nerve repair, other facial nerve re-animation procedures should be utilized to enhance the functional and cosmetic result.

Discussion

Evidence-Based Medicine Question

Can facial nerve tumors be effectively treated with SRS?

There are a variety of techniques of SRS including frame-based linear accelerator, gamma knife, or mobile linear accelerator. Potential advantages of SRS treatment include avoidance of surgery, potential arrest of tumor growth, and possible preservation of facial nerve function. SRS aims to minimize the risks of long-term complications associated with conventional external beam radiation therapy such as osteonecrosis, skin breakdown, potential development of a malignant tumor, and acute cranial nerve dysfunction. SRS has been most commonly described for treatment of tumors that are presumed to be facial nerve schwannoma. Most reported cases of SRS treatment of facial nerve schwannomas indicate no worsening in facial nerve function after treatment. Recent studies have indicated that these approaches afford excellent tumor control and a low rate of new cranial nerve deficits.[5] However, studies with longer term follow-up are required to provide a true comparison between treatment modalities.

Editorial Comment

The management of facial nerve schwannoma has become more conservative over time, and the ideal treatment algorithm continues to develop. The underlying challenge is trying to predict the natural history

and progression of a lesion where a presumptive histopathologic diagnosis is based on the combination of the patient's signs and symptoms and the interpretation of radiologic imaging. The skull base team, consisting of neurotology, neurosurgery, and head and neck surgeons, collaborates in the decision regarding recommended intervention and execution. This undertaking requires the surgical skills needed in optimizing the surgical approach, decompressing or resecting the tumor, and reconstructing with the goal of preserving or restoring facial nerve function while achieving a watertight closure and minimizing postoperative dysfunction. The role of SRS is in evolution for primary management and adjuvant care.

Review Questions

1. Which approach provides access to the full length of the intratemporal facial nerve?

   a. Transcanal

   b. Transmastoid

   c. Middle fossa

   d. **Translabyrinthine**

   e. Retrosigmoid

2. What is the ideal manner for surgical repair of the facial nerve?

   a. Removal of excess facial nerve to keep anastomosis taut

   b. **Approximation of nerve ends without tension**

   c. Application of tissue glue

   d. Imbrication of epineurium

   e. Utilization of nerve graft

3. Preoperative CT scan indicates a tumor centered on the geniculate ganglion with evidence of bony remodeling and intratumoral bone spicules. This finding is most consistent with which tumor type?

a. Schwannoma

b. **Hemangioma**

c. Paraganglioma

d. Granular cell tumor

e. Metastatic thyroid carcinoma

4. After surgical re-anastomosis of the facial nerve, what is the ultimate expected functional result of facial nerve function?

a. I–II

b. II–III

c. **III–IV**

d. IV–V

e. V–VI

Acoustic Neuroma

Moises A. Arriaga, and Joshua M. Sappington

Introduction

Acoustic neuroma (AN) and vestibular schwannoma (VS) are the most common lesions arising within the posterior cranial fossa. They are well-circumscribed, benign, encapsulated tumors that arise from Schwann cells of the vestibular nerve and usually originate in the internal auditory canal (IAC). Typically the tumors are slow growing (1 to 2 mm per year); some do not grow at all after discovery and others expand to life-threatening dimensions.

The three modern strategies for managing AN are **observation** with serial imaging, **stereotactic radiation (**SR**)**, and **surgical removal.** Surgical removal is the only curative strategy and will be the focus of this chapter.

Key Operative Learning Points

1. AN management is based on tumor size, location, the patient's hearing and health status, and patient/surgeon preference.

2. The translabyrinthine (TL) approach allows for a direct route to the cerebellopontine angle (CPA) and for identification of the facial nerve within its vertical segment as well as its course through the IAC.

3. The retrosigmoid (RS) and middle fossa (MF) are the two approaches that allow removal of the tumor and potential preservation of hearing for appropriately selected patients. With both approaches, tumor resection and facial nerve function are of primary importance, with hearing preservation being a secondary though very important objective.

Preoperative Period

History

1. History of present illness
   a. Gradual hearing loss
   b. Five percent of AN patients present with sudden hearing loss.
   c. Asymmetric hearing loss should be assumed to be an AN until proven otherwise.
   d. Vestibular symptoms are usually motion intolerance rather than acute vertigo.
   e. Facial nerve dysfunction is rarely a presenting symptom in AN.
   f. Patients with a large AN may have cranial nerve dysfunction leading to hypoesthesia (CN V), diplopia (VI), dysphagia (CN IX, X), hoarseness, and aspiration. Such tumors can cause increased intracranial pressure leading to headaches and papilledema.
2. Past medical history
   a. Previous schwannoma or meningioma: Neurofibromatosis-2 (NF-2) is an autosomal dominant but a previous AN on the contralateral side or meningioma or a family history of NF-2 requires thorough evaluation. NF-2 management is different from sporadic AN management, which is the subject of this chapter.
   b. Medical illness
   c. Surgery
   d. Family history
   e. Medications, vitamins, and supplements

Physical Examination

In addition to a complete head and neck examination,

1. Microscopic otoscopy: A tympanic membrane perforation raises the risk of postoperative cerebrospinal fluid (CSF) otorrhea and the

possibility of an inflamed mastoid, which would affect the selection of a transtemporal approach.

2. Cranial nerve: A systematic examination of all nerves (especially VII)

3. Nystagmus: Bruns' nystagmus in large tumors with brainstem compression reveals coarse, slow-beating nystagmus on ipsilateral gaze (brainstem induced) and fine beating nystagmus on contralateral gaze (vestibular induced).

4. Vestibular examination: Gait testing, Fukuda stepping test and head thrust tests identify vestibulopathy.

Relevant Testing

1. Audiogram: Air, bone, and speech audiometry objectively document hearing levels. Fifty decibels Speech Response Threshold (SRT) (or Pure Tone Average (PTA)) and 50% speech discrimination are the lower limit in considering hearing preservation surgery.

2. Vestibular: AN patients undergo a complete vestibular testing battery that includes ROTO (rotational chair), VEMP (vestibular evoked myogenic potentials), and VNG (videonystagmography). Documentation of pretreatment vestibular function is a baseline for future comparison and patient education about postoperative symptoms and a guide for perioperative vestibular physical therapy.

3. Facial: A preoperative electroneuronography (ENoG) abnormality identifies preoperative facial nerve compromise.

4. ABR (audiometric brainstem response) is used in large lesions as a baseline for intraoperative contralateral brainstem monitoring during surgery and to assess the preoperative status of the cochlear nerve if hearing preservation surgery is being considered.

Imaging

1. MRI with gadolinium of the IAC is the gold standard for diagnosing AN. The sensitivity approaches 100%; however, false positive results are possible.[1]

2. T2 sequences can identify the nerve of origin of the tumor and whether there is a cap of CSF at the fundus that may facilitate preservation of hearing in an MF or RS approach.

3. CT with contrast is not as sensitive as MRI. Currently MRI with contrast can identify lesions as small as 1 to 2 mm.

4. CT combined with ABR: A recent meta-analysis found that pooled sensitivity for ABR was 82.0% for all tumors, and for tumors greater than 1 cm this rose to 95.6%.[2] For patients that cannot complete MRI, ABR with CT may offer an alternative means of diagnosis.

5. CT without contrast is used for surgical planning in all three surgical approaches. For TL surgery, the mastoid pneumatization, distance between the sigmoid and the IAC, and the height of the jugular bulb relative to the IAC are the important features. For the MF approach, the relationship between the arcuate eminence and superior canal (SSC) and the pneumatization over the IAC are important. In RS surgery, the pneumatization of the petrous bone, position of the sigmoid sinus, jugular bulb, and vertical height of the IAC are important features.

Indications

1. Treatment strategy: Patients with AN are offered three management options: observation, SR, and microsurgical resection. The surgeon individualizes recommendations in every case.

2. Observation ("watch and scan") is increasingly used as initial tumor management for AN. A central tenant of skull base surgery is to avoid any additional morbidity with treatment, which is greater than what would be expected with the natural course of the disease.[3] The Denmark experience reveals that within the first 5 years, 17% of intrameatal tumors and 28.9% of extrameatal tumors grew, while 45% lost class A hearing after 5 years regardless of tumor growth.[4] The critical issue with observation is that it this strategy requires close follow-up, as we are not currently able to predict which tumors will grow.

3. SR for AN includes stereotactic radiosurgery, which is a one-time treatment, and hypofractionated SR (radiotherapy) in which the treatment is divided into three to five doses. Based on Lars Leksell's innovations, the goal of SR is prevention of tumor growth to preserve

neurologic function. The initial high-dose treatment plans (16 Gy marginal) have been replaced with lower dose 12 Gy single dose or 18 Gy fractionated with similar tumor control rates as previous regimens but with less risk of cranial neuropathy or brainstem complications.[5,6] Since no pathologic specimen is obtained, SR risks radiating a malignant lesion with inadequate dosage; close follow-up is essential. Special considerations in radiation include the following:

a. Control rates: Control in growing tumors is approximately 80% to 85% versus 90% to 95% when all lesions are included.

b. Radiation-induced malignancy: There have been eight cases of radiation-induced malignancy confirmed with microsurgical resection following stereotactic radiotherapy documented in the literature.[7]

c. Hearing preservation: Initial hearing preservation deteriorates over time—only 20% retain useful hearing after five years in the Mayo series.[8]

d. Type of radiation: Gamma Knife versus CyberKnife versus other LINAC systems:

In our practice, only tumors with documented growth are radiated, and younger patients are typically not radiated. We use CyberKnife or Gamma Knife Icon because it is a frameless stereotactic system that permits fractionation with high precision.

4. Microsurgical resection: The only curative treatment for AN is microsurgical resection. Patients who undergo gross total resection (GRT) benefit from excellent tumor control, management of mass effect, pathologic diagnosis of benign schwannoma, and less intense imaging regiment postoperatively. The best results are obtained at skull base centers that treat a high volume of AN.[9] Tumors may be managed by one of three lateral skull base approaches: TL, MF, and RS craniotomy. Age, hearing status, tumor size, and location all play a role in determining the approach for each patient.

a. TL: Popularized by the pioneering work of Drs. William House and William Hitselberger, TL is the prototypical neurotologic, collaborative skull base surgical approach.

1) TL sacrifices hearing as a part of the approach.

2) TL is recommended for patients without serviceable hearing and in cases where hearing preservation is unlikely.

3) The primary advantages of TL are little to no brain retraction, reliable identification of the facial nerve at the meatal foramen, and no intradural drilling, thus reducing the risk of postoperative headache.

b. RS

1) Hearing preservation: The modern RS is a versatile approach allowing for a wide view of the posterior fossa with hearing preservation for tumors with limited lateral extension into the IAC. MRI T2 sequence imaging can determine the extent of tumor penetration into the IAC.

2) Hearing preservation with posterior fossa extension: One advantage of RS over MF is that RS allows for hearing preservation in instances where tumors extend more than 0.5 cm into the CPA.

3) When hearing preservation is not an option, the decision between RS and TL for medium and larger tumors is the surgeon's preference. The authors usually select TL due to less brain manipulation than with the RS approach.

c. MF approach:

1) Hearing preservation: MF is an extradural subtemporal technique to access the IAC and is used for hearing preservation with small laterally based lesions.

2) Limitation: The major limitations to MF are that it provides poor access to the posterior fossa and requires temporal lobe retraction. The addition of temporal lobe retraction adds a minimal risk of seizure, aphasia, and stroke specifically to this approach, and caution should be used in elderly patients due to age-related changes in the dura. Depending on the nerve of origin of the tumor, the risk of facial paresis may be slightly greater in the short term with the MF when compared to other approaches; however, by 1 year the difference is not significant.[10]

5. Treatment selection

a. Patient education: Detailed information is presented regarding all treatment strategies.

b. Risks:

1) Observation: Patients are educated that their tumor may grow, and there is no good means of determining which tumors grow prior to observation, that hearing may deteriorate, and that they may still require either microsurgical resection or stereotactic radiotherapy.

2) Surgery: Specific risks include bleeding, infection, facial paralysis, hearing loss, balance disturbance, CSF leak, stroke, prolonged headache, need for tracheostomy, gastrostomy, and locked-in syndrome or death.

3) Informational materials: Patients are provided with a booklet, recommendations for web-based link(s), and a book chapter on CPA tumor management as reliable resources for them to refer to after their appointment.

4) Radiation: Patients are advised that the risks are similar to surgery but may take years to manifest. Risks specific to radiation include radiation-induced hydrocephalus, hearing loss, facial nerve dysfunction, and the risk of radiation-induced malignancy.

Contraindications

1. Contraindications to microsurgery are mainly related to medical issues. If a patient cannot tolerate general anesthesia, then the tumor is observed; and if it demonstrates growth, stereotactic radiotherapy is offered with possible CSF diversion for hydrocephalus.

2. For patients with tumors that reach or compress the brainstem, microsurgical resection is offered in place of stereotactic radiotherapy or observation. Tumor swelling is common for 18 months following SR. Accordingly any brainstem or cerebellar compression identified prior to treatment contraindicates radiation.

Preoperative Preparation

1. See "Relevant Test" section for audiologic and imaging requirements.

2. Cessation of anticoagulants

3. Preoperative consultation for medical clearance

Operative Period

Anesthesia

1. General

Positioning

1. TL: Supine with the head in a foam donut

2. MF: Supine in neurosurgical pins. The flexible MF retractor could damage the brainstem if it is affixed to the bed and the patient were to move from lightening of anesthesia. By attaching the retractor to head pins, the retractor and the patient's head move as a unit, and inadvertent patient movement does not pose a danger related to retractor damage.

3. RS: Both lateral recumbent position and, more recently, prone positioning in neurosurgical head pins are used, depending on surgeon preference.

Preoperative Medication

1. Antibiotics:

   a. Systemic: A first-generation cephalosporin intravenously prior to incision (unless the patient is allergic to penicillin)

   b. Drill irrigation fluid with antibiotics (cefazolin in patients who are not allergic—otherwise plain saline)

   c. Wound irrigation fluid with antibiotics

2. Steroids: Dexamethasone 10 mg prior to incision

3. Antivirals: Preoperative famciclovir 500 mg three times daily for 3 days preoperative and 4 days postoperatively to minimize the chance of

viral reactivation and delayed facial palsy from Bell's palsy (see Evidence-Based Medicine section)

Monitoring

1. Facial nerve monitoring
2. For hearing preservation: Ipsilateral ABR
3. For large AN: Contralateral ABR and CN X via EMG endotracheal tube

Instruments and Equipment to Have Available

1. Middle ear and skull base microsurgical instrument sets
2. Operative microscope with capability for face-to-face orientation for four-handed tumor resection technique
3. High-speed otologic drill
4. MF retractor for procedures using this approach

Key Surgical Landmarks

1. Facial nerve: In all approaches, the facial nerve is an important landmark that needs to be preserved in its intratemporal and intracranial potions.

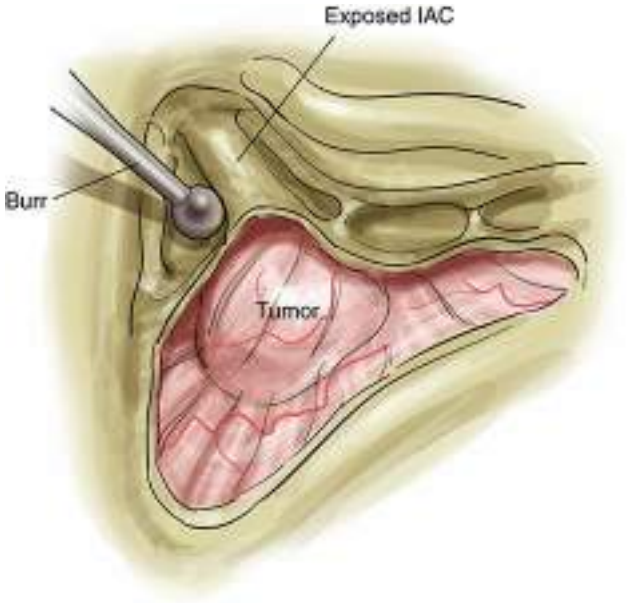

FIG. 140.1 The IAC is skeletonized and bone is removed to expose 180 to 270 degrees of the canal. The facial nerve is identified as it exits the IAC at Bill's bar. *IAC,* Internal auditory canal. With permission from Brackmann D, Shelton C, Arriaga MAA: Otologic Surgery, 4th ed. Philadelphia, PA: Elsevier; 2015 [Fig. 49.12 in source].

2. Labyrinth: The lateral canal for TL and SSC for MF approach are important for orientation.

3. Orientation of cranial nerves within the IAC

Prerequisite Skills

1. Knowledge of the temporal bone

2. Knowledge of posterior fossa anatomy

3. Microsurgical technique

4. Experience in interpreting auditory feedback from the facial nerve monitoring system

Operative Risks

1. Bleeding: Intracranial bleeding during or after surgery

2. Facial nerve injury: Even with an intact nerve, an immediate or delayed facial nerve paralysis is possible.

3. CSF leak: The use of hydroxyapatite cement during closure of TL and RS approaches has helped decrease postoperative CSF leak rates dramatically. Inadequate sealing of opened petrous air cells around the IAC may also result in CSF rhinorrhea.

4. Stroke

5. Infection: Meningitis and wound infection

Surgical Technique

Translabyrinthine Approach (Figs. 140.1 to 140.3)

1. C-shaped postauricular incision with staggered periosteal incisions permit elevation of soft tissue to expose temporal bone.

2. A complete mastoidectomy includes uncovering the MF and posterior fossa dura and the sigmoid sinus.

3. Labyrinthectomy

4. Identification of the facial nerve in the mastoid segment

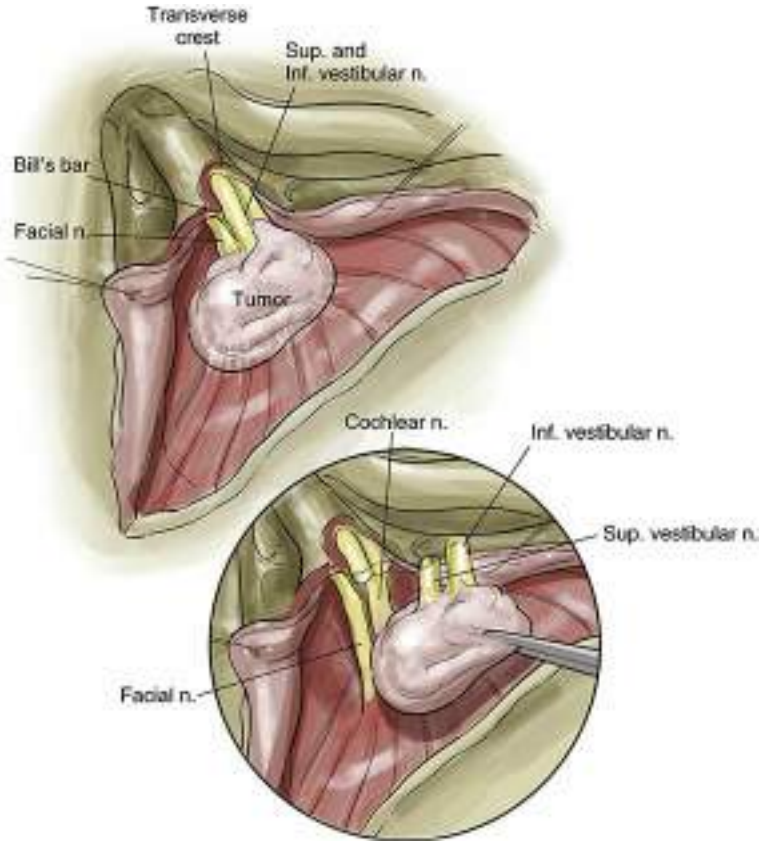

FIG. 140.2 The vestibular nerve and tumor are separated from the facial nerve in the internal auditory canal and dissected to the porous acousticus and cerebellopontine angle. *Inf.,* Inferior; *n.,* nerve; *Sup.,* superior. With permission from Brackmann D, Shelton C, Arriaga MAA: Otologic Surgery, 4th ed. Philadelphia, PA: Elsevier; 2015 [Fig. 49.14 in source].

FIG. 140.3 With the two-surgeon, four-hands technique, the surgeons can sit or stand opposite each other and assist each other in the same manner as open surgery with both sets of instruments in the surgical field by retracting, suctioning, stimulating, or exposing tissue and advancing the operation as a team.

5. An inferior trough is drilled between the IAC and the jugular bulb, with the cochlear aqueduct as the anterior-inferior limit.

6. A superior trough is created between the MF dura and the IAC; 270-degree exposure of the IAC dura is adequate exposure.

7. At the IAC fundus, the transverse crest separates the inferior vestibular nerve (IVN) and superior vestibular nerve (SVN).

8. Obliteration of the Eustachian tube includes removing the incus, transecting the tensor tendon and packing the Eustachian tube with alternating pieces of temporalis muscle and Fibrillar Surgicel.

9. IAC facial nerve identification requires transecting the SVN at the vertical crest (Bill's bar). Dissection of the tumor along the facial nerve continues medially until the plane of dissection is obscured at the porous acousticus. The two-surgeon, four-handed technique permits rapid debulking of a large AN in the CPA.

10. The final remnants of the tumor and capsule are removed using continuous facial nerve monitoring as the tumor capsule is removed. When gross total removal is not possible, some tumor may be left on the facial nerve for its preservation. Such "near-total" removal results in a low risk of recurrence; however, continuing prospective studies of this strategy are under way.

11. Adipose tissue harvested from the left lower quadrant or acellular dermal substitute is placed in the dural defect. Hydroxyapatite cement is then used to reconstruct the craniotomy defect, forming a watertight reconstruction.

12. The musculoperiosteal flaps are closed and the skin reapproximated with 2-0 Vicryl suture. The skin is closed with a running locked 3-0 Vicryl rapide suture, which provides a second discrete layer of closure diminishing a potential CSF leak. Sterile Steri-Strips are applied and a

plastic cup fastened with elastic straps is placed.

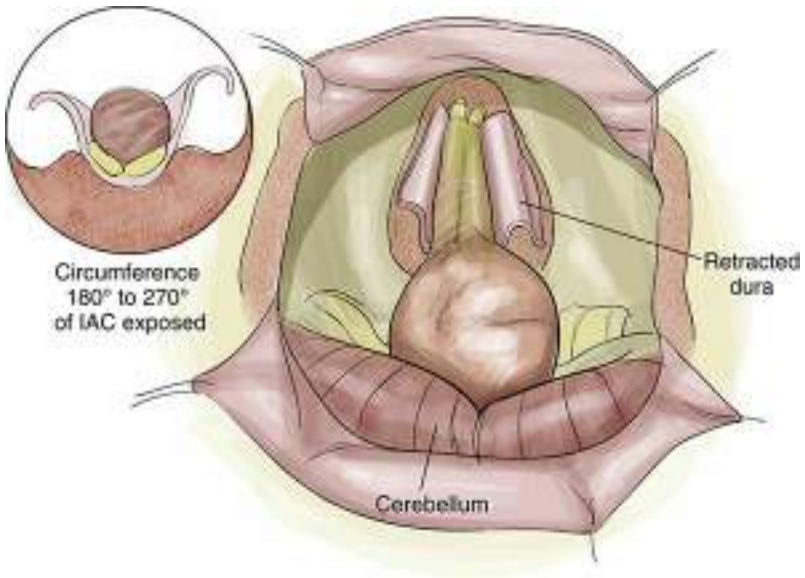

FIG. 140.4 After incising the overlying dura, the internal auditory canal is exposed approximately 180 degrees by drilling troughs on either side. *IAC,* Internal auditory canal. With permission from Brackmann D, Shelton C, Arriaga MAA: Otologic Surgery, 4th ed. Philadelphia, PA: Elsevier; 2015 [Fig. 50.6 in source].

Retrosigmoid Approach (Fig. 140.4)

1. An incision is made in the retromastoid area through skin to nuchal musculature. Musculoperiosteal flaps are raised exposing RS bone.

2. An RS craniotomy is performed using the sigmoid and transverse sinus as landmarks. The craniotomy is carried anteriorly to the sigmoid and superiorly to the transverse sinuses.

3. Mastoid air cells are occluded with bone wax.

4. A dural incision exposes the cerebellum.

5. CSF release: Gently supporting the cerebellum with a Telfa strip and suction tip allows opening the cisterna magna. Patiently releasing CSF avoids injury to the cerebellum.

6. With the cerebellum relaxed and tumor exposed, the IAC can be drilled. If the CPA component of the tumor inhibits drilling of the IAC,

tumor debulking exposes the petrous bone for IAC drilling.

7. If the AN extends into the IAC, the dura is reflected inferiorly as a semicircular flap. The IAC is drilled 270 degrees in circumference. In hearing preservation cases, the medial two-thirds of the IAC can be exposed. Further lateral exposure risks entrance into the inner ear.

8. Tumor resection techniques are the same as in TL.

9. Air cells of the IAC are occluded with bone wax and a small muscle plug is placed in the IAC.

10. The subarachnoid space is filled with saline, and the dura is closed primarily or with a graft.

11. Hydroxyapatite cement is used to reconstruct the craniotomy site.

12. Wound closure is the same as TL.

Middle Fossa Approach (Fig. 140.5)

1. A preauricular vertical incision is made through skin to the temporalis muscle. The temporalis muscle is then divided, exposing the lateral aspect of the skull and squamous portion of the temporal bone.

2. Care is taken to identify the level of the zygomatic root as a landmark for the level of the floor of the MF.

3. A 5 cm by 5 cm craniotomy bone flap is centered on the root of the zygoma.

4. The craniotomy is refined so that it is flush with the level of the floor of the MF. The dura is then raised in a posterior-to-anterior fashion off of the floor of the MF to protect the geniculate ganglion and facial nerve, which are dehiscent in up to 15% of cases.

5. The dura is elevated anteriorly up to the foramen spinosum (middle meningeal artery) and medially to the superior petrosal sinus and the crest of the petrous bone. A MF retractor is used. While many types are available, we use two retractor spatulas supporting the dura attached to adjustable “goose-neck” arms, which are connected to the Mayfield head frame.

6. Antidromic greater superficial petrosal nerve (GSPN) stimulation

identifies the geniculate ganglion.

7. The SSC is identified directly, or if necessary, the mastoid air cells are opened from the tegmen to reveal it. The SSC is "blue lined" and can be occluded with bone wax, SSC occlusion widens the exposure by using the hearing-preservation labyrinthine occlusion techniques from vestibular surgery.

8. Drilling proceeds from medial to lateral to expose the IAC. Exposure is limited anteriorly by the close relationship of the cochlea to the lateral third of the canal anteriorly.

9. The dura of the IAC is opened, and the intracanalicular tumor is removed by first separating the anteriorly placed facial nerve from the tumor. To maximize hearing preservation, a medial to lateral dissection helps protect the cochlear nerve fibers at the habenula perforata. The bony IAC defect is covered with adipose tissue or acellular dermal substitute.

10. Temporal lobe retractors are removed, and the bone flap is replaced with plates and screws.

11. The temporalis fascia is closed with Vicryl.

12. The skin closure is the same as TL and RS.

Common Errors in Technique

1. Inadequate bone removal in TL surgery

2. Poor placement of craniotomy in MF and RS will create difficulties with medial exposure and tumor resection.

3. Attempts at facial nerve stimulation and dissection are not advisable when the nerve is firing and indicating irritation. It is better to stop and wait to proceed, as nerve changes cannot be monitored while it is firing.

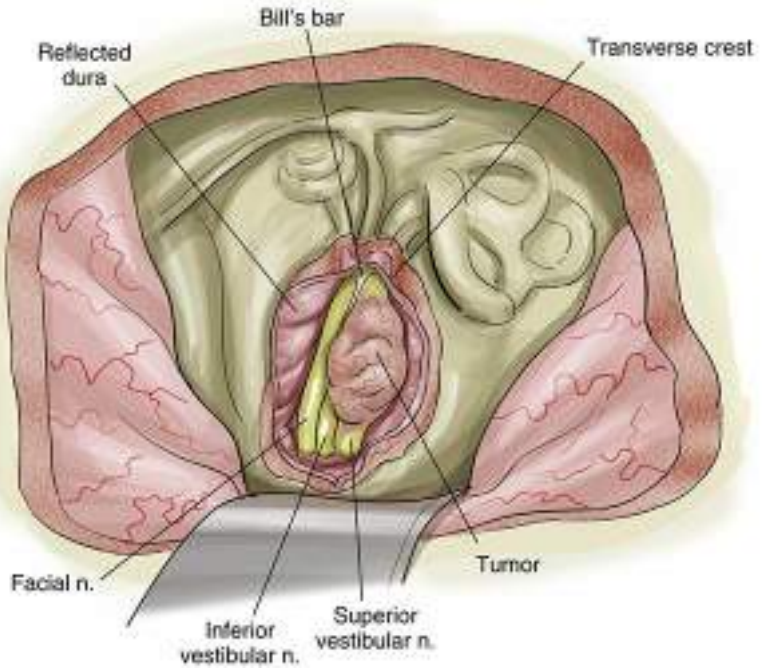

FIG. 140.5 An intracanalicular acoustic tumor is dissected from the facial and cochlear nerves. With permission from Brackmann D, Shelton C, Arriaga MAA: Otologic Surgery, 4th ed. Philadelphia, PA: Elsevier; 2015 [Fig. 48.8 in source].

Postoperative Period

Postoperative Management

1. ICU for the first 1 to 2 days

2. Head CT and temporal bone CT are obtained on the first postoperative morning. If CT does not demonstrate intracranial bleeding, SQ heparin is used for venous thrombosis prophylaxis.

3. Complete blood count (CBC) and metabolic bloodwork

4. Patients are encouraged to ambulate. Early postoperative vestibular physical therapy has lowered our average postoperative stay for AN to 3.5 days by hastening vestibular compensation.

Complications

1. Facial paralysis:

   a. Intact nerve: If the nerve stimulates with low current at the end of the case, a favorable outcome is likely. If the patient has a delayed facial nerve paralysis, the prognosis also has a favorable outcome.

   b. Incomplete eye closure: Use lubricating drops, lubricating ointment at night, and a moisture chamber to protect the eye. In cases with poor intraoperative facial stimulation or paralysis longer than a month, insertion of a platinum eyelid weight protects the eye until facial function recovers.

   c. Nerve transection: Immediate direct repair is best; when necessary, nerve substitution (V to VII or XII to VII) provides facial function.

2. CSF leak:

   a. Incision: Additional sutures with a tight mastoid dressing usually resolve the drainage. If leakage persists, a lumbar drain is placed.

   b. Rhinorrhea: A lumbar drain is the initial treatment. If a lumbar drain fails to stop the CSF leak, then the leak is repaired surgically. The approach to close the CSF leak is dependent on the approach and patient hearing status. If the approach was a MF or RS, then the wound is opened, explored, and any open air cells are occluded. If the patient did not retain hearing, then the eustachian tube can be obliterated with muscle and Surgicel or hydroxyapatite cement. Some surgeons report transection and closure of the ear canal and mastoid obliteration.

   c. Recalcitrant leaks: Allow for closure of the ear canal with removal of all squamous epithelium of the ear canal and tympanic membrane and obliteration of the Eustachian tube, middle ear, and mastoid.

3. Hemorrhage: Intracranial bleeding is managed based upon the location and size of the bleeding.

4. Hearing loss: Despite attempts to preserve hearing and even with good ABR waveforms at the end of the case, hearing can be lost. Numerous techniques for hearing rehabilitation for unilateral sensorineural loss include CROS hearing aids and implantable bone vibration devices (e.g., BAHA, PONTO, and Sophono).

5. Headache: Moderate postoperative pain can be controlled with

temporary analgesics. To limit headaches, special attention is placed on limiting intradural spread of bone dust or avoiding direct adhesion of muscle to dura with cranioplasty techniques. While prolonged headache with TL and MF is unusual, RS patients can suffer from severe discomfort, requiring long-term use of narcotics.

Alternative Management

For every patient with an AN observation, stereotactic radiotherapy and microsurgery are the available options of management.

Discussion

Evidence-Based Medicine Questions

Which is preferred—complete resection versus subtotal or near-total resection?

If small remnants of the tumor do not cause clinical problems for operated patients, then leaving the tumor on critical structures may limit surgical morbidity. While preliminary indications are encouraging, a prospective longitudinal trial is under way to understand the long-term implications of this strategy.

Can treatments for viral reactivation prevent delayed facial weakness after acoustic tumor surgery?

A provocative retrospective report from the House Ear Clinic suggests that pretreatment with steroids and antivirals (similar to protocols for Bell's palsy) are effective at preventing delayed paralysis.

What are the trends in AN management?

A recent retrospective review of the surveillance, epidemiology, and end results program (SEER) database reviewed the management of 8330 patients from 2004 to 2011. The review found that approximately 48% of patients underwent microsurgical resection, 24% radiation alone, and 29% observation. Interestingly, within the cohort that had surgery, 18% underwent subtotal resection, and of that subcohort, 13.4% received postoperative radiation therapy. Multivariable regression demonstrated

that younger patients and patients with larger tumors underwent surgery. Overall rates of surgery decreased, observation increased, and radiation stayed constant.[3]

The senior author's (Arriaga's) experience mirrors the SEER database trends. Between 1991 and 2015, in a series of 1709 AN, 50% were treated with microsurgery. In our series, the specific management strategy was observation 47%, TL 32%, RS 7%, MF 11%, and SR 3%.

Editorial Comment

The authors have had early experience with using a prone position for the RS approach. They anticipate sharing this experience in the pending literature. The lateral decubitus or park bench position with Mayfield head pins is currently the more common position.

The preoperative battery of auditory, vestibular, and facial nerve testing can provide information regarding the functional status of both the ipsilateral and contralateral seventh and eighth nerves. This can help guide the process of planning preoperative counseling and intervention. It could be predictive of comprised hearing and facial nerve outcomes. Vestibular physical therapy can be initiated prior to surgery to facilitate postoperative rehabilitation. Each surgical team should decide the degree of testing they think is warranted in managing their patients undergoing surgery or even radiation therapy.

Barry Hirsch

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. A patient presents with a 2.8-cm CPA lesion with less than 50% SDS and greater than 50 dB SRT. Which of the following is the worst approach?

   a. **Middle fossa**

   b. Retrosigmoid

   c. Transcochlear

d. Translabyrinthine

2. A 24-year-old patient presents with a 2.5-cm CPA lesion that enhances on T1 with gadolinium. The MR demonstrates considerable brainstem compression. What is the management option for the patient?

   a. **Microsurgical resection**

   b. Observation and follow with repeat imaging

   c. Stereotactic radiotherapy

   d. Discharge from clinic

3. A 65-year-old man presents with a complaint of hearing loss. An audiogram demonstrates asymmetric sensorineural hearing loss and poor speech discrimination on the affected side. He has no other complaints. What is the next step in his evaluation?

   a. CT head

   b. CT temporal bone

   c. **MR IAC with and without contrast**

   d. CT temporal bone with contrast

4. The previous patient presents as described in question 3 but recently had a pacemaker placed. What is the best next step?

   a. CT head with contrast and obtain an ABR

   b. MR IAC with and without contrast

   c. **CT temporal bone with contrast and obtain an ABR**

   d. CT temporal bone with contrast

5. A 55-year-old female presents with a 1.9-cm IAC lesion that enhances with gadolinium on T1 imaging. The tumor is confined primarily to the CPA with minimal if any IAC extension. Her audiogram demonstrates an SRT of 25 dB and SDS of 83%. What is the best surgical approach if she wishes to preserve hearing?

   a. **Retrosigmoid**

   b. Transcochlear

c. Translabyrinthine

d. Middle fossa

Resection of the Temporal Bone

Stephanie Moody Antonio

Introduction

Resection of the temporal bone may be indicated as a component of management for advanced cancers of the parotid gland, peri-auricular skin, and neck, as well as primary lesions of the external auditory canal (EAC), middle ear, and mastoid. The anatomy of the temporal bone is complex with implications for the spread of cancer from one anatomical region through pathways that expand the need for more encompassing extirpative surgery. Partial or complete resection of the temporal bone introduces cosmetic and functional consequences that must be considered and weighed against the risks of leaving residual cancer, which is the primary risk factor for recurrence and subsequent mortality. Although radiotherapy plays an important role in the management of carcinoma in the temporal bone region, it has significant limitations; therefore, only surgical treatment is curative. Complete resection with wide margins is the only viable option; therefore, it is important to have a thorough knowledge of the anatomy of the entire region and an excellent surgical technique.

Key Operative Learning Points

1. Primary malignancy of the temporal bone is rare, but resection of the temporal bone also may be required for peri-auricular skin cancer, parotid, metastatic disease, or other soft tissue cancers with secondary spread to the temporal bone. An appropriate margin may require resection of adjacent functional structures, such as the bony ear canal, tympanic membrane, facial nerve, or dura.

2. The diagnosis of cancer of the temporal bone should be considered for a patient with long-standing otorrhea, otalgia, facial nerve paralysis, or a mass or ulcer of the EAC.

3. The modified Pittsburgh staging system for primary lesions of the temporal bone is predictive of the outcome.

4. Partial resection and mastoidectomy for biopsy should be avoided.

5. The primary goal of surgery is complete resection with clear margins, which is the best predictor of a good outcome.

Preoperative Period

History

- Squamous cell carcinoma of the EAC has a reported incidence of approximately 1 per 1 million per year. Other pathologies may involve the temporal bone, including basal cell carcinoma, adenocarcinoma, and adenocystic carcinoma.
- Primary malignancies of the temporal bone may also arise in the EAC, middle ear, mastoid and, rarely, in the jugular foramen and petrous apex.
- Secondary tumors may involve the temporal bone as a result of spread from adjacent structures, such as the concha, pinna, parotid gland, and dura.
- Metastasis to the temporal bone from distant sites can also occur, often at the petrous apex.
- Carcinoma of the ear canal may be difficult to distinguish from chronic otitis externa, malignant otitis externa, cholesteatoma of the ear canal, temporal bone osteonecrosis, and otitis media.
- Symptoms include:
  - Persistent, deep-seated, unrelenting pain
  - Bloody otorrhea
  - Hearing loss
  - Weakness of the facial nerve
  - Deficits of other cranial nerves
  - Diffuse edema or stenosis of the ear canal

- Maintain a high index of suspicion for any condition of the EAC that does not respond to topical or systemic antibiotic treatment.
- Cancer of the temporal bone may occur in younger people who are more likely to have aggressive disease.

Physical Examination

- Findings include a friable, necrotic, bloody broad-based mass, polyp or ulceration, or diffuse thickening or stenosis of the EAC.
- Define the involvement of cartilaginous and bony canal with microscope examination of the ear.
- Evaluate the function of the facial nerve and other cranial nerves.
- Determine whether the cancer appears to involve the tympanic annulus or the tympanic membrane, middle ear (middle ear mass or effusion), neck (masses or tenderness), and temporomandibular joint (TMJ) (trismus).
- Perform an audiogram.

Imaging

- Determine the extent of disease for staging using examination and imaging.
- Usually, both magnetic resonance imaging (MRI) and computed tomography (CT) will be required to adequately stage the disease process.
  - High-resolution thin cut CT of the temporal bone
  - MRI of the skull base with and without contrast
  - CT or MRI of the neck with contrast
- Encroachment of cancer in the region of the internal carotid artery (ICA) should be investigated with CT angiography or angiography with the balloon occlusion test if resection of the ICA is considered. Venography is helpful for evaluation of the dural sinuses.
- Screen for additional pathology with chest radiography and liver

function testing.

- In malignant tumors with a high predilection for systemic spread, such as melanoma, CT scanning of the chest, abdomen, and pelvis, as well as whole-body bone scanning, should be performed.
- Positron emission tomography (PET) may be considered for the evaluation of local involvement and distant metastasis.
- While a survey of the extent of disease with combined imaging modalities is generally predictive of intraoperative findings, the extent of the cancer may be underestimated, especially with respect to spread posteriorly, superiorly, and medially.[1]

TABLE 141.1

Modified Pittsburgh Staging System for Primary Cancers of the Temporal Bone

T1	Tumor limited to the EAC; no bone erosion or soft tissue extension
T2	Tumor with limited bone erosion to the EAC or <0.5 cm of soft tissue involvement
T3	Tumor with full-thickness EAC bone erosion, <0.5-cm soft tissue involvement, or tumor in the middle ear or mastoid
T4	Tumor eroding the cochlea, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen, or dura; or >0.5 cm soft tissue involvement; or facial nerve paresis

EAC, External auditory canal.

Indications

- Primary cancer of the EAC can be staged according the modified Pittsburgh system[2] as T1 through T4, depending on the degree of bone, cartilage, and soft tissue involvement (Table 141.1).
- Sleeve resection of skin of EAC for very limited lesions of the external auditory meatus and lateral EAC
- Lateral temporal bone resection for lesions limited to the EAC (T1, T2)
- Subtotal temporal bone resection for cancer invading the middle ear and mastoid (T3, T4)
- Total temporal bone resection for cancer extending to the petrous apex
- Cancer extending to the TMJ, neck, dura, or infratemporal fossa (ITF) will require resection including these regions

Contraindications

- Extension into the cavernous sinus and brain parenchyma makes total extirpation of the cancer nearly impossible, and the possibility of cure becomes unlikely, even with the addition of aggressive adjuvant radiation therapy and chemotherapy.
- Involvement of the internal carotid canal is also problematic, but it is not an absolute contraindication to surgical resection.
- Compromised medical status precluding a prolonged general anesthetic and recovery.

Preoperative Preparation

- Biopsy is performed by direct incision; a staging mastoidectomy is not appropriate because it reduces the reliability of staging radiography and it may compromise the surgical margins of resection.
- A team approach is often necessary for advanced cancer, including the cooperation of a Neurotologist, Head and Neck Surgeon, Reconstructive Surgeon, Neurosurgeon, Pathologist, Radiation Oncologist, and Intensivist, as well as experienced nursing teams.
- Consider whether a simultaneous osseointegrated implant for hearing device or prosthetic ear is indicated, or discuss with the patient that these options may be considered after primary surgical management of the cancer has been completed.
- The patient's medical status should be optimized before surgery. Significant conditions, such as coronary artery disease, chronic obstructive pulmonary disease, diabetes mellitus, bleeding disorders, and malnutrition should be identified and treated preoperatively.

Operative Period

Anesthesia

- General oral endotracheal anesthesia

- Arterial line for surgery involving more than a lateral temporal bone resection
- Urinary catheter
- Avoid neuromuscular blocking agents
- Furosemide and mannitol, 0.25 to 0.5 g/kg, 30 minutes before intracranial dissection

Positioning

- Place the patient supine with appropriate padding, head turned with the affected ear up.
- If intracranial or more extensive dissection is planned, a Mayfield clamp may be used.
- Secure the patient to the table with 4-inch tape across the shoulders, hips, and thighs.
- Use sequential compression stockings on the patient.
- Prep the primary surgical site, neck, and planned graft sites.

Perioperative Antibiotic Prophylaxis

- A third-generation cephalosporin with cerebrospinal fluid (CSF) penetration, such as ceftriaxone, is administered perioperatively.

Monitoring

- Facial nerve monitoring from the orbicularis oris and orbicularis oculi
- Cranial nerves IX and X are monitored in some cases

Instruments and Equipment to Have Available

- Otologic microscope

- Plastics microscope if a free flap is anticipated
- Otologic drill
- Otologic mastoid and middle ear dissection set
- Head and neck instrument set
- Monopolar and bipolar electrocautery for both otologic and head and neck teams
- Prass or Kartush probe for direct facial nerve stimulation
- Fine straight and gently curved osteotome and mallet
- Osseointegrated implants for bone-conduction hearing device and/or prosthetic auricle (Vistafix)

Key Anatomic Landmarks

- The cartilaginous portion of the EAC is a poor barrier to the spread of neoplasm. Cancers in this area can erode through skin, cartilage, and soft tissue to invade the parotid gland anteriorly or the concha and postauricular sulcus posteriorly (Fig. 141.1A and B).
- The fissures of Santorini are vertical fissures in the cartilaginous EAC that allow direct access of cancer from the skin of the EAC to the periparotid tissues.
- The bony ear canal provides a more resistant barrier to direct invasion. Cancer in this area tends to track medially through the tympanic membrane into the middle ear and mastoid spaces.
- The foramen of Huschke is a defect in the anterior inferior tympanic ring that usually closes by 5 years of age, which provides a potential pathway between the bony EAC and the soft tissues of the parotid area and TMJ.
- Cancer may invade from the middle ear along the Eustachian tube to the ICA, Meckel's cave, and the cavernous sinus.
- Superior extension through the tegmen tympani and tegmen mastoideum may result in involvement of the middle fossa dura and the temporal lobe.

- Medially, the otic capsule provides a barrier to the spread of cancer, but the round and oval windows can be penetrated allowing for invasion through the vestibule and into the internal auditory canal (IAC) and posterior fossa.

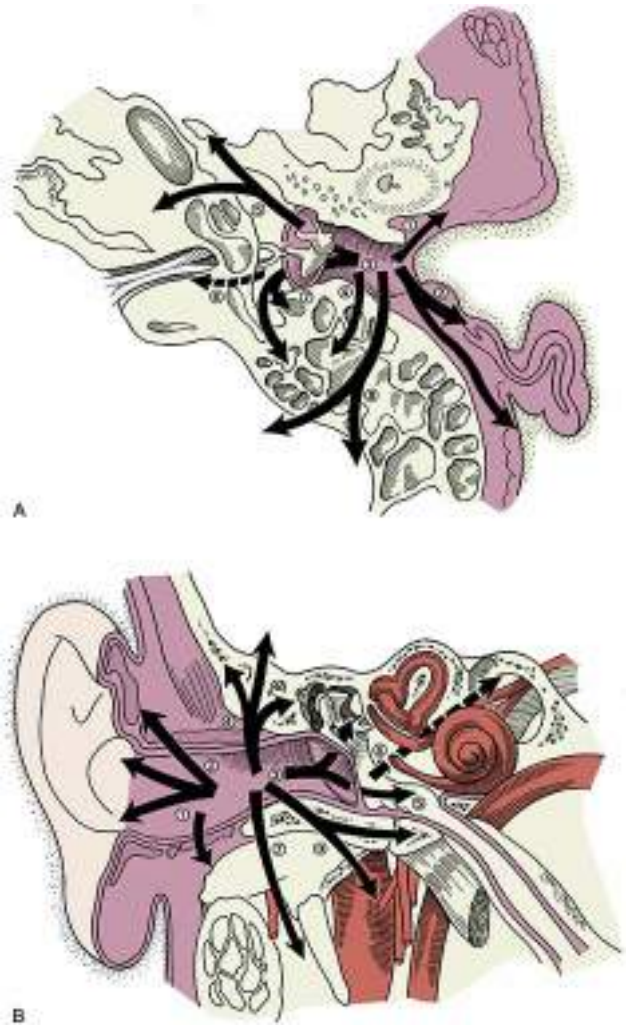

FIG. 141.1 Axial **(A)** and coronal **(B)** temporal bone anatomy showing pathways of spread of cancer *(1)* anteriorly through the cartilaginous canal into the parotid, *(2)* through the concha into the postauricular soft tissues, *(3)* through the tympanic membrane, *(4)* posteriorly into the mastoid, *(5)* medially to the carotid artery and Eustachian tube, *(6)* medially to the otic capsule through the round and oval windows, *(7)* along the facial nerve either inferiorly to the infratemporal fossa or medially to the internal auditory canal, *(8)* through the mastoid,

posterior fossa tegmen, and sigmoid sinus, and *(9)* inferiorly to the jugular foramen, carotid artery, and lower cranial nerves.

- The facial nerve provides a pathway for the spread of cancer intracranially, into the neck through the stylomastoid foramen, or into the ITF via the greater superficial petrosal nerve.
- Posteriorly, cancer can invade the posterior fossa plate, dura, and sigmoid sinus.
- Extension inferiorly leads to involvement of the jugular foramen and neck.
- Lymphatic drainage of the EAC extends anteriorly to the parotid and periparotid lymph nodes, inferiorly to the internal jugular lymph nodes, and posteriorly to the mastoid lymph nodes. The lymphatic drainage pathways from the middle ear and mastoid have not been well defined, but they are believed to be of only minor importance, because nodal metastasis from a malignancy limited to the middle ear and mastoid is rare.

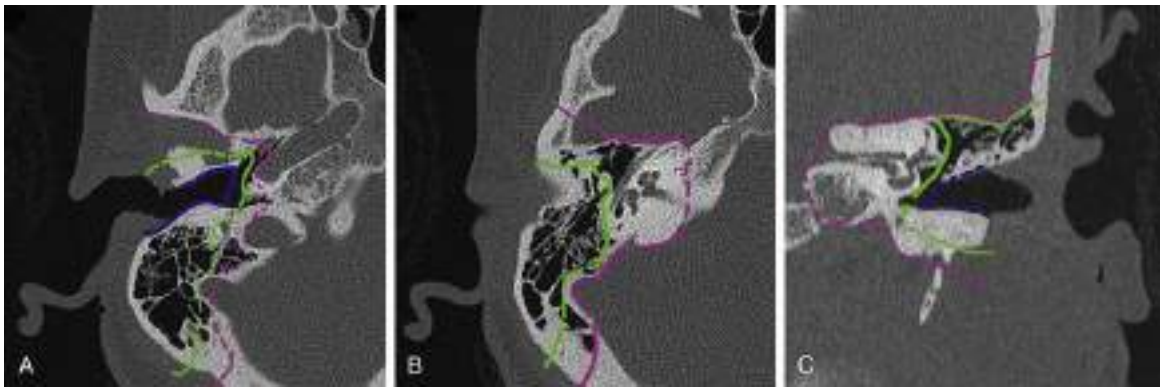

FIG. 141.2 Three types of temporal bone resections: sleeve resection *(blue line)*, lateral temporal bone resection *(green line)*, and total temporal bone resection *(pink line)*. Dotted lines indicate where the extension of resection may take place depending on the extent of the disease. **A**, Axial CT at the level of the EAC showing jugular bulb, carotid, and vertical portion of facial nerve. **B**, Axial CT at the level of the cochlea, the horizontal

segment of the facial nerve, and the petrous apex. **C**, Coronal CT at the level of the EAC and IAC.

Prerequisite Skills

- Advanced mastoidectomy
- Closure of external auditory meatus
- Auriculectomy
- Neck dissection
- Parotidectomy
- Facial nerve decompression/resection
- Microvascular anastomosis
- Osseointegrated implantation
- Craniotomy
- Dural resection and reconstruction
- Dissection of ITF
- Dissection of jugular bulb
- Local myofascial rotation flap
- Split-thickness skin graft
- Microvascular reconstruction

Operative Risks

- Deformity
- Loss of ability to wear glasses
- Hearing loss
- Vertigo
- Facial nerve paralysis

- Blood loss
- Infection
- Wound complications
- Paralysis of cranial nerves IX, X, XI, XII
- CSF leak
- Meningitis
- Temporal lobe edema or infarction
- Generalized cerebral ischemia

Surgical Technique

Lateral Temporal Bone Resection

1. This is appropriate for cancer limited to the EAC without penetration medially through the tympanic membrane.

2. The anatomic unit removed en bloc is the EAC, the tympanic membrane, and the malleus (Fig. 141.2A to C).

3. The boundaries of resection include the middle ear cavity medially, the TMJ capsule anteriorly, the zygomatic root superiorly, the mastoid cavity posteriorly, and the ITF inferiorly. Laterally, the resection can include the concha, as well as portions of the pinna, depending on the extent of the cancer.

4. Inject the proposed incision sites with 2% lidocaine with 1:100,000 epinephrine for hemostasis.

5. Make a circumferential incision around the concha for cancer involving only the EAC and extend as needed for a wide skin margin. If the upper one-third of the pinna can be preserved, it offers some advantage for patients who wear glasses; but otherwise, there is minimal advantage to saving small portions of the pinna.

6. Make a wide incision 3 cm behind the postauricular sulcus extending into the neck if neck dissection is anticipated (Fig. 141.3).

7. After elevating the skin a short distance anteriorly, the dissection is

directed medially through the fibroperiosteal layer to the mastoid cortex.

8. Elevate the subperiosteal flap and connect the conchal incision circumferentially with the postauricular wound lateral to the temporalis fascia and parotid fascia, and continue elevation anteriorly until the masseter muscle is identified.

9. Send the skin margin for frozen section.

10. Oversew the lateral margin of the EAC to prevent tumor spillage.

11. Perform a complete mastoidectomy. Avoid over-thinning the bony ear canal to the point of exposing the cancer.

12. Open the facial recess and extend it by sacrificing the chordae tympani nerve.

13. Inspect the middle ear through the facial recess to verify the absence or presence, of penetration of the cancer through the tympanic membrane.

14. Identify the facial nerve and dissect it to the stylomastoid foramen.

15. Separate the incudostapedial joint and remove the incus.

16. Cut the tensor tympani tendon.

17. Inferiorly, drill between the facial nerve and the annulus of the tympanic membrane toward the anterior wall of the EAC until the capsule of the TMJ and the periosteum of the anterior tympanic ring are reached.

FIG. 141.3 A typical incision for a primary lesion of the external auditory canal including a circumferential incision through the cartilaginous canal and a wide postauricular incision.

18. Superiorly, drill through the air cells of the zygomatic root between the tegmen tympani and the epitympanum to expose the endosteum of the glenoid fossa.

19. Once this bony dissection has been completed, the EAC is attached anteriorly by the thin tympanic plate.

20. The spread of cancer anteriorly or inferiorly into the TMJ or ITF can be treated by extension of the surgical resection into these areas.

21. An osteotome is inserted through the extended facial recess to the bone just lateral to the Eustachian tube orifice. A few gentle taps on the osteotome will complete the osteotomy, and the EAC can be dissected from the TMJ capsule.

22. Pack the Eustachian tube.

23. Perform a superficial parotidectomy with facial nerve dissection.

24. Remove the EAC with the parotid tissue.

25. Orient the specimen for the pathologist.

26. The neck dissection, if done, is usually performed as a separate specimen.

27. Use an inferiorly based temporalis muscle flap to fill the defect. This is facilitated by the removal of the root of the zygoma.

28. Close the skin defect at the concha primarily or with a split-thickness skin graft.

Subtotal Temporal Bone Dissection

1. This is appropriate for cancer that extends medially to the tympanic membrane and invades the middle ear, hypotympanum, otic capsule, facial nerve, or mastoid.

2. The main specimen typically includes the EAC, tympanic membrane, superficial or total parotid, mandibular condyle, and facial nerve. In most cases, additional bone is removed piecemeal, by drilling the otic capsule, tegmen, bony plate of posterior fossa, and jugular bulb, although this portion of the temporal bone may be removed en bloc. The resection may include dura, temporal lobe, and contents of the ITF.

3. Margins are the middle fossa dura superiorly, the posterior fossa dura and sigmoid sinus posteriorly, the IAC anteriomedially, the base of the skull and jugular bulb inferiorly, and the petrous apex medially.

4. Perform a lateral temporal bone dissection.

5. Expose and control the critical neurovascular structures of the neck and perform a neck dissection based on the degree of nodal involvement.

6. Disconnect the sternocleidomastoid muscle from the mastoid tip to expose the digastric muscle and transverse process of the atlas exposing the jugular vein, carotid artery, and lower cranial nerves at the skull base.

7. Thin and resect the tegmen mastoideum and posterior fossa plate, exposing the jugular bulb.

8. If facial nerve preservation is planned, decompress the entire nerve.

9. Perform the translabyrinthine approach to the IAC or expose the IAC through a middle fossa crainiotomy. Open the IAC and transect the cochlear and vestibular nerves and mobilize or transect the facial nerve.

10. If cancer has infiltrated the protympanum, the dissection will include resection of the mandibular condyle and dissection of the ITF with total

parotidectomy, transposition of the carotid artery, resection of the Eustachian tube, cranial nerve V3, and the adjacent skull base as needed.

11. Drill out the remainder of the otic capsule containing the cochlea and the vaginal process between the jugular bulb and the ICA leaving only the anterior petrous apex. Expose the ICA in its vertical and horizontal segments.

12. If cancer involves the lateral wall of the sigmoid sinus or jugular bulb, ligate the internal jugular vein and sigmoid sinus. Open and pack the jugular bulb to control the bleeding from the inferior petrosal sinus.

13. If cancer is present on the medial wall of the jugular bulb, the resection must be extended into the pars nervosa. If the decision is made to do this, remove the medial wall of the jugular bulb and the contents of the par nervosa, including cranial nerves IX, X, and XI.

14. Resect the involved dura with margins and repair with a fascial or pericranial graft. If there is limited invasion of the temporal lobe, it may be resected, albeit with a small potential for cure.

15. Cover the IAC with fascia and fibrin glue.

16. Reconstruct the soft tissue defect with a microvascular free flap.

Total Temporal Bone Resection

1. This is indicated for a tumor invading the Eustachian tube or extending into the petrous apex.

2. Remove the remaining anterior petrous apex after a subtotal temporal bone resection.

3. Gain proximal and distal control of the intrapetrous ICA.

4. Mobilize the ICA from the skull base.

5. Drill the remaining petrous apex and resect or obliterate the Eustachian tube.

6. Reconstruction is similar to the subtotal temporal bone resection with dural repair and free flap.

Common Errors in Technique

- Although it may be tempting to try to employ less extensive resections for limited cancers of the lateral ear canal or bony canal, procedures such as sleeve resections, resection limited to the cartilaginous canal, or radical mastoidectomy often lead to long-term management problems with poor healing, collapse of the canal, cholesteatoma, and cerumen impaction. Therefore, a lateral temporal bone resection is the minimal procedure for cancers of the cartilaginous or bony EAC.
- For cancers limited to the EAC, avoid violation of the bony EAC and annulus during lateral temporal bone resection, which would potentially expose the surgical field to the cancer.
- Remain oriented to the location of the Eustachian tube orifice during osteotomy to avoid injury to the carotid artery.
- Careful pathologic evaluation is critical to understand long-term prognosis and prescribe adjuvant therapy. It is helpful to send multiple frozen sections during dissection, making sure the identity of each specimen is clearly defined and communicated to the nursing and pathology team. Ideally, the surgeon will personally orient the specimen for the pathologist in the operating room so that they can identify margins that are potentially close and should be examined by frozen section.
- Since the extent of disease is sometimes difficult to appreciate preoperatively, especially in the case of soft tissue tumors, such as adenocarcinomas or adenocystic carcinoma, the surgical team and patient must be prepared to extend the dissection as necessary.
- If a laceration of the ICA occurs, it is managed by primary repair, patch, bypass grafting using the saphenous vein, or sacrifice without reconstruction. Be prepared to know whether the patient can tolerate sacrifice of the vessel by obtaining a preoperative balloon occlusion test.
- Damage to the vein of Labbé can lead to significant temporal lobe infarction with aphasia if on the dominant side as well as seizures. When packing or ligating the sigmoid or transverse sinus it is important to stay far anterior to the insertion of the vein of Labbé into the transverse sinus.
- Assure complete closure of the Eustachian tube as it offers a potential

route for contamination of the surgical wound from the nasopharynx and route for CSF leakage.

- Although pedicled flaps are sometime adequate, free microvascular flaps offer the most flexible options for closure of large defects after subtotal and total temporal bone dissections.
- Dural closures should be watertight. Avoid active suction drains close to or communicating with the site of dural repair. Obliterate dead spaces with reconstruction and perform a watertight closure of the skin.
- If a tracheostomy is performed, avoid communication between the tracheostomy and the neck dissection. When drainage of the neck wound is needed, the potential for CSF leak into the neck is high. A pathway for CSF flow from the neck to the tracheostomy wound would carry a great potential for contamination and serious infection.

Postoperative Period

Routine Postoperative Management

- If the intracranial cavity was opened, the patient should be admitted to the neurointensive care unit, frequent neurologic monitoring should be ordered and a CT scan should be performed in the morning.
- Monitor pulmonary and cardiovascular status, and record fluid input and output.
- Keep the head of the bed elevated, use stool softeners, and ask the patient to avoid straining.
- Advance the diet as tolerated.
- Prescribe perioperative antibiotics for 24 hours.
- The patient must wear compression stockings.
- Continue the mastoid dressing for 3 to 5 days; remove and replace to check the wound on days 1 to 2.
- Remove any skin bolsters at day 5.

- If a flap was used, avoid pressure dressings and keep the flap exposed so the viability can be readily monitored.
- Monitor for CSF leak.
- Monitor for venous congestion of any remaining pinna and microvascular flaps.
- Prevent exposure keratitis and corneal ulceration with routine eye care for patients with facial paralysis. Apply saline eye drops every 1 to 2 hours during the day and ophthalmic lubricant at night. At night, apply lubricant and tape the eye closed with a Steri-Strip or thin paper tape. Taping may also be helpful to reduce ectropion and enhance eye blink during the day by fashioning a sling along the lower eyelid and a tape "weight" along the upper eye lid. A plastic eye shield (moisture chamber) is also useful. If facial nerve function is expected to return within a few months, as occurs after facial nerve transposition, the patient usually requires no further treatment. If recovery from facial nerve dysfunction is expected to take longer or if the dysfunction will be permanent, a gold or platinum weight is placed in the upper eyelid and a lateral tarsal strip is performed in a separate setting.
- If the lower cranial nerves were functional preoperatively and required transection intraoperatively, perform a tracheostomy and consider a type I thyroplasty with or without vocal cord medialization.
- Patients with more extensive dissections may benefit from physical therapy to initiate gait training and vestibular therapy.
- Radiation treatment is begun approximately 6 weeks after surgery, or when adequate wound healing has occurred.
- Postoperative surveillance with imaging is performed at 3 months and every 6 months thereafter.
- A prosthetic ear may be applied either with adhesive or by osseointegrated implants. A prosthesis is pursued after adequate time for radiation treatments and wound healing.
- Hearing loss may be alleviated with a bone conduction device or CROS hearing aid if the pinna is present.

Acute Postoperative Complications

- Aspiration pneumonia
- Meningitis
- CSF leak
  - If the leakage occurs through an incision, the area of dehiscence is reinforced with horizontal mattress sutures (sterile technique) and a pressure dressing.
  - CSF leaks that persist for more than 24 hours should be managed with a lumbar drain.
  - The use of antibiotics prophylactically in the presence of a CSF leak is controversial.
  - If the CSF leak persists after 3 to 5 days of lumbar drainage, exploration is indicated.
- Acute intracranial hemorrhage
  - The signs of acute intracranial hemorrhage are altered sensorium or loss of consciousness. Focal neurologic deficits, including fixed and dilated pupils, bradycardia, and hypertension can also occur.
  - A CT scan without contrast enhancement is performed. The patient's condition is temporized by the administration of mannitol, 0.25 to 0.5 g/kg intravenously, and hyperventilation if intubated. If the patient's vital signs are unstable or there is evidence of brain stem herniation, emergent exploration is warranted. A ventriculostomy can be performed to rapidly decompress the increased intracranial pressure. The craniectomy or craniotomy is reopened, and the blood clot is evacuated. The source of bleeding is sought and controlled.
- Wound complications
  - Careful clinical evaluation (pinprick test) and/or routine Doppler ultrasound is performed to detect any impending compromise of pedicled and free flaps. If vascular compromise does occur, the patient is taken back to the operating room for an alternative flap or revision of the vascular anastomosis.
  - Wound dehiscence occurs most frequently at the distal edge of a pedicled flap.

Alternative Management Plan

1. Postoperative radiotherapy is indicated for T3 and T4 lesions and should be strongly considered for a T2 lesion. Surgery alone is curative for T1 lesions, assuming adequate margins are obtained. Radiotherapy is also considered for aggressive pathologic features, such as perineural invasion, close margins, nodal involvement, and extracapsular spread.[3]

2. Radiotherapy alone offers a poor survival rate.

3. The role of preoperative or postoperative chemotherapy is unclear, but has been shown to have some promise for advanced disease.[4]

Discussion

Evidence-Based Medicine Question

Unanswered questions plague the clarification of the optimal management of tumors in the region of the temporal bone. The role of elective neck dissection, parotidectomy, primary radiotherapy, and chemotherapy need further clarification. The outer limits of surgically resectable cancer and the role of total temporal bone resection and piecemeal resection for advanced or recurrent cancer, especially with involvement of the dura or brain, remain controversial.[3,5] Emerging reports of the use of chemotherapy are promising, but yet unproven.[4] The applicability of any of the treatment protocols and prognostic indicators to control secondary spread to the ear canal, mastoid, and temporal bone is unclear.[6] Addressing these controversies with high quality evidence remains a significant challenge. The world literature is replete with case series and a few systematic reviews, most of which are marred by small samples, heterogeneity of the histology, clinical settings, non-standardized staging and treatment protocols, and inadequate clinical details. Meta-analysis and systematic reviews are difficult to produce due to the rarity of the disease, the variability in surgical approaches and definitions, the challenges in determining the extent of the disease, the variances in reporting clinical details, and the lack of an AJCC-endorsed internationally accepted standardized staging system.

Editorial Comment

Dr. Moody has comprehensively organized a complex topic into the contemporaneous format of this textbook. This chapter covers the diagnosis, evaluation, staging, treatment options, and surgical procedures necessary to manage this potentially aggressive disease. As with most diagnoses of cancer, early recognition and intervention offers the best opportunity for cure. This relatively rare diagnosis makes it difficult to devise treatment strategies or protocols for trials among oncology teams.

The Department of Otolaryngology at the University of Pittsburgh created a recognized staging system for carcinoma of the temporal bone. Others are also available. It is important to have a unifying staging system in order to provide meaningful comparisons of outcomes across contributing institutions.

Much planning is needed in surgically addressing this disease. The participation of other disciplines is needed to optimize the surgical resection and achieve safe, functional, and cosmetically appealing reconstruction. Clinical and radiologic long-term monitoring is mandatory for tumor surveillance. Along with MR imaging, PET scanning offers another means of assessing the resected area deep to flap reconstruction.

Review Questions

1. Based on the Pittsburgh staging system for cancers of the temporal bone, how would a cancer that erodes the bony canal wall, but does not involve the middle ear, soft tissue, or facial paralysis be staged?

   a. T1

   b. T2

   c. T3

   d. **T4**

2. Radiotherapy is indicated for which cancers?

a. Cancer staged T2, 3, or 4

b. Cancer with perineural invasion

c. Cancer with positive margins

d. **All of the above**

3. Routine preoperative evaluation for cancer of the ear canal should include:

a. High resolution CT of the temporal bone

b. MRI of the skull base and neck with contrast

c. PET scan

d. **a and b**

4. Treatment of stage T1N0 cancer of the external auditory canal requires:

a. **Lateral temporal bone resection alone**

b. Lateral temporal bone resection, parotidectomy, and neck dissection

c. Postoperative radiotherapy

d. Sleeve resection

5. The most important prognostic indicator for long-term survival is:

a. Age

b. **Positive margins**

c. Lymph node metastasis

d. Postoperative radiotherapy

Glomus Tumors

C. Y. Joseph Chang

Introduction

Paraganglioma or glomus tumor is a tumor of the neuroendocrine system derived from neural crest cells and chemoreceptor cells. Although most tumors are sporadic, familial glomus tumors may occur in 20% of patients with glomus tumors. Some of the tumors are multicentric and bilateral at the time of presentation, which typically occur at an earlier age in successive generations in families harboring genetic mutations. Glomus tumors are slow-growing, invasive, highly vascular neoplasms that are in proximity to the important temporal bone structures that can include the facial nerve, internal carotid artery (ICA), and lower cranial nerves. Glomus tympanicum tumors typically arise in the middle ear space and may involve the middle ear with or without extension to the hypotympanum, attic, and mastoid, and rarely, the ICA and petrous apex or intracranial areas. These tumors typically do not involve the lower cranial nerves, so the cranial nerve morbidity from treatments is usually limited to the facial nerve and hearing/vestibular apparatus. In contrast, glomus jugulare tumors arise in the jugular foramen and typically involve the superior and lateral wall of the jugular bulb. In addition to the cranial nerves at risk for glomus tympanicum tumors, the lower cranial nerves, IX, X, XI, and sometimes XII, may be involved and place the patient at significant risk for dysphagia, dysphonia, and shoulder dysfunction that may be extremely debilitating.

Two classification systems have been offered for nomenclature and staging. Fisch described and modified a classification system based on the size and extent of the tumor (Box 142.1). The other classification system was devised by Glasscock and Jackson (Box 142.2). Both classifications address the pertinent issues of tumor size, petrous apex or carotid artery involvement, and intracranial extension. This provides

critical information necessary to design an operative approach and plan.

Treatment options for glomus tumors of the temporal bone include observation with serial scanning to monitor for growth, microsurgical excision, and radiation therapy (XRT). For advanced tumors that approximate or involve the lower cranial nerves, the standard practice in the past consisted of aggressive surgical removal with possible adjuvant radiation in some cases. Complete surgical resection of these tumors minimizes the chance for recurrence but may result in significant morbidity. This treatment may incur lower cranial dysfunction, requiring the need for a tracheotomy, nasogastric tube placement, or percutaneous gastrostomy feeding tube, along with complications of aspiration, pneumonia, malnutrition, and weakness of the shoulder and tongue. In addition, sacrifice of the ICA is avoided as much as possible to prevent the morbidity of ischemic cerebral damage.

Radiation therapy does not eliminate the tumor but is intended to halt tumor progression. Proponents for surgery have suggested that radiation is indicated for palliation, following incomplete tumor excision or for patients who are medically infirm or elderly. However, there is strong evidence indicating that radiotherapy could also be considered the definitive treatment strategy for skull base glomus tumors. Glomus jugulare tumors have traditionally been treated by fractionated XRT. Newer techniques using a frame-based linear accelerator, gamma radiation from cobalt delivered through the Gamma Knife, or photon beam from a robot-mounted mini-linear accelerator such as the CyberKnife are available for single or multiple focused treatments (fractions), providing submillimeter accuracy in treatment delivery.

Based on the apparent success of varied radiation procedures, the management recommendations have evolved recently to treatment options that preserve function as much as possible. This approach may entail observation, primary radiation, or subtotal function preserving tumor resection followed by observation or radiation of the residual tumor.

Key Operative Learning Points

- Surgical treatments for glomus tympanicum tumors are typically limited to tympanoplasty and mastoidectomy dissections.

- Surgical treatments for glomus jugulare tumors are more extensive and, in addition to those noted previously, include various degrees of infratemporal fossa dissection, exposure of the skull base from the upper neck, possible petrous apex, and intracranial exposures.
- If the lower cranial nerves of the jugular foramen are to be preserved, the medial wall of the jugular bulb must be left intact, and care should be taken not to compress the contents of the pars nervosa.
- For jugulare tumors, the facial nerve may be managed by the fallopian bridge technique in most cases and facial nerve transposition for very extensive tumors.
- The prevention of cerebrospinal fluid (CSF) leak in cases of dural penetration can be managed with various techniques, from adipose tissue graft packing of a more isolated posterior temporal bone CSF leak with preservation of the hearing mechanism to eustachian tube (ET) and external auditory canal (EAC) closure and possible use of a temporalis muscle rotation flap.

Preoperative Period

History

1. History of present illness

   a. Pulsatile tinnitus

   b. Hearing loss

   c. Dizziness: Vertigo and/or imbalance

   d. Otalgia

   e. Facial weakness or twitching

   f. Dysphagia

   g. Hoarseness

   h. Shoulder weakness and/or pain

   i. Dysarthria, tongue dysfunction

   j. Labile hypertension, tachycardia, headache, perspiration, pallor, and

nausea—may indicate a significant catecholamine release from the tumor requiring medical management

2. Past medical history

   a. Prior treatment with surgery or radiation

   b. Medical illness such as coronary artery disease, lung disease, bleeding disorders

   c. Family history of vascular or endocrine tumors

BOX 142.1 Glomus Tumor Classification: Fisch

Type	Description
A	Tumor limited to middle ear cleft (promontory)
B	Tumor confined to middle ear, hypotympanum, and mastoid
C_1	Tumor eroding jugular bulb and carotid foramen; not invading carotid artery
C_2	Tumor involving infralabyrinthine and apical temporal bone; erosion of vertical carotid artery
C_3	Tumor involving infralabyrinthine and apical temporal bone; erosion of horizontal carotid artery
C_4	Tumor involving infralabyrinthine and apical temporal bone; tumor grows to foramen lacerum and cavernous sinus
D_1	Intracranial tumor <2 cm
D_2	Intracranial tumor >2 cm; e, extradural; i, intradural
Di_3	Unresectable intracranial extension

Data from Fisch U: Infratemporal fossa approach for glomus tumors of the temporal bone. Ann Otol Rhinol Laryngol 91:474-479, 1982, and Fisch U, Mattox D: Classification of glomus temporal tumors. In Fisch U, Mattox D (eds): Microsurgery of the Skull Base. Stuttgart and New York: Georg Thieme; 1988, pp 149-153.

BOX 142.2 Glomus Tumor Classification: Glasscock-Jackson

Type	Description
Glomus Tympanicum	
I	Small mass limited to promontory
II	Tumor completely filling middle ear space
III	Tumor filling middle ear and extending into mastoid
IV	Tumor filling middle ear, extending into mastoid or through tympanic membrane to fill external auditory canal; may extend anterior to carotid
Glomus Jugulare	
I	Small tumor involving jugular bulb, middle ear, and mastoid
II	Tumor extending under internal auditory canal; may have intracranial extension
III	Tumor extending into petrous apex; may have intracranial extension
IV	Tumor extending beyond petrous apex into clivus or infratemporal fossa; may have intracranial extension

Data from Jackson CG, Glasscock ME, Harris PF: Glomus tumors: diagnosis, classification, and management of large lesions. *Arch Otolaryngol* 108:401-410, 1982.

Physical Examination

1. Otologic evaluation: Ear microscopy or endoscopy
   a. Vascular middle ear lesion
   b. Tympanic membrane involvement
   c. Extension into the ear canal
   d. Brown's sign: Tumor blanching with ear insufflation
   e. Tuning fork

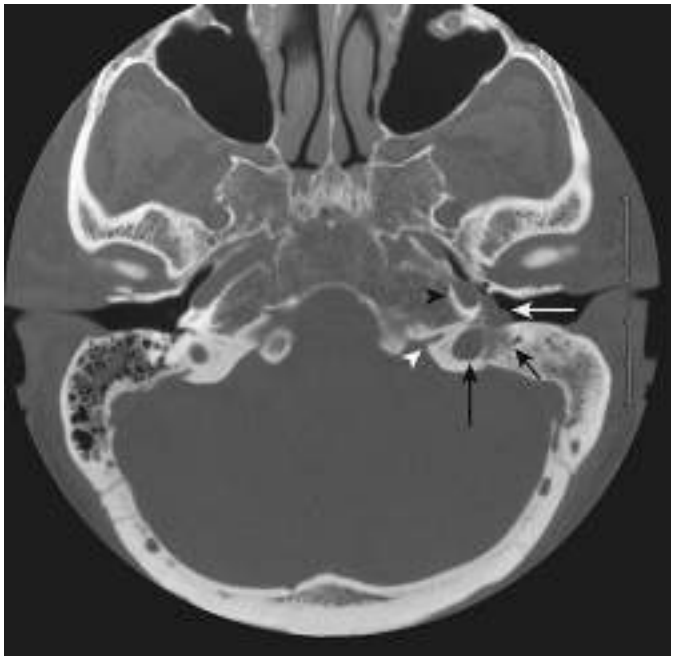

FIG. 142.1 Bone-windowed CT scan demonstrating the left middle ear and a hypotympanic mass *(white arrow)* infiltrating and eroding bone between the carotid artery *(black arrowhead)*, the jugular vein *(large black arrow)*, and the medial aspect of the facial nerve *(small black arrow)*. The pars nervosa is not affected *(white arrowhead)*.

2. Balance evaluation
   a. Gait
   b. Tandem gait
   c. Romberg test
3. Cranial nerve evaluation
   a. Facial nerve
   b. Cranial nerves IX, X, XI, XII
4. Neck: Mass in the upper neck
5. Audiologic evaluation
   a. Pure tones
   b. Speech discrimination scores
   c. Tympanogram

Imaging

1. Computed tomography (CT) of the temporal bone with 0.6 mm axial and coronal cuts (Fig. 142.1)
   a. Opacification or soft tissue masses of the middle ear, attic, or mastoid
   b. Bony erosion along the jugular bulb and jugular foramen
   c. Involvement of the ICA
   d. Erosion of bone along the posterior petrous bone that could indicate extension of the tumor into the posterior fossa
   e. Bony erosion into the otic capsule

2. Magnetic resonance imaging (MRI) with gadolinium of the brain, internal auditory canal, and neck

   a. Enhancing lesion involving the middle ear, attic, mastoid, hypotympanum, jugular foramen, petrous apex, internal carotid artery, or intracranial areas

   b. Flow void within the sigmoid sinus, jugular bulb, and jugular vein

   c. Identification of any synchronous tumors of the head and neck or skull base

3. Angiography: Four-vessel cerebral arteriogram may be done during preoperative tumor embolization if embolization is planned.

   a. Tumor blush

   b. Identification of feeder vessels

   c. Identification of any synchronous vascular tumors of the head and neck or skull base

4. Magnetic resonance angiography (MRA) or CT angiography (CTA) may be done as a noninvasive alternative to angiography, although it is not as sensitive as formal angiography.

Indications

1. The main goal of intervention is to prevent and/or halt the progression of bothersome symptoms and to avoid incurring additional symptoms.

   a. Pulsatile tinnitus

   b. Hearing loss

   c. Dizziness

   d. Dysphagia

   e. Hoarseness

   f. Shoulder dysfunction

   g. Symptoms related to catecholamine release

2. Most symptomatic glomus tympanicum tumors can be surgically removed with limited risk of significant morbidity.

3. Many glomus jugulare tumors can be removed completely with mild risk of increased morbidity, unless there is involvement of the jugular foramen pars nervosa, significant ICA involvement, or intracranial extension.

4. Tumors that involve structures that will incur significant patient morbidity associated with total resection may be considered for alternative treatments.

a. Observation with serial MRI

b. Subtotal resection (STR), leaving tumors in sensitive areas, followed by options of observation or radiation

c. Primary radiation options

5. Most small to medium tumors can also be considered for observation with serial MRI versus primary radiation.

Contraindications

1. Advanced age and medical comorbidities with increased risk for general anesthesia may make any surgical option too risky for some patients.

2. Patients with pre-existing dysphagia related to prior cerebrospinal accident (CVA) or other diseases not related to the tumor may not tolerate treatment related injury to the lower cranial nerves.

Preoperative Preparation

1. Medical treatment of any tumor-associated elevation of circulating catecholamines—alpha and beta blockade

2. Angiographic embolization of tumor, in most cases of glomus jugulare tumors, typically 1 to 2 days prior to surgery

3. If there is significant involvement of the ICA that may be at risk for vascular injury, the patient typically undergoes balloon test occlusion with xenon perfusion to see if sacrifice of the carotid will be tolerated. Alternatively, a protective ICA stent may be placed.[1]

4. Type and cross 2 to 4 units of red blood cells when operating on

glomus jugulare tumors.

Operative Period

Anesthesia

General

Positioning

Supine: The patient's head is turned away from the surgeon.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin. The antibiotic regimen is the standard protocol for prophylactic antibiotic coverage. Administer clindamycin if patient is allergic to penicillin.

Monitoring

- Facial nerve monitoring
- Cranial nerve IX to XII monitoring for extensive skull base glomus jugulare tumor
- Somatosensory monitoring for potential carotid artery involvement

Instruments and Equipment to Have Available

1. Operating microscope
2. Standard ear surgery set
3. Otologic drill
4. Standard neurosurgical set, including retractors, for intracranial extension

5. Variety of hemostatic agents (Surgicel, Avitene, Surgifoam)

Key Anatomic Landmarks

1. Facial nerve along the vertical and horizontal segments, identified by the oval window niche, horizontal semicircular canal, and stylomastoid foramen

2. Lower cranial nerves as they exit the jugular foramen. Cranial nerve IX remains medial to the jugular vein. Cranial nerve X tracks between the jugular vein and carotid artery. Cranial nerve XI crosses lateral to the jugular vein as it extends to the posterior neck. Cranial nerve XII tracks lateral to the carotid artery as it extends anteriorly deep to the anterior belly of the digastric muscle.

3. The petrous ICA lies medial to the eustachian tube, foramen ovale, and foramen spinosum.

Prerequisite Skills

1. Tympanoplasty with mastoidectomy; facial recess

2. Infratemporal fossa skull base dissection

3. Muscle rotation flaps for reconstruction

Operative Risks

1. Inability to control hemorrhage

2. Injury to the facial nerve

3. Injury to the lower cranial nerves

4. Cochleovestibular damage

5. CSF leak

6. ICA injury

7. Arterial or venous CVA

Surgical Technique

Glomus Tympanicum Tumors

The surgical approach for glomus tympanicum tumors is dictated by the size of the tumor. Small tumors limited to the mesotympanum and hypotympanum without involvement of the jugular bulb are removed through a transcanal approach. This is predicated on favorable anatomy of the bony ear canal. Larger lesions usually require a postauricular approach to provide greater exposure, including possible mastoidectomy and opening of the facial recess. A canaloplasty is also necessary when the inferior annulus is not adequately visualized through the external auditory meatus due to tortuosity of the ear canal or significant tumor extension into the hypotympanum.

- Adequate injection of the ear canal and postauricular sulcus with 1% lidocaine with 1:100,000 epinephrine
- For a postauricular approach, a lateral and posterior ear canal skin flap is created with superior, inferior, and connecting incisions halfway into the bony ear canal.
- The postauricular incision is made 3 mm posterior to the sulcus, and the incision is connected with the ear canal incision. The meatal flap is retracted with a half-inch Penrose drain, and the pinna is reflected anteriorly with a Weitlaner retractor.
- The previously made vertical meatal flap incision defines the lateral margin of the tympanomeatal flap.
- The tympanomeatal flap is created after the inferior to anterior canal wall incision is made. The anterior incision is carried further superiorly, depending on the extent of tympanic annulus elevation needed.
- The middle ear is entered medial to the fibrous annulus, which is elevated as far anteriorly as needed to access the entire tumor. Care is taken not to incise the tumor in order to prevent hemorrhage (Fig. 142.2).
- For small tumors of the middle ear, the vascular pedicle is typically

located on the promontory. The tumor can be gently manipulated until the pedicle is visualized. The pedicle may be transected, and the hemorrhage may be controlled with the application of bone wax or Surgicel.

- Microbipolar cautery may also be used, but due to the risk of injury to the cochlea, excessive use of bipolar cautery should be avoided.
- For larger tumors involving the hypotympanum and protympanum, there may also be vascular pedicles in both areas that cannot be accessed without debulking the tumor.
- The tumor may need to be debulked first after shrinking the tumor with the bipolar cautery. Once the vascular pedicles are found and transected, the hemorrhage may be controlled with the application of bone wax or Surgicel. Cotton pledgets soaked in epinephrine (adrenalin) also provide hemostasis.
- For tumors extending to the epitympanum or mastoid, a canal wall up (CWU) mastoidectomy may also be needed. This exposure is typical for that required for removal of cholesteatoma (see Chapter 134).
- If feasible, the middle ear, hypotympanic, and protympanic areas of the tumor should be removed with control of the tumor vascular supply first to reduce the hemorrhage related to dissection of the remaining tumor. Bipolar cautery may still be needed for the attic and mastoid tumor removal.
- The ossicular chain may require disarticulation with removal of the incus and malleus head for complete removal of the tumor. In this case, the ossicular chain reconstruction may be performed after tumor removal (see Chapter 132). In some cases, only a temporary separation of the incudostapedial joint is necessary, with replacement of the lenticular process of the incus to the stapes capitulum after removal of the tumor.
- If there is tumor infiltration to the stapes obturator foramen and footplate, complete tumor removal may be difficult with mechanical techniques. The Diode or argon laser with 0.2-mm fiberoptic probe may be used at a setting of 1 to 2 watts, 0.2-second single shot duration to vaporize the tumor in this area, taking care not to injure the stapes footplate of horizontal facial nerve. The CO_2 laser may also be used,

but it typically requires a higher power setting of 2 to 5 watts for optimal results.

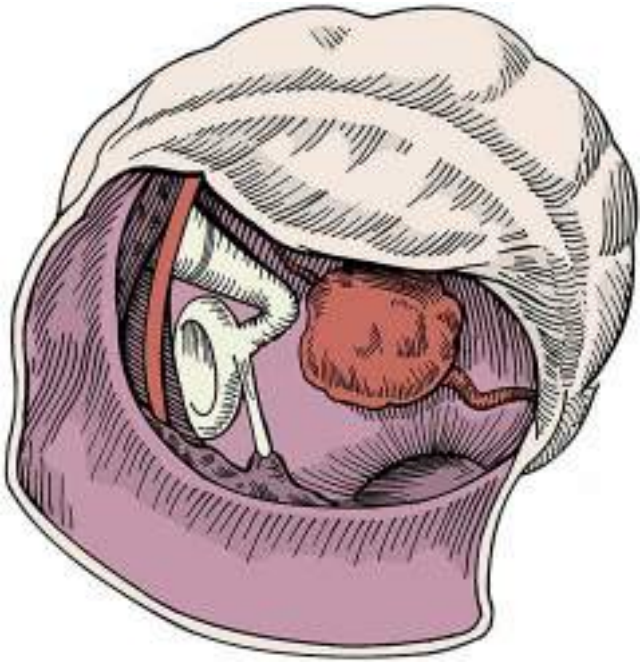

FIG. 142.2 Transtympanic approach to a glomus tumor isolated within the middle ear.

- In rare cases, the tumor has invaded the area inferior to the hypotympanum toward the jugular bulb. In tympanicum tumors, there is typically no tumor invasion into the wall of the jugular bulb, so opening of the sigmoid sinus will not be needed. The infratympanic facial recess approach is extended (Fig. 142.3). It may also be necessary to create a "fallopian bridge" by skeletonizing the distal vertical portion of the facial nerve in order to remove the entire tumor (see Fig. 142.3).
- If a tympanic membrane (TM) perforation has been made during tumor removal, it can be repaired using the standard medial graft technique (see Chapter 131).
- The middle ear is packed with Gelfoam or Surgicel, depending on the degree of hemostasis needed. The ear canal is packed with Gelfoam.
- The postauricular wound is closed in layers.
- A mastoid dressing is applied if a postauricular approach is used.

Glomus Jugulare Tumors

Most glomus jugulare tumors involve the middle ear, jugular bulb, and hypotympanic air cells without intracranial involvement. The tumor may erode bone near the vertical carotid artery and/or jugular foramen pars nervosa (Fisch type C_1 and C_2, Glasscock-Jackson jugulare type I and 2).

- A postauricular mastoidectomy incision located 3 cm posterior to the pinna extends over the lower border of the mastoid tip, through an upper neck skin crease, toward the greater cornu of the hyoid bone. The incision in the neck is carried through the subcutaneous tissue and platysma muscle, with preservation of the greater auricular nerve (Fig. 142.4).
- If the there is no cervical extension of tumor, the main reason for the cervical incision is to obtain inferior control of the jugular vein. In this case, the cervical dissection can be kept separate from the postauricular dissection to minimize the risk of CSF leak into the neck if there is dural penetration related to tumor removal.

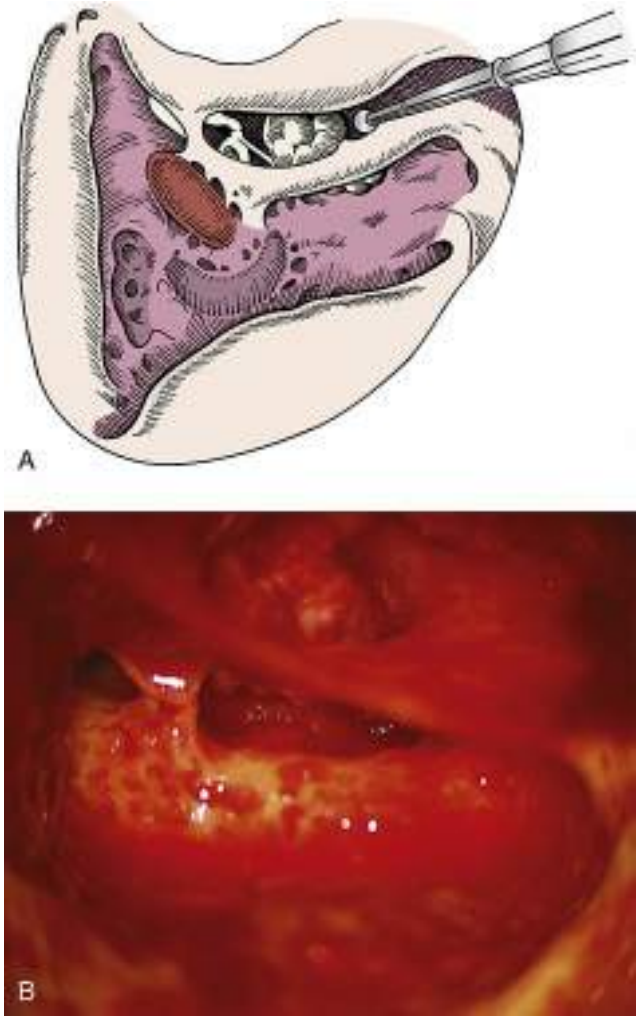

FIG. 142.3 **A,** Access to the glomus tumor in the middle ear and hypotympanic space is achieved by extending the facial recess approach. Opening the retrofacial infralabyrinthine air cells provides exposure of the posterior margins of the tumor. **B,** Surgical photo of extended facial recess approach providing access to the hypotympanum.

- The temporal bone dissection described for the transmastoid glomus tympanicum tumor is performed.
- The facial recess is opened, and the chorda tympanic nerve is sacrificed to form an extended facial recess approach. Retrofacial and infralabyrinthine air cells and bone are removed to the stylomastoid foramen. The facial nerve is skeletonized, leaving eggshell-thin coverage, creating a "fallopian bridge" (see Fig. 142.3).

- The digastric ridge is delineated within the mastoid cavity. Dissection is continued anteriorly toward the stylomastoid foramen. The mastoid tip may have to be removed. It is sometimes necessary to expose the posterior fossa dura both posterior and anterior to the sigmoid sinus. The sigmoid sinus is also decompressed. Some bone is left over the proximal sigmoid sinus near the sinodural angle (above Donaldson's line). The sigmoid sinus is carefully dissected free from the overlying roof of bone. This exposure provides access to extraluminal packing or suture ligation of the sinus. Dissection is continued along the sigmoid sinus toward the jugular bulb. All bone must be removed from this area (Fig 142.5).

FIG. 142.4 The postauricular incision is carried into the neck. The carotid artery, jugular vein, and lower cranial nerves are isolated. The sternocleidomastoid and digastric muscles are retracted.

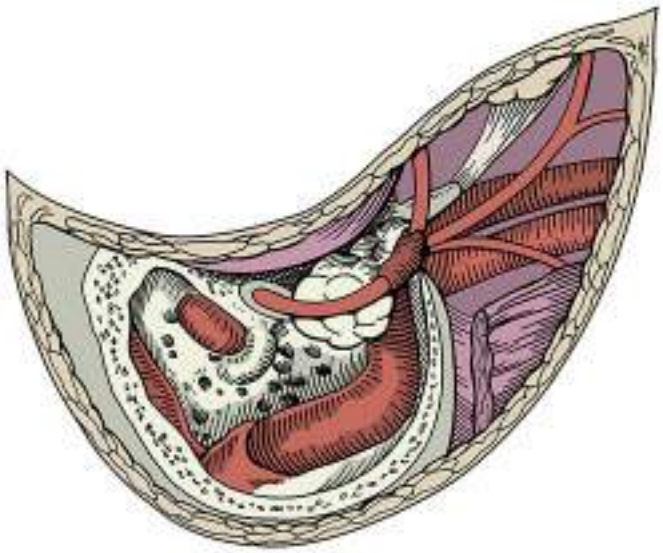

FIG. 142.5 Canal wall down transmastoid tumor dissection isolating the sigmoid sinus, vertical facial nerve along the extended facial recess, digastric ridge, neck vessels, and lower cranial nerves.

- Prior to opening the sigmoid sinus to expose the intraluminal portion of the tumor, proximal and distal control of the sigmoid sinus must be achieved. The superior portion of the sigmoid sinus may be occluded by either extraluminal packing or ligation. Extraluminal occlusion is performed with oxidized cellulose that is packed under a retained shelf of bone covering the proximal sigmoid sinus. If this is not successful or feasible, ligation of the sinus is performed by making small openings in the dura anterior and posterior to the sigmoid sinus. An aneurysm needle is passed from posterior to anterior deep to the sigmoid sinus. The needle is blindly passed medial to, but hugging, the sigmoid sinus, avoiding injury to the intracranial contents (cerebellum). A long 2-0 silk ligature is passed through the aneurysm needle up to its midlength, and the aneurysm needle is withdrawn. The suture is then cut in half, so as to leave two separate ligatures (Fig. 142.6). A small piece of muscle is harvested and placed over the sigmoid sinus, and the first suture is tied and secured. The second suture is similarly tied, thus providing double ligation and occlusion of the proximal sigmoid sinus.
- The jugular vein in the neck is then doubly ligated. If the tumor extends into the cervical portion of the jugular vein, the proximal

stump of the jugular vein in the neck is dissected superiorly toward the jugular bulb and fossa (Fig. 142.7). Care is taken to preserve the spinal accessory nerve. It is usually necessary to pass the proximal stump of the jugular vein medial to the spinal accessory nerve in order to facilitate the superior dissection. If the tumor does not extend into the cervical area, the tied off jugular vein may be left in situ. The distal extratemporal ICA should be in direct view as the jugular vein is dissected toward the jugular bulb. The styloid process and its muscular attachments may need to be removed in order to gain access to the skull base.

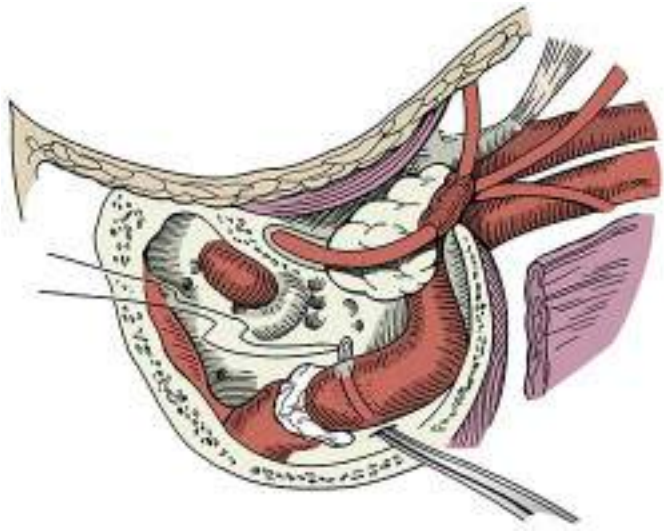

FIG. 142.6 The extended facial recess approach exposes the tumor in the hypotympanum. The vertical portion of the facial nerve remains in place. The proximal sigmoid sinus can be isolated by extraluminal packing or suture ligation.

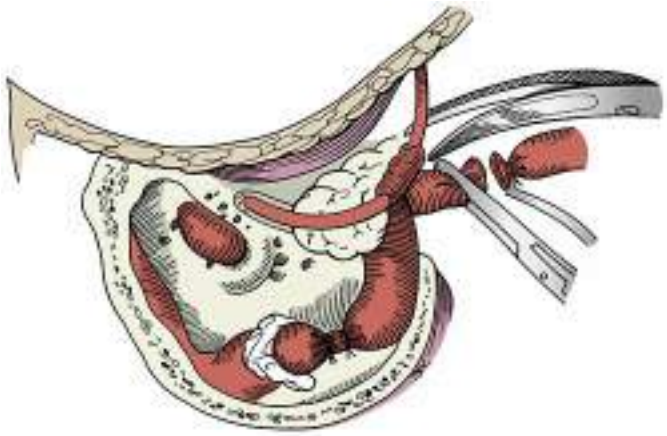

FIG. 142.7 Proximal control of the sigmoid sinus is achieved. Surgicel packing can also be used to occlude the proximal sigmoid sinus. The jugular vein is divided, and the proximal segment is dissected into the jugular fossa. The anterior plane of dissection is along the carotid artery, which is shown in Fig. 142.6.

- The tumor may now be removed in a piecemeal fashion to the remnant around the sigmoid sinus and jugular bulb. In addition to bipolar cautery, small cotton balls or cottonoid patties soaked with 1:1000 epinephrine may be used to compress sites of bleeding during removal of the tumor.
- The sigmoid sinus is opened distal to the ligatures in order to inspect the intraluminal contents. Usually, the medial wall of the sigmoid sinus is not invaded by a tumor unless there is intracranial extension. The inferior aspect of the sigmoid sinus is incised in a longitudinal direction toward the jugular bulb. The tumor is sequentially isolated from a posterior-to-anterior direction, dissecting the superior, lateral, and inferior walls of the sigmoid sinus from the medial wall. Bipolar coagulation is usually needed to obtain hemostasis and shrink the tumor. The lateral and superior aspect of the jugular bulb are dissected toward the superior extent of the tumor.
- The tumor often occludes the jugular bulb. However, once the tumor is removed from this area, brisk bleeding may be encountered from the multiple orifices of the inferior petrosal sinus and condylar vein. The medial jugular bulb is packed with oxidized cellulose. This dissection is performed medial (deep) to the vertical portion of facial nerve and

stylomastoid area. Care must be taken to avoid trauma or pressure to the medial (deep) surface of the facial nerve. The tumor often remains in the hypotympanum and middle ear. This is removed by working both medial and lateral to the facial nerve.

- Dissection medial to the medial wall of the jugular bulb will entail dissection of the lower cranial nerves. The recent trend is not to remove this portion of the tumor unless absolutely necessary, in order to reduce the risk of postoperative dysphagia and other lower cranial nerve morbidities. The remaining tumor may be observed or treated with radiation.
- Certain intraoperative findings may necessitate a canal-wall-down procedure. The first is the need for increased exposure of tumor invading the carotid artery. Also, limited space in the retrofacial and infralabyrinthine areas may require transposition of the facial nerve in order to provide adequate exposure of the tumor. Reconstruction of the tympanic membrane and ossicular chain can still be performed as needed.
- Unless the medial wall of the jugular bulb, sigmoid sinus, or posterior fossa dura is penetrated, CSF is not encountered. The dead space created by the removal of bone and tumor may be partially obliterated with abdominal adipose tissue if CSF leak is a concern. Otherwise, the defect may be left aerated. Packing of the ear canal is identical to that described previously. A Penrose drain is placed deep to the cervical skin flaps if there has been a significant neck dissection. A Hemovac drain can also be used, but suction is turned off after 1 day, as it will tend to suck air through the eustachian tube. The postauricular wound is closed in three layers, reapproximating the musculoperiosteum, subcutaneous tissue, and skin.

Large Glomus Jugulare Tumors (Fisch Type C_2 or Greater)

Glomus tumors that invade the petrous apex, horizontal portion of the ICA, and/or cavernous sinus require a postauricular infratemporal exposure (see Chapter 121) in addition to the temporal bone portion of the dissection described in the previous section. Typically, the ear canal will need to be removed and the meatal opening closed. If there has been

a significant dural resection, eustachian tube closure and abdominal fat obliteration of the skull base defect will be needed (see Chapter 144 and Chapter 121).

The vertical segment of the facial nerve may interfere with access to large tumors filling the jugular fossa and invading the carotid artery. Facial nerve transposition is sometimes necessary to achieve optimal exposure.

- The facial nerve is decompressed from the geniculate ganglion to the stylomastoid foramen with cutting and then diamond burrs. Favorable anatomy may permit more limited mobilization of the facial nerve from its second genu.
- Precise dissection and isolation of the facial nerve in the stylomastoid foramen is difficult. The transposition is facilitated by cutting the remaining tendon and posterior belly of the digastric muscle within the mastoid proximal to the stylomastoid foramen.
- The muscle, along with the contents of the stylomastoid foramen, is elevated from the underlying bone in a posterior-to-anterior direction. The facial nerve is then dissected away from the fallopian canal. The cuff of fibrous tissue surrounding the facial nerve is sutured anteriorly to the periparotid fascia, providing retraction of the vertical and horizontal facial nerve (Fig. 142.8).

Common Errors in Technique

1. Inadequate exposure of the infratemporal fossa based on incomplete surgical planning may lead to less than expected degree of tumor removal.

2. The surgeon must be prepared to control a CSF leak if the dura is entered. Not anticipating this event may lead to serious wound and infectious complications.

3. Overaggressive dissection of the jugular foramen pars nervosa will lead to significant dysfunction of the lower cranial nerves postoperatively.

4. Inadequate planning for ICA management may result in catastrophic hemorrhage or cerebrovascular accident (CVA).

Postoperative Period

Postoperative Management

1. Check hematocrit if there was significant blood loss.
2. Monitor for CSF leak—rhinorrhea or otorrhea or wound leak
3. Evaluate lower cranial nerve function.
   a. Dysphagia
   b. Hoarseness/aspiration: Vocal cord function
   c. Dysfunction of the shoulder
   d. Dysfunction of the tongue

Complications

1. CSF leak (see Chapter 144 and Chapter 124)
   a. Lumbar drainage for 3 to 5 days
   b. Pressure mastoid dressing and pressure dressing to the neck as tolerated
   c. Surgical repair if needed
2. Dysphagia and hoarseness (see Chapter 46)
   a. Standard barium swallow study versus flexible endoscopic evaluation of swallowing with sensory testing (FEEST)
   b. Appropriate diet based on degree of dysphagia
   c. Nasogastric or gastric tube while non per oris
   d. Vocal cord medialization laryngoplasty with or without cricopharyngeal myotomy as needed (see Chapter 5)
3. Shoulder dysfunction
   a. Physical therapy as needed

Alternative Management Plan

1. Observation with serial imaging

2. Radiation therapy

   a. Stereotactic radiosurgery (SRS, single fraction)

   b. Stereotactic radiotherapy (multiple fractions)

   c. External beam radiation

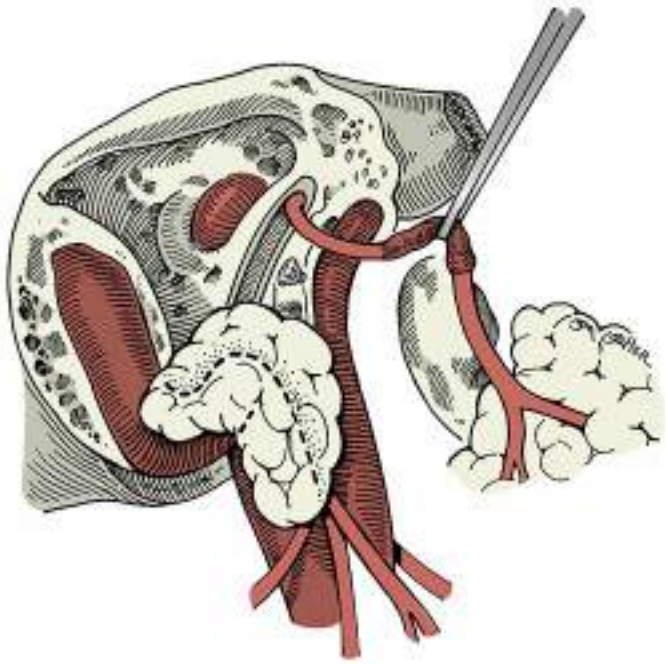

FIG. 142.8 The facial nerve has been mobilized anteriorly, exposing the tumor in the mastoid, middle ear, and jugular bulb areas. The tendons attached to the styloid process have been divided. Retraction of the mandible permits isolation of the carotid artery.

   d. Stereotactic radiosurgery or radiotherapy may provide effective control of tumor when given as the primary modality of treatment, following recurrence of tumor, or as part of the planned strategy for subtotal resection.

Discussion

Evidence-Based Medicine Questions

What is the long-term tumor control rate with surgical resection and/or radiation?

In patients who undergo gross total tumor resection, the long-term recurrence rate is very low, especially for glomus tympanicum tumors.[2] For glomus jugulare tumors, the data are difficult to interpret due to the heterogeneity of tumor parameters and treatments. A recent meta-analysis[3] revealed that patients treated with subtotal resection were observed for 72 ± 7.9 months and had a tumor control rate of 69%. Those who underwent gross total resection (GTR) had a follow-up of 88 ± 5.0 months and a tumor control rate of 86%. Those treated with STR and SRS were observed for 96 ± 4.4 months and had a tumor control rate of 71%. Patients undergoing SRS alone had a follow-up of 71 ± 4.9 months and a tumor control rate of 95%. The difference in outcomes could be due to a combination of treatment effects versus differences in tumor parameters or other differences between groups.

What is the long-term lower cranial nerve dysfunction associated with treatment of glomus jugulare tumors?

The lower cranial nerve function is typically very good if the tumor does not involve the pars nervosa of the jugular foramen. If the pars nervosa requires dissection, there is a high incidence of persistent lower cranial nerve dysfunction. A significant number of patients who had pre-existing dysfunction or developed new dysfunction postoperatively will likely require adjuvant treatments.[4]

Radiation options provide a treatment alternative with improved lower cranial nerve dysfunction. Martin et al.[5] reported that pre-existing cranial neuropathies improved in 20% and remained stable in 77% after radiosurgery. One patient had worsened lower cranial nerve function. The function of all previous intact nerves was preserved after radiosurgery. The 5- and 10-year actuarial control rates were 97% and 94%, respectively.

Editorial Comment

The diagnosis and management of paraganglioma (glomus tumors) of the head and neck have become more sophisticated and challenging. Approximately 20% of patients with glomus tumors have a genetic

familial predisposition, with these patients being more likely to have multicentric and bilateral tumors, often presenting at a younger age. There are four paraganglioma loci (paraganglioma [PGL] 1, 2, 3, and 4) on two chromosomes responsible for inheritance. Mutations of the succinate-dehydrogenase (SDH) genes are linked to familial autosomal dominant patterns of inheritance. Identification of a patient carrying the mutation prompts full investigation of other tumor foci and the need to screen family members.

The pendulum is swinging in terms of management strategies for glomus jugulare tumors. The advancements in surgical resection and reconstruction techniques fostered aggressive interventions in removing these vascular tumors. Decades ago, the method for treatment was full course external beam radiation. Improvement in methods of embolization, intraoperative stabilization of blood pressure by skilled anesthetists, and reliable, effective methods of wound closure promoted multidisciplinary surgical teams to address these tumors. The significant morbidity experience by patients when the lower cranial nerves were sacrificed forces reconsideration as to the most appropriate intervention. Today, patients with large jugular paraganglioma and normal lower cranial nerve function are steered away from aggressive surgery alone. Subtotal resection is advocated with planned postoperative stereotactic radiation to the remainder of the tumor. It remains to be seen in the next 10 to 20 years if radiation both minimizes harm and offers long-term tumor control.

This chapter provides an excellent overview of the surgical management of jugulotympanic paraganglioma. The appropriate preoperative preparation and surgical planning can be tailored to safely offer resection based on the factors outlined previously. Familiarity with the skull base anatomy, surgical techniques, and the potential collaboration with colleagues from interventional radiology, plastics, neurosurgery, and radiation oncology provide strategies for optimal management.

Review Questions

1. Which modality is the best to evaluate for intracranial extension of glomus tumor?

   a. CT

   b. Arteriogram

   c. **MRI**

   d. Nuclear medicine scan

   e. a and b

2. Complications related to dissection of the jugular foremen pars nervosa do not include

   a. **Dysfunction of the tongue**

   b. Dysfunction of the vocal cord

   c. Dysfunction of the shoulder

   d. Pharyngeal dysphagia

   e. c and d

3. In order to preserve lower cranial nerve function, the following structure must be preserved

   a. Fallopian canal

   b. **Medial wall of the jugular bulb**

   c. Lateral wall of the jugular bulb

   d. Anterior belly of the digastric

   e. Posterior canal wall

Cholesterol Granulomas and Congenital Epidermoid Tumors of the Temporal Bone

Julie P. Adelman, and Pamela Roehm

Introduction

Benign lesions of the temporal bone present treatment challenges due to their central location among critical neurovascular structures. These lesions may remain undetected for years due to their insidious growth pattern and are often diagnosed incidentally by radiologic imaging. Larger lesions can encroach upon adjacent neurovascular structures, presenting with hearing loss, tinnitus, vertigo, cranial neuropathies, or headaches. Accurate diagnosis of petrous apex lesions is made possible by computed tomography (CT) and magnetic resonance imaging (MRI) characteristics. The surgical approach to lesions of the petrous apex varies based on the type and location of the lesion (Fig. 143.1).

The petrous apex is a pyramidal bony structure at the most medial aspect of the temporal bone (Fig. 143.2). At its base is the otic capsule, the canal of the tensor tympani muscle, and the petrous carotid artery. The superior boundary is the floor of the middle cranial fossa, extending from the arcuate eminence of the superior semicircular canal to the Meckel cave. The jugular bulb, vertical petrous carotid canal, and inferior petrosal sinus make up the inferior border. Posteriorly, the petrous apex is bounded by the posterior cranial fossa, extending from the posterior semicircular canal and endolymphatic sac to the petroclinoid ligament. Anteriorly, the petrous bone articulates with the greater wing of the sphenoid bone, extending medially to the foramen lacerum. The petrous bone articulates with the squamous portion of the temporal bone at its lateral edge.

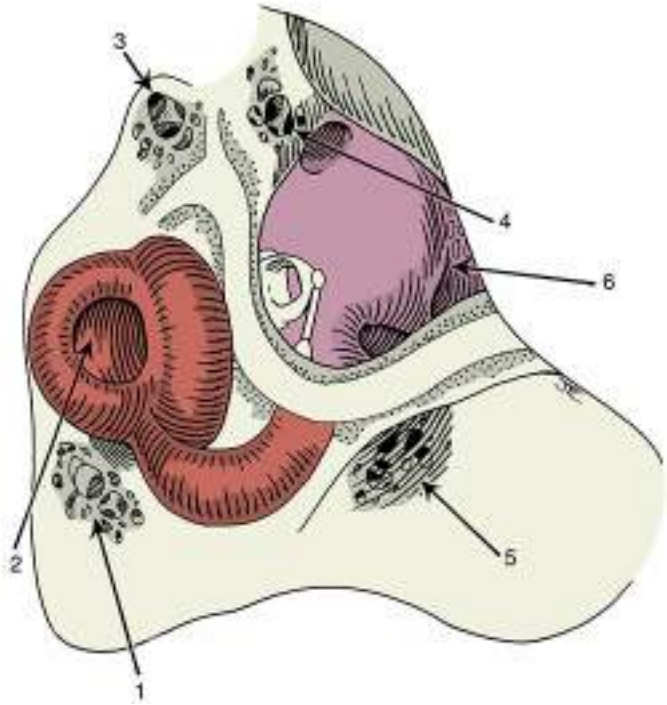

FIG. 143.1 Approaches for petrous apex cholesterol granuloma drainage. *1,* Supralabyrinthine tract inferior to the middle fossa dura; *2,* subarcuate tract through the superior semicircular canal; *3,* air cells of the root of the zygoma; *4,* small triangular region of bone between the genu of the carotid artery and the cochlea; *5,* retrofacial infralabyrinthine tract; *6,* infracochlear air cell tract.

The petrous apex may be divided into anterior and posterior portions by a vertical line drawn in the coronal plane through the internal auditory canal. Use of this plane as a dividing line can help determine the appropriate approach to lesions of the petrous apex.[1] Most petrous bones are filled with bone marrow or alternatively comprised of dense bone. However, 30% of petrous apices are pneumatized.[2] Pneumatization of the petrous apex may be highly variable and can differ from side to side in the same patient.

Although rare, there are a wide variety of lesions of the petrous apex. Asymmetric fatty marrow and unilateral opacification of the petrous apex air cells are the most commonly identified radiologic "abnormalities" of the petrous apex. It is important to correctly diagnose these entities, as they may be confused with dangerous pathologies, resulting in misdiagnosis and unnecessary evaluation or intervention.

These lesions typically do not require surgical intervention and can be managed effectively by observation alone.[3] Unilateral effusions may be noted in pneumatized petrous apexes. These almost uniformly cause consternation in radiologists, who often describe these as "petrous apicitis" or as tumors of the petrous apex. If asymptomatic, these do not require further treatment. If effusions cause troublesome symptoms, initial treatment includes a trial of antibiotic and steroids, with surgical drainage reserved for recalcitrant cases.[4]

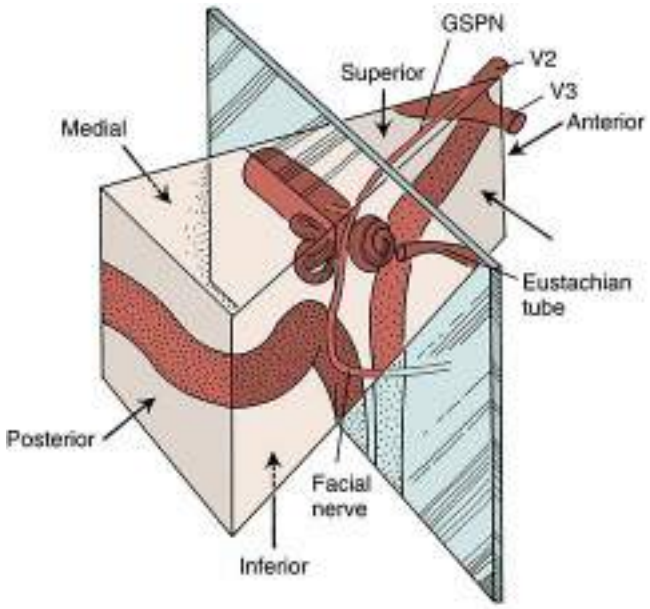

FIG. 143.2 Petrous portion of the temporal bone. A coronal plane through the internal auditory canal separates the posterior and anterior petrous apex. The greater superficial petrosal nerve (GSPN) runs along the superior surface of the petrous bone. The gasserian ganglion and the mandibular division of the trigeminal nerve are located in the apex. *V2*, second branch of trigeminal nerve, *V3*, third branch of trigeminal nerve.

True lesions of the petrous apex can be categorized as cystic or solid. Cystic lesions include cholesterol granulomas, congenital epidermoid tumors (cholesteatomas), and mucoceles. Solid lesions of the petrous apex include chondromas, chondrosarcomas, and metastatic carcinomas. All of these pathologies can be more rarely identified within the other portions of the temporal bone. Lesions of the temporal bone are often

asymptomatic and increasingly identified serendipitously on imaging for other complaints. When symptomatic, these lesions cause complaints of headaches or signs due to impingement on neurovascular structures. Within the petrous apex, hearing loss is the most common presenting symptom (64%), followed by dizziness (49%), headache (43%), tinnitus (40%), and facial twitching (14%). Trigeminal paresthesia may also occur.[5] Symptoms more rarely reported include cranial neuropathies, facial paralysis, and diplopia. Eustachian tube involvement may present as recurrent otitis media or otorrhea.[6]

Cholesterol granulomas are the most common cystic lesion of the petrous apex (0.6 cases per million per year), occurring 10 times more frequently than cholesteatomas and 40 times more frequently than mucoceles.[4] A cholesterol granuloma is an intraosseous cyst with a fibrous lining, filled with a brown-yellow fluid composed of cholesterol crystals and inflammatory cells (Fig. 143.3). Cholesterol granulomas form as a result of anaerobic catabolism of blood and blood products. The blood products incite a foreign-body giant cell inflammatory response. They can form anywhere within pneumatized spaces of the temporal bone. Cholesterol granulomas lack a true epithelial lining and therefore do not require complete excision.

Congenital epidermoid tumors and acquired cholesteatomas are the second-most common lesions of the petrous apex. These slow-growing tumors comprise 4% to 9% of petrous apex lesions.[7,8] Epidermoids and cholesteatomas are sac-like cysts, lined by stratified squamous epithelium that contains keratin debris. The microscopic appearance of congenital epidermoids and acquired cholesteatomas is identical.[9] These lesions behave aggressively with the potential for progressive expansion and destruction of surrounding structures. Congenital epidermoid tumors are thought to arise from epithelial rests deposited within the temporal bone in early embryonic development. Acquired cholesteatoma occurs from medial spread of cholesteatoma originating within the middle ear or mastoid. These patients are more likely to present with symptoms of chronic otitis media.

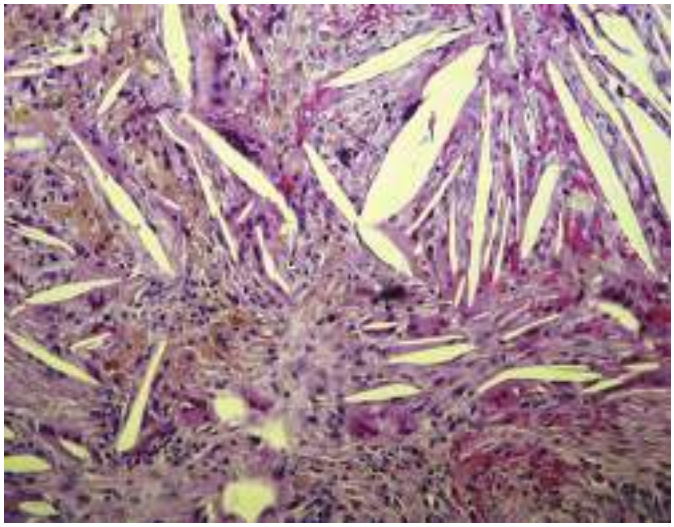

FIG. 143.3 Histopathology of cholesterol granuloma. Note the large cholesterol crystal surrounded by giant cells, macrophages, and fibrous connective tissue.

Like most lesions of the petrous apex, epidermoids often present when they become large. They produce symptoms by compression of the Eustachian tube, internal auditory canal, and cranial nerves or by putting tension on the surrounding dura; by the time most epidermoids are detected, cranial neuropathies are present (85%). In a series of 25 patients with cholesteatomas of the petrous apex, hearing loss was the most common presenting symptom (64%), followed by facial weakness (56%), dizziness (44%), otorrhea (32%), trigeminal paresthesia/neuralgia (12%), and cranial nerve VI palsy (4%).[10] These tumors often involve vascular structures as well, including the carotid artery. For these reasons, complete surgical resection of epidermoid tumors in this location can be difficult and recurrence can occur even with adequate exposure due to inability to remove all of the epidermoid from critical structures. The most common site for recurrent petrous epidermoids is in the region of the carotid artery.[10]

The common benign lesions of the petrous apex, cholesterol granulomas and petrous apex epidermoids, are often indistinguishable by history and physical examination alone, but typically can be diagnosed definitively by appropriate imaging (Table 143.1). Increasingly, benign lesions of the petrous apex are detected serendipitously on imaging ordered for other indications. If this occurs, appropriate imaging must still be performed to determine the type of

lesion and its extent. Accurate diagnosis is required prior to surgical management, because the approach for these lesions differs radically.

High-resolution temporal bone CT is valuable in both diagnosis and treatment planning. Cholesterol granulomas and petrous apex epidermoids are nonenhancing iso- or hypodense masses on brain-weighted algorithms. Irregularities and erosion of the temporal bone around the mass on CT indicates a more aggressive lesion (tumor or cholesteatoma; Fig. 143.4A), whereas smooth, thickened borders around the mass indicate benign, less-aggressive lesions (cholesterol granulomas) that have slowly increased in size over time (see Fig. 143.4B). High-resolution temporal bone CT is invaluable in delineating the precise anatomic relationship of the lesion to structures including the otic capsule, middle ear, carotid artery, and middle and posterior fossa. This detail is essential in determining the feasibility of different surgical approaches.

MRI of the brain and temporal bones is also a critical component of preoperative imaging. T1 signal hyperintensity indicates the presence of adipose tissue, blood, or proteinaceous fluid. T2 signal hyperintensity indicates the presence of water. Cholesterol granulomas have a very distinct appearance on MRI imaging (Fig. 143.5). Because cholesterol granulomas are composed of the breakdown product of blood and inflammatory products, they produce hyperintensity on both T1- and T2-weighted MRIs. In addition, cholesterol granulomas do not enhance with gadolinium. Other lesions of the petrous apex, including epidermoids, mucoceles, unilateral benign effusions, arachnoid cysts, and neoplastic lesions, tend to be iso- or hypointense compared with brain on T1 imaging. Epidermoids and acquired cholesteatomas are characteristically hyperintense on T2-weighted MRI and often do not enhance with gadolinium (if they do, the pattern of enhancement is irregular; Fig. 143.6A). On diffusion-weighted imaging (DWI), cholesteatomas are hyperintense (see Fig. 143.6B), whereas mucoceles, effusions, and arachnoid cysts are hypointense. Neoplasms are isointense on DWI. MRI also provides soft tissue detail and information about intracranial extension or involvement of neurovascular structures.

TABLE 143.1

Imaging Characteristics of Petrous Apex Lesions

	High-Resolution CT		MRI of Brain and Brainstem/Internal Auditory Canals				
Lesion	Bone Windows	Brain Windows	With Contrast	T1	T2	T1 with Contrast	DWI
Cholesterol granuloma	Smooth, thickened borders	Hypodense	No enhancement	Hyperintense	Hyperintense	No enhancement	Low intensity
Cholesteatoma or epidermoid	Irregular borders	Iso- or hypodense	No enhancement	Isointense	Hyperintense	No or irregular enhancement at borders	High intensity
Petrous apicitis	Irregular borders	Iso- or hypodense	Enhances	Hypointense	Hyperintense	Rim enhancement	Low intensity
Effusion	Fluid density with intact trabeculae and smooth ± thickened borders	Hypodense	No enhancement	Hypointense	Hyperintense	No enhancement	Low intensity
Mucocele	Smooth borders ± thickening, absent trabeculae	Hypodense	No enhancement	Hypointense	Hyperintense	No enhancement	Low intensity
Bone marrow	Non-expansile area with small bone trabeculae present	Iso- or hypodense	No enhancement	Hyperintense (suppresses with fat suppression)	Isointense	No enhancement	Low intensity
Encephalocele	Smooth borders	Iso- or hypodense	No or mild enhancement	Isointense	Isointense	No or mild enhancement	Low intensity
Arachnoid cyst	Smooth borders ± thickening	Hypodense	No enhancement	Hypointense	Hyperintense	No enhancement	Low intensity

Postoperative imaging is a crucial component of the care of lesions of the petrous apex. Following drainage of a cholesterol granuloma, the drained cavity may fill with fluid and thus make detection of a recurrence by CT difficult. However, serous fluid and recurrent cholesterol granuloma will have different appearances on T1-weighted

images. Serous fluid-filled cavities will have decreased signal intensity, whereas recurrence will remain hyperintense on T1-weighted imaging.[6] After resection of a petrous apex epidermoid, either MRI or CT can be used to monitor for recurrence.

a. History of otologic surgery

4. Family history

a. Family history of otologic disease

b. Family history of hearing loss

5. Social History

Physical Examination

1. Vital signs.

2. Examination of the head and neck including laryngoscopy.

a. General appearance.

b. Pneumatic otoscopy (assess external auditory canal, tympanic membrane, and middle ear).

c. Cranial nerve examination

Audiometry

1. Pure-tone audiogram

2. Speech thresholds using spondees

3. Word recognition

4. Tympanometry

5. Additional testing, such as auditory brainstem responses (ABRs) and caloric testing of vestibular function may also be indicated.

Imaging

1. High-resolution temporal bone CT
    a. Important in delineating bony structures and precise anatomic relationships
    b. Provides information about the behavior of the lesion with respect to involvement of the bone.
    c. Enables the surgeon to evaluate appropriate surgical approaches based on anatomy.
2. MRI
    a. Can differentiate between many lesions by characteristics of T1- and T2-weighted imaging.
    b. Some lesions enhance with gadolinium, whereas others do not.
    c. DWI helps to distinguish epidermoids from other lesions.
    d. MRI can be valuable for determining recurrence of cholesterol granuloma.

Indications

1. Cholesterol granuloma
    a. Large lesions causing hydrocephalus or other complications related to brain and brainstem compression
    b. Lesions causing cranial neuropathies
    c. Pathology causing severe or uncontrollable pain
    d. Cholesterol granulomas can be treated effectively by drainage into the mastoid cavity, middle ear, sphenoid sinus, or middle fossa. The goal of surgical drainage for cholesterol granulomas is to maintain permanent drainage of the cavity to prevent recurrence.
2. Epidermoids and acquired cholesteatomas should always be removed in their entirety if possible.

Contraindications

1. Small, asymptomatic cholesterol granuloma

2. Medical comorbidities with increased risks from general anesthesia

Preoperative Preparation

1. Discontinue antiplatelet drugs and warfarin prior to neurosurgical approaches.

2. Obtain image guidance scans if intraoperative guidance will be used.

Operative Period

Anesthesia

1. The procedure is performed under general anesthesia with orotracheal intubation.

2. Paralytic agents should not be used.

Positioning

1. The patient is positioned supine with the head extended for intranasal approaches.

2. The patient should be placed supine with the head turned toward the contralateral ear for middle fossa or lateral transtemporal procedures.

Perioperative Antibiotic Prophylaxis

1. First-generation cephalosporin

2. Clindamycin in the patient who is allergic to penicillin

Monitoring

1. Facial nerve monitoring is indicated for all mastoid and skull base approaches and strongly recommended for transnasal approaches for larger lesions.

2. Facial, lower cranial nerve, and somatosensory monitoring are used, especially if the surgical approach is in proximity to those nerves and the carotid artery.

3. Additional ipsilateral cranial nerve monitoring as indicated by the size of the lesion.

4. ABR monitoring for middle fossa approaches.

Instruments and Equipment to Have Available

1. Transmastoid and middle ear approaches
   a. Middle ear and mastoid set
   b. High-speed otologic drill and burs
   c. Binocular operating microscope
   d. 3-mm diameter 0- and 30-degree otoendoscopes.
   e. Silastic stent or drainage catheter
2. Middle fossa approaches
   a. Neurosurgical instruments including malleable retractors and adjustable brain retractors
   b. Basic middle ear and mastoid sets
   c. High-speed otologic drill and burs
   d. Silastic stent or drainage catheter
   e. Binocular operating microscope
3. Transsphenoidal approaches
   a. 0-, 30- or 45-, and 60-degree endoscopes
   b. Endoscope cleaning device
   c. Transsphenoidal endoscopic instrument set
   d. Suction bipolar
   e. Endoscopic bipolar

f. Silastic stent or drainage catheter

Prerequisite Skills

1. Middle ear and mastoid approaches
   a. Tympanoplasty
   b. Canaloplasty
   c. Mastoidectomy
   d. Canal wall down (CWD) mastoidectomy
2. Middle fossa approaches
   a. Craniotomy
   b. Knowledge of the anatomy of the middle fossa
3. Transsphenoidal approaches
   a. Endoscopic sphenoidotomy
   b. Transsphenoidal pituitary approach

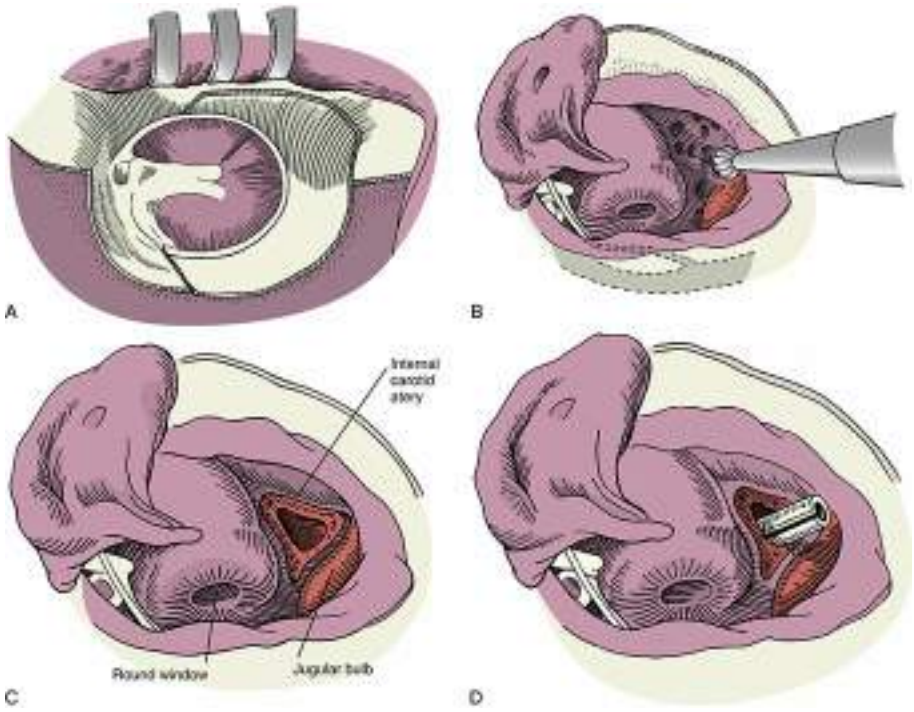

FIG. 143.7 Infracochlear approach. **A,** The superiorly

based tympanomeatal flap is incised. The prominent anteroinferior bony canal wall will be removed. **B,** The superiorly based tympanomeatal flap is elevated to expose the mesotympanum and hypotympanum. A cutting burr is used to remove the prominence of the anterior canal wall and the inferior tympanic ring for further exposure of the hypotympanum. Care is taken posteriorly to avoid the vertical portion of the facial nerve. **C,** A diamond burr is used to remove the hypotympanic air cells. The limits of dissection are the internal carotid artery anteriorly, the jugular vein posteroinferiorly, and the basal turn of the cochlea superiorly. **D,** A rolled Silastic sheet is placed in the opening of the fistula from the cystic cavity to the hypotympanum.

Operative Risks

1. For all approaches
   a. Facial nerve paresis/paralysis
   b. Hearing loss
   c. Wound infection
2. For middle ear and mastoid approaches, additional risks include the following:
   a. Bleeding from the internal carotid artery and jugular bulb
   b. Tympanic membrane perforation
3. For middle fossa approaches, additional risks include the following:
   a. Cerebrospinal fluid leak
   b. Bleeding from the middle meningeal artery
   c. Bleeding from the internal carotid artery
   d. Cerebrovascular accident
4. For transsphenoidal approaches, additional risks include the following:
   a. Cerebrospinal fluid leak

b. Bleeding from the carotid

c. Blindness

d. Diplopia

Surgical Technique

The selection of the appropriate surgical approach for a given petrous apex lesion is based primarily on the patient's preoperative hearing and balance status and the location of the lesion relative to the surrounding neurovascular structures. Approaches may be divided into hearing-preservation and non-hearing-preservation techniques.

Infracochlear Approach

The infracochlear approach was initially described by Ghorayeb and Jahrsdoerfer. This hearing-preservation approach has the advantage of providing a dependent drainage pathway from the cyst into the middle ear space (Fig. 143.7A–D). Although the window of exposure is narrower than that achieved using the infralabyrinthine approach, the approach is more direct. This technique has the added benefit of increased safety in patients with a high jugular bulb. This approach is infrequently used for cholesteatomas, but occasionally may be indicated in patients with small cholesteatomas in this area who have intact hearing. For patients with cholesteatoma, no stent is required.

1. A post auricular incision is made through the skin.

2. A Palva flap is elevated, exposing the bony external auditory canal.

3. A superiorly based tympanomeatal flap is created by incising the canal skin at the bony-cartilaginous junction.

4. The hypotympanum is exposed by removing anterior and inferior tympanic bone using an otologic drill.

5. The chorda tympani nerve is followed posteroinferiorly to find the facial nerve.

6. The jugular bulb and petrous carotid artery are identified.

7. Dissection anteromedially between the jugular bulb and carotid artery

is performed using diamond burrs and curettes.

a. The round window is the superior boundary of dissection.

8. The cyst is entered medially and its contents removed.

a. Visualization of the cavity can be aided by intraoperative otoendoscopy.

b. For cholesterol granulomas, the cyst cavity is irrigated copiously with sterile saline.

9. Silastic tubing is inserted to stent the drainage pathway.

a. The lateral end of the tubing should extend into the middle ear.

10. The bony canal defect can be repaired using bone pate collected during drilling of inferior tympanic ring.

11. The tympanomeatal flap is placed back into position.

12. The external auditory canal is packed with Gelfoam.

13. The post auricular incision is closed.

Retrofacial Infralabyrinthine Approach

The infralabyrinthine approach provides a direct route to most petrous apex cholesterol granulomas (Fig. 143.8). This approach should be used with caution in patients with high-riding jugular bulbs, because adequate visualization of this structure is not afforded by this approach.

1. A post auricular incision is made, and the auricle is reflected anteriorly.

2. A Palva flap is elevated, and the bony external auditory canal is exposed.

3. A complete mastoidectomy is performed.

4. The sigmoid sinus is skeletonized and may be decompressed as needed.

5. The facial nerve, posterior semicircular canal, and jugular bulb are identified.

6. Using diamond burrs and curettes, the infralabyrinthine air cell tracts

are followed anteromedially until the lesion is encountered.

7. The cyst contents are removed and the cavity irrigated.

8. A Silastic stent is placed in the cyst cavity, extending into the mastoid.

9. The musculoperiosteal flap and skin incisions are closed, and a mastoid dressing is placed.

Middle Cranial Fossa Approach

This hearing-preservation approach provides access to the petrous apex from above the auricle (Fig. 143.9). The middle fossa approach has fallen out of favor for drainage of cholesterol granulomas, because it does not often allow long-term drainage of the cyst. The cyst must be removed in its entirety to successfully treat a cholesterol granuloma using this approach. It retains its usefulness for epidermoids and benign and malignant tumors within the area.

1. A question-mark-shaped incision (reverse question mark on the right) is made through the skin and subcutaneous tissue above the auricle, extending 1 cm within the crease just anterior to the pinna to the superior edge of the tragus.

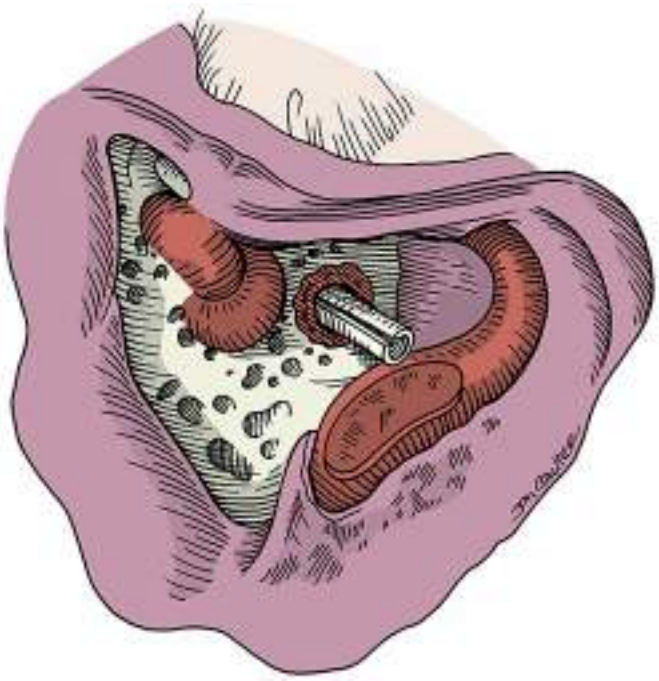

FIG. 143.8 Retrofacial infralabyrinthine approach. A transcortical mastoidectomy is performed to identify the antrum, posterior semicircular canal, facial nerve, digastric ridge, and jugular bulb. A Silastic tube from the mastoid into the cyst provides drainage and aeration.

2. A stepped incision is made through the temporalis muscle and fascia and they are elevated anteriorly, exposing the root of the zygoma.

3. A middle fossa craniotomy is performed just superior to the pinna.

4. The bone flap is removed, and the dura is dissected off the floor of the middle cranial fossa from posterior to anterior.

5. A self-retaining temporal lobe retractor is placed.

6. The middle meningeal artery, arcuate eminence, and geniculate ganglion are identified.

7. Further dissection is directed by location of the lesion.

Endoscopic Transsphenoidal Approach

With the development of minimally invasive, endoscopic techniques and intraoperative image guidance, endonasal transsphenoidal approaches to appropriately selected lesions of the petrous apex can be performed. This approach leaves both hearing and balance intact.

Endoscopically, the petrous apex may be entered by a medial approach with lateralization of the internal carotid artery, or by a transpterygoid infrapetrous approach. For benign lesions of the petrous apex, the risks associated with carotid manipulation are considered too great; this approach will not be discussed.

1. For medial transsphenoidal approaches, the patient is placed supine on the operating table and the nasal mucosa is decongested with both topical and injected agents.

   a. Image guidance is used during these surgeries. The images (sinus CT ± MRI) are registered prior to beginning the procedure.

2. The middle turbinates are outfractured or trimmed to allow visualization of the sphenoid ostia.

3. The mucosa overlying the sphenoid and posterior nasal septum is cauterized.

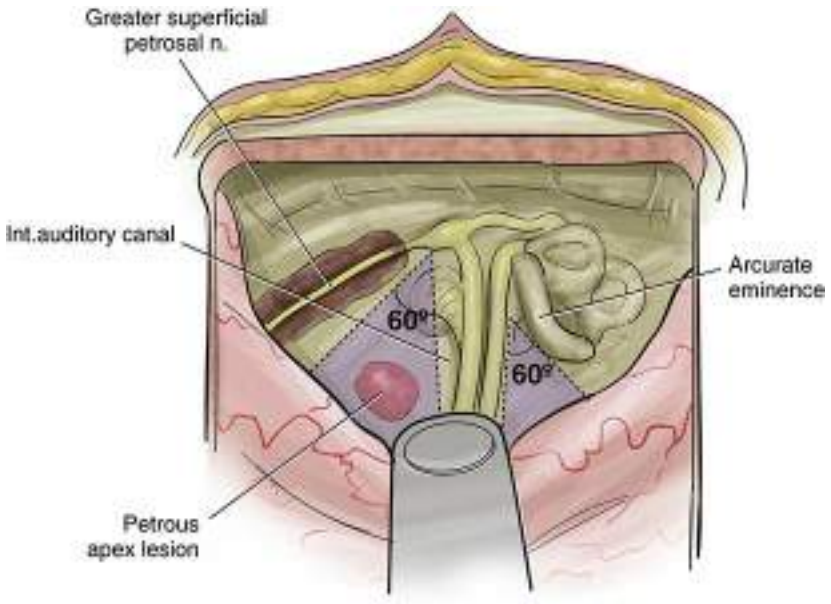

FIG. 143.9 Middle cranial fossa approach to the petrous apex, with typical site of lesion shown.

4. The posterior nasal septum is transected at the bony-cartilaginous junction and detached from the sphenoid rostrum.

5. 1.0 to 1.5 cm of the posterior septum is removed to facilitate visualization and manipulation of surgical instruments.

6. Bilateral sphenoidotomies are performed.

7. The operative landmarks including the planum sphenoidale, sella, clivus, optic canal, and carotid canal are identified.

8. The mucosa of the sphenoid sinus is removed.

9. A diamond burr may be used to thin the bony posterior wall of the sphenoid sinus at the medial wall of the lesion.

10. When the bone is thin enough, a Kerrison ronguer is used to unroof the cyst.

11. The contents of the cyst are then drained, and the region should be irrigated copiously.

12. A Silastic stent is placed through the opening into the cyst.

13. Doyle splints and nasal packing are placed in the nares bilaterally and removed on the third postoperative day.

14. The patient can be discharged on the day of surgery.

A more extensive approach may be necessary if the sphenoid sinus is poorly pneumatized or the cyst is located in a more posterolateral position. In such circumstances, the medial approach may be used. This modified technique involves decompression of the internal carotid artery and creation of a larger medial approach. The internal carotid artery is located by identifying the Vidian artery and nerve. The Vidian nerve can be identified by entering the pterygopalatine fossa and dissecting laterally until the nerve is seen exiting from the pterygoid canal. By removing bone medial and inferior to the canal, the operative field is widened by several millimeters and the internal carotid artery can be identified at its second genu. (See Chapter 120)

The most significant complication of this approach is recurrence due to stenosis of the drainage pathway, even with the use of a stent.

Tympanomastoidectomy with Exteriorization

Lesions of the petrous apex can be marsupialized and drained externally, often into a CWD mastoidectomy cavity (Fig. 143.10). Although cochlear hearing can be preserved by this approach, the patient will experience a maximum conductive hearing loss following the procedure.

1. A postauricular skin incision is made and the pinna retracted anteriorly.

2. A large, anteriorly based postauricular musculoperiosteal flap is elevated.

3. The mastoid antrum, incus, and horizontal semicircular canal are identified and are used as landmarks.

4. A tympanomeatal flap is elevated, and the middle ear is entered

5. The incudostapedial and incudomalleolar joints are disarticulated, and the incus is removed.

6. The posterior canal wall is taken down, and the facial ridge is lowered

to the level of the external auditory canal.

7. The skin of the external auditory canal and tympanic membrane are completely removed.

8. Drilling continues anteriorly through the zygomatic root until the geniculate ganglion is identified, and dissection is carried out along the greater superficial petrosal nerve.

9. Dissection along this nerve opens the petrous apex through the air cells of the zygomatic root.

10. The contents of the cholesterol granuloma are removed, and the cavity is irrigated.

11. The external auditory meatus is then closed.

12. The postauricular incision is closed, and a mastoid dressing is applied.

Translabyrinthine Approach

This approach accesses lesions located in both the anterior and posterior petrous apices (Fig. 143.11). One disadvantage of this procedure is that residual ipsilateral hearing and vestibular function are sacrificed. Patients with preoperative residual vestibular function will require hospitalization for supportive therapy during the acute phase of their vestibular compensation. Patients who had no preoperative ipsilateral vestibular function and in whom the cerebrospinal space is not entered can be discharged on the day of surgery.

1. A C-shaped postauricular incision is made and the auricle is reflected anteriorly.

2. An incision is made in the periosteum along the temporal line superiorly and carried inferiorly to the mastoid tip.

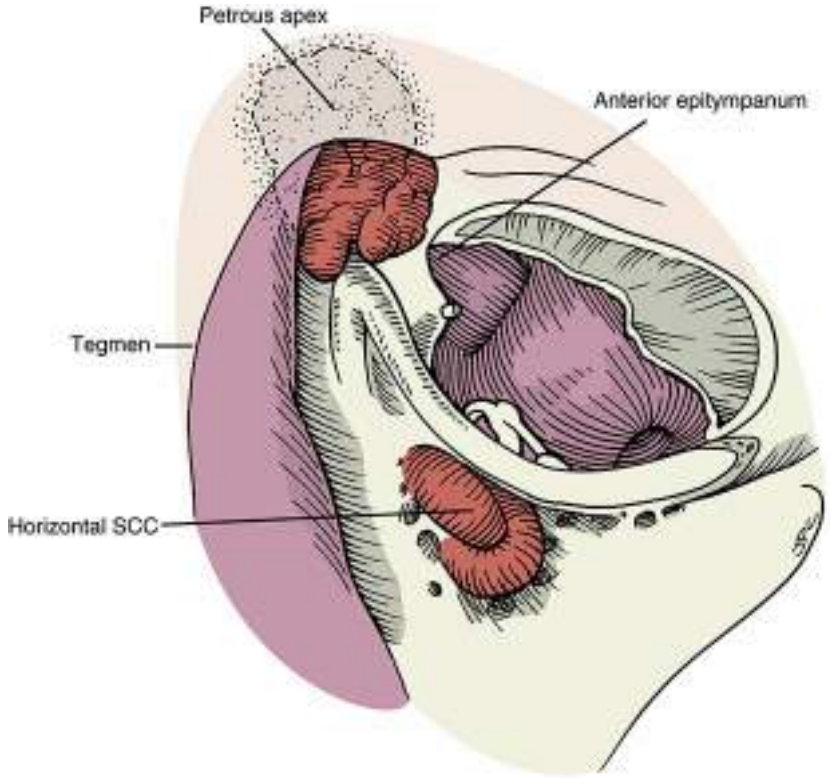

FIG. 143.10 Tympanomastoid exteriorization. A canal wall down (CWD) mastoidectomy is used to expose the anterior epitympanum and the cholesteatoma in the petrous apex *(shown in gray)*. Dissection along the greater superficial petrosal nerve opens the petrous apex through the air cells of the zygomatic route. *SCC,* semicircular canal.

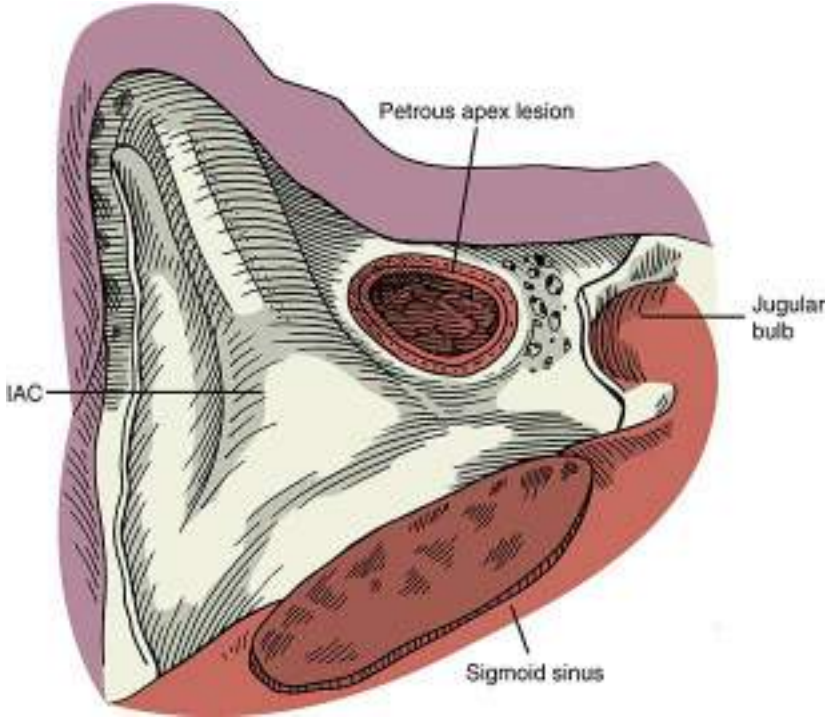

FIG. 143.11 Translabyrinthine approach to the petrous apex. The internal auditory canal (IAC) is skeletonized to create an inferior and superior trough around the porus acousticus. Care is taken to avoid the cochlear aqueduct and jugular bulb.

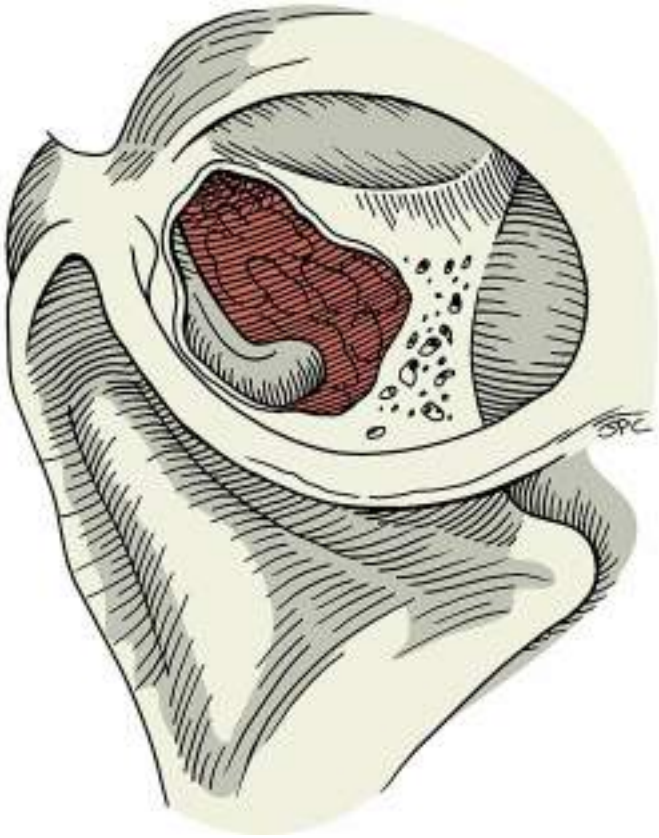

FIG. 143.12 Transcochlear approach to the petrous apex. The contents of the epidermoid tumor are removed while leaving the matrix lining intact.

3. The musculoperiosteal flap is elevated, exposing the external auditory canal.

4. A complete mastoidectomy is performed.

5. The mastoid antrum is entered, and the lateral semicircular canal is identified.

6. After identification of the posterior and superior semicircular canals, a labyrinthectomy is performed.

7. The internal auditory canal is identified but not entered.

8. The cyst is entered, and the contents of the cyst are drained.

9. The cavity is irrigated, and a drain is placed.

10. The musculoperiosteal flap is closed with absorbable sutures.

11. The skin incision is closed in layers, and a mastoid dressing is placed.

Transcochlear/Transotic Approaches

The transcochlear approach is an extension of the translabyrinthine approach that involves removal of the otic capsule in its entirety and can be useful when access to the anterior petrous apex is necessary (Fig. 143.12). This approach would not necessarily require rerouting of the facial nerve, depending on the angle of approach to the petrous apex. In these approaches, a blind-sac closure of the external auditory canal is performed. Both approaches result in loss of ipsilateral hearing and vestibular function.

1. A postauricular incision is made, and the auricle is reflected anteriorly.

2. A Koerner flap is elevated.

3. A CWD mastoidectomy is performed.

4. The tympanic membrane and ossicles are removed.

5. The chorda tympani nerve is cut, the tympanic bone is removed, and the facial ridge is lowered.

6. A labyrinthectomy may be performed if required.

7. The internal auditory canal is identified, and the facial nerve is either skeletonized leaving a thin bridge of bone or decompressed and dissected free.

8. The greater superficial petrosal nerve is identified and transected.

9. The bone of the cochlea is removed

10. Drilling is carried out anteriorly to expose the vertical and horizontal portions of the internal carotid artery.

11. The lesion is encountered and completely excised.

12. The Eustachian tube is plugged with muscle.

13. The cavity is obliterated with adipose tissue to contain a cerebrospinal fluid (CSF) leak if created.

14. The external auditory meatus is closed.

Common Errors in Technique

Cholesterol Granuloma

1. Failure to place an adequate drain.
   a. Recurrence occurs in 83% of patients without drain placement.
   b. The most common cause of recurrence in patients following drain placement is obstruction of the drainage pathway by fibrous tissue (18%).

Cholesteatoma

1. Failure to remove the cholesteatoma completely.[7]
2. Late recurrence (13%).[7]

Postoperative Period

Postoperative care after surgical treatment of a petrous apex lesion is highly dependent on the approach used. The extent of the operative procedure and the ease with which the procedure was performed should be taken into account when determining postoperative management (Fig. 143.13).

1. Following transmastoid, infracochlear, or infralabyrinthine procedures:
   a. The patient may be discharged the same day or after 23-hour observation. The mastoid dressing is removed on the first postoperative day following transcanal/transmastoid approaches.
   b. Start topical antibiotic drops postoperatively for 1 week following infracochlear or infralabyrinthine approaches or after transmastoid procedures where dissolvable packing is left in the ear canal.
   c. See patients 1 week postoperatively for check of the postauricular incision.
   d. See patients at 1 and 3 months postoperatively.
   e. Postoperative audiogram and CT or MRI 2 to 3 months following surgery.
2. Following translabyrinthine, transotic, and transcochlear approaches:

a. Hospitalization for 3 to 7 days for supportive therapy (IV hydration, antiemetics, and vestibular suppressants) during the immediate postoperative vestibular compensation period, depending on the amount of preoperative vestibular function present in the ipsilateral ear.

   1) Patients with preoperative loss of vestibular function will not require extensive hospitalization postoperatively.

b. Vestibular suppressants should be discontinued 2 to 3 days after surgery to allow central vestibular compensation to occur.

c. Obtain MRI or CT imaging to monitor the surgical site at 2 to 3 months.

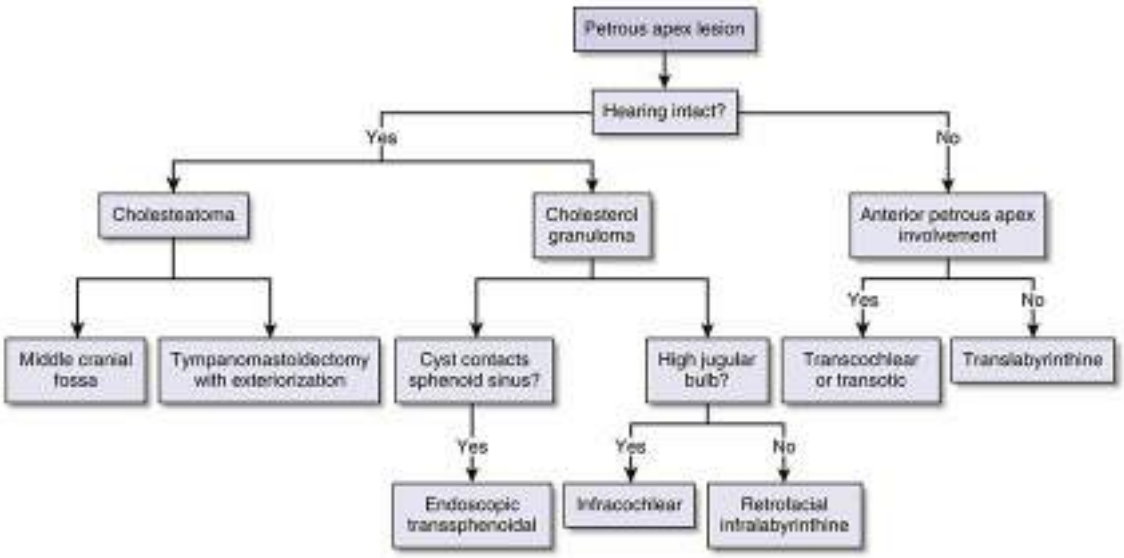

FIG. 143.13 Algorithm for management of benign lesions of the petrous apex.

3. Following middle fossa craniotomy, translabyrinthine, transcochlear, transotic, and other approaches that enter the cerebrospinal fluid space:

a. Patients should be monitored in a neurosurgical intensive care unit for 2 to 5 days for signs of CSF leak, meningitis, mental status changes, neurovascular injury, diabetes insipidus, cerebral salt-wasting syndrome, and other neurosurgical complications.

b. Obtain MRI or CT imaging postoperatively to assess and monitor the surgical site.

Complications

Complications are highly dependent on the surgical approach used and the extent of resection needed to treat the lesion effectively.

1. Recurrence/residual disease
    a. Cholesterol granuloma
        1) Observe if asymptomatic.
        2) Revision surgery by the same or an alternative approach.
    b. Cholesteatoma or epidermoid
        1) Revision surgery by the same or an alternative approach.
2. Tympanic membrane perforation
    a. Myringoplasty.
    b. Tympanoplasty.
3. Hearing loss
    a. Hearing aids. Conventional hearing aids can be used for conductive, mixed, or sensorineural hearing losses ranging from mild to severe.
    b. Contralateral routing of signals (CROS)/Bi-CROS aids or a bone-anchored hearing device can be used to remediate a unilateral profound hearing loss.
    c. Ossiculoplasty can be used to repair conductive hearing loss due to ossicular discontinuity.
4. Vertigo
    a. Losses due to approaches through the peripheral vestibular system can be treated with short-term use of vestibular suppressants with subsequent vestibular physical therapy.
    b. Dizziness due to benign paroxysmal positional vertigo can be treated with the Epley maneuver.
5. Cranial nerve deficits
    a. Facial nerve
        1) Facial nerve deficits due to intraoperative facial overstimulation

improve spontaneously.

2) If the facial nerve is transected intraoperatively, it should be repaired by end-to-end anastomosis or cable graft.

3) If the facial nerve is injured intraoperatively but not completely transected, it can be observed and tested postoperatively. If postoperative electroneurography (ENOG) shows a decrease of greater than 90% to 95% function within the first 2 weeks after surgery, operative exploration and decompression should be performed.

4) Long-term facial nerve deficits may require gold or platinum eyelid weight placement and/or lower lid tightening to protect the cornea.

5) Long-term facial nerve deficits may be treated with a number of techniques, including hypoglossal-to-facial anastomosis, temporalis muscle or fascia graft, facelift, brow lift, gracilis muscle transfer, or cross-facial grafting (see Chapter 180).

b. Cranial nerve (CN) IV and VI injury

1) Many deficits may be short term.

2) Deficits can be treated with prisms.

3) Long-term deficits can be treated with strabismus surgery or long-term use of prisms.

c. Lower cranial nerve injury

1) Deficits in the lower cranial nerves are rare. Primary treatment should focus on swallowing function, including use of vocal fold medialization techniques to improve function.

6. CSF leak

a. Lumbar drain

b. Operative CSF leak repair

7. Vascular injury or bleeding

a. Should be controlled intraoperatively.

b. Bleeding from the carotid artery or other vessels occurring postoperatively can be treated with endovascular stent placement or

revision surgery.

8. Wound infection

   a. Typically respond to oral or IV antibiotic therapy.

   b. Abscesses require operative incision and drainage.

Alternative Management Plan

These benign lesions of the petrous apex do not respond to chemotherapy or radiation. If asymptomatic, cholesterol granulomas of the petrous apex can be observed with serial imaging. Cholesteatomas of the petrous apex should always be removed unless the patient's medical status is too poor to undergo surgery.

Discussion

Evidenced-Based Medicine Question

Question: Does placement of a drain or stent improve longer-term successful drainage of petrous apex cholesterol granulomas?

Answer: Placement of a drain into the cholesterol granuloma significantly lowers the rates of both reaccumulation (18% reaccumulate with a drain vs. 83% without) of the cholesterol granuloma and the need for reoperation. If a drain cannot be placed, full removal of the cyst wall with obliteration of the potential space using an adipose tissue graft or temporalis rotation flap is recommended.

Editorial Comment

The petrous apex approaches the midline of the skull base making safe access a potential challenge. The authors have pointed out that understanding the pathology helps to determine whether a cyst or granuloma should be drained or a tumor, such as an epidermoid, should be resected or exteriorized. Large epidermoid tumors have a higher incidence of persistence or recurrence due to difficulty in completely removing the entire tumor. Epidermoids have a tendency to line vessels

and dura and insinuate between nerve fibers.

MRI and CT scans are complementary in the information they provide. They not only reveal the nature of the pathology, but provide a surgical strategy for accessing the tumor. Advances in expanded endoscopic transnasal surgery have significantly enhanced access options and control of the pathology. This is an enhanced skill set that is needed, especially if the carotid artery is to be mobilized. Procedures can connect the cyst cavity with the nasopharynx with a drainage tube emptying into a region that can be monitored endoscopically. This may not be as readily apparent with transmastoid procedures, because the catheter is medial to the tympanic membrane or in the mastoid cavity. The role of postoperative imaging remains critical in monitoring the status of the operative site. New imaging techniques using diffusion weighted sequences augment the sensitivity for differentiating recurrence of epidermoid tumor.

A close working relationship among the disciplines of radiology, otolaryngology, neurosurgery, anesthesiology and neurophysiology monitoring provide the resources to render a working diagnosis and surgical strategy for safely dealing with the pathology.

Review Questions

1. A cholesterol granuloma will have which characteristic features on MRI?

   a. Hyperintense on T1, hypointense on T2

   b. Hyperintense on T2, hypointense on T1

   c. **Hyperintense on both T1 and T2**

   d. Hypointense on both T1 and T2

2. Which approach is unsuitable for patients with high-riding jugular bulbs?

   a. Infracochlear approach

b. **Infralabyrinthine approach**

c. Middle fossa approach

d. Transsphenoidal approach

3. Which of the following approaches will preserve hearing?

a. Translabyrinthine

b. Transcochlear

c. **Infracochlear**

d. Transotic

Cerebrospinal Fluid, Otorrhea and Encephalocele

Esther X. Vivas

Introduction

Cerebrospinal fluid (CSF) leak of the temporal bone results from having a connection between the air-containing spaces of the temporal bone and the intracranial subarachnoid space. The connection is by way of defect(s) in the tegmen mastoideum or tegmen tympani with or without the presence of a concurrent encephalocele (Fig. 144.1) or meningoencephalocele. CSF collects in the middle ear and mastoid, and the egress of fluid is by way of a defect in the tympanic membrane or bony ear canal resulting in CSF otorrhea. With an intact tympanic membrane, fluid can drain down the Eustachian tube causing CSF rhinorrhea. The most common etiology of CSF otorrhea is a head injury with a fracture of the temporal bone, followed by iatrogenic injury or erosive changes from chronic otomastoiditis. Spontaneous or idiopathic CSF otorrhea is rare. In the pediatric population, CSF leaks are commonly associated with congenital malformations of the temporal bone. Congenital temporal bone CSF fistulas are rare and categorized as perilabyrinthine or translabyrinthine depending on the route of CSF transmission. These patients are more likely to present with meningitis or sensorineural hearing loss. Adults with spontaneous CSF otorrhea typically present with common otologic complaints of unilateral aural fullness or hearing loss, and typically have normal inner ear anatomy. As a result, the diagnosis can be elusive. A common initial diagnosis is chronic serous otitis media (CSOM). In this situation, a CSF leak becomes highly suspicious following myringotomy or placement of a tympanostomy tube. This often results in clear, watery otorrhea that is persistent and frequently pulsatile. Confirmation of the fluid as CSF can be achieved by obtaining an assay for beta-2 transferrin, which is highly

sensitive and specific for detection of CSF, though vitreous and perilymph also contain the protein.[1] Meningitis with concurrent middle ear effusion is a rare and more serious presentation. Chronic intracranial hypertension, such as that seen with benign or idiopathic intracranial hypertension (IIH), is known to predispose to CSF leaks, including CSF otorrhea.[2] This syndrome is particularly prominent in obese, middle-aged women, and may be associated with headache, pulsatile tinnitus, and visual changes. There has been much investigation in trying to understand the mechanism for elevated ICP, and linking this process to the underlying pathophysiology seen in patients with IIH. Numerous reports have established an association between elevated intracranial pressure (ICP) and spontaneous CSF otorrhea.[3-7] Aberrant arachnoid granulations overlying the posterior fossa plate and the floor of the middle fossa potentially leading to bony erosion and CSF leak have also been reported in the literature. Unfortunately, due to the rare incidence of this disease, an established pathophysiology for spontaneous or idiopathic CSF leak is lacking. Patients with a history of chronic otitis can develop cholesteatoma that may erode into the otic capsule as well as through the middle or posterior fossa plates. Primary or metastatic malignant tumors to the temporal bone may also lead to bone erosion and CSF leak. In adults, the most common tumors are epithelial tumors and paragangliomas. In children, it is rhabdomyosarcoma.

Once the diagnosis is made, surgical repair is warranted because of the increased risk for developing central nervous system complications and infections, such as meningitis. An exception is CSF leak secondary to fractures of the temporal bone. Bed rest and elevation of the head results in spontaneous resolution in up to 90% of these patients; however, a lumbar drain (LD) may also be required with recalcitrant high volume leaks. Iatrogenic injury during mastoid or middle fossa surgery is typically recognized at the time, and immediate repair obviates subsequent management. The options for surgical repair vary according to the size and site(s) of the leak.[8,9]

Key Operative Learning Points

1. CSF otorrhea may be acquired or spontaneous.

2. Imaging is essential in determining the size and location of a defect(s).

3. Regardless of the etiology, surgical repair is recommended, and the surgical technique is dictated by the site of the leak. An exception is CSF leak secondary to trauma, which typically resolves spontaneously.

4. All surgical repairs should employ a multilayer reconstructive technique, preferably with autologous tissue to minimize the chances of postoperative infection and foreign body reactions. The sources of anatomic materials include bone, free tissue grafts, or vascularized flaps

5. Surgical repair can be performed via transmastoid or middle fossa approaches or a combination of these. Obliteration of the middle ear may be required in particular circumstances.

6. Synthetic materials, such as bone cement substitutes also may be used in conjunction with autologous material.

7. CSF diversion via LD is often employed in the immediate postoperative period, especially in the repair of spontaneous middle fossa defects.

8. Intraoperative measurement of intracranial pressures may reveal elevated ICP in patients with spontaneous leaks, particularly in middle-aged obese women. However, pressures may be deceivingly normal as the result of active CSF egress through the defect.

Preoperative Period

History

1. History of present illness

   a. Duration of symptoms; specifically ask about the duration of the hearing loss, aural fullness, or otorrhea.

   b. If otorrhea is present, has it responded to medical management such as topical drops or oral antibiotics?

   c. Is there concurrent rhinorrhea?

   d. Are the symptoms unilateral or bilateral?

   e. Determine if symptoms were spontaneous, insidious, or temporally related to trauma or surgery.

f. Ask about the presence of headaches, particularly about morning headaches, stiff neck, or visual changes.

g. Are there vestibular symptoms?

h. Specifically ask about sound or Valsalva-induced vertigo.

i. Is there pulsatile tinnitus?

2. Past medical history

a. Ask about prior surgical interventions.

b. Specifically ask about prior otologic or neurologic surgery.

c. Is there a history of head trauma?

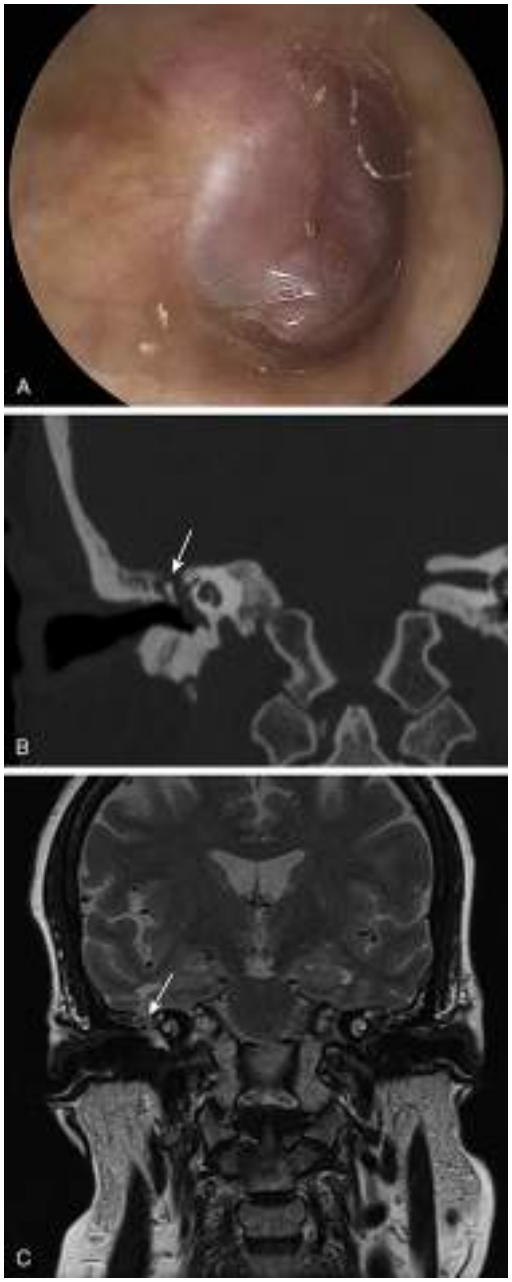

FIG. 144.1 **A,** Photo of a right ear canal. The tympanic membrane is bulging and pulsating due to the presence of an encephalocele. **B,** Coronal cut of a T2 weighted MRI image from the same patient, illustrating a right temporal lobe encephalocele into the middle ear. **C,** Coronal image of a CT of the temporal bones from the same patient. Image illustrates a tegmen tympani bony defect with right temporal lobe encephalocele into the middle ear.

d. Evaluate for history of chronic or recurrent otitis media.

e. Specifically elicit a history of meningitis.

f. Assess for history of malignancy.

g. Is the patient on anticoagulation therapy?

Physical Examination

1. Vital signs and body mass index (BMI) should be obtained.

2. A comprehensive examination of the head and neck should be performed, including thorough evaluation of cranial nerve function.

3. A tuning fork examination for the initial evaluation of hearing followed by comprehensive audiometry is essential.

4. Otomicroscopy is required to fully evaluate the tympanic membrane and middle ear.

5. The middle ear should be carefully inspected for the presence of fluid or mass lesions, such as encephaloceles (Fig. 144.1A).

6. Transmitted pulsations are often present.

7. CSF fluid is clear and at times difficult to see on examination; pneumatic otoscopy is helpful and may stimulate the formation of bubbles unmasking underlying fluid.

8. Diagnosis may be elusive, but usually becomes evident following a myringotomy, and manifests as clear watery otorrhea that is persistent and frequently pulsatile.

9. Assess for Tullio phenomenon in patients with vestibular complaints as there may be a concurrent superior semicircular canal (SSC) dehiscence.

10. If there is a tympanic membrane perforation or a pressure equalizer (PE) tube present, the most typical finding is pulsatile clear otorrhea. However, concurrent otitis media also may be present, making the initial diagnosis more difficult.

11. The fluid should be collected and sent off for B-2 transferrin assay.

12. Have the patient bend forward and place the head between their knees for several minutes as this may elicit CSF rhinorrhea.

13. If the tympanic membrane is intact and rhinorrhea cannot be elicited,

consider aspirating middle ear fluid with a long 25G needle to obtain a specimen for B-2 assay.

14. Look for clear drainage in the posterior pharynx when performing the examination of the oral cavity.

15. A comprehensive eye examination for papilledema should be performed in patients with spontaneous CSF leak and risk factors for IIH.

16. A lumbar puncture can be performed pre- and postoperatively to identify elevated ICP in patients with spontaneous CSF leaks.

Imaging

Computed tomography (CT) of the temporal bones requesting thin axial and coronal reconstruction should be the initial imaging study obtained (see Fig. 144.1B).

Magnetic resonance imaging (MRI) w/wo contrast with T1 and T2 axial and coronal reconstructions through the temporal bones evaluates for cephalocele, and are complementary to CT images. Coronal FIESTA or constructive interface in steady state (CISS) sequences can depict CSF extrusion and brain herniation (see Fig. 144.1C).

Cisternography is no longer a routinely used imaging modality in the evaluation of these patients.

Indications

1. Nontraumatic CSF leaks should be addressed surgically unless the patient is deemed too frail and a high surgical risk.

2. Small defects of the tegmen mastoideum can typically be addressed with transmastoid approaches.

3. Multiple or large defects can be addressed with a middle fossa approach.

4. Tegmen tympani defects are best accessed with a middle fossa approach.

5. Defects in the otic capsule or tegmen mastoideum associated with

chronic middle ear disease are approached in the standard tympanomastoid fashion.

6. In the absence of useful hearing, the middle ear may be obliterated and the ear canal closed.

Contraindications

1. Medical comorbidities with an unacceptable risk for general anesthesia.

2. Metastatic malignancy to the temporal bone.

3. Patients who cannot tolerate discontinuing anticoagulation therapy due to high cardiovascular risk.

4. CSF leaks secondary to temporal bone trauma should initially be managed conservatively.

Preoperative Preparation

1. Confirmation of CSF by way of a positive B-2 transferrin assay.

2. Preoperative comprehensive audiometry.

3. Preoperative videonystagmography (VNG) in patients with vestibular complaints.

4. Preoperative imaging is essential with CT *and* MRI as these are complimentary.

5. Ophthalmology evaluation for patients with risk factors for IIH.

6. Neurosurgical involvement is encouraged for a joint surgical team approach; particularly in the presence of large or multiple defects with an encephalocele(s) that will require a middle fossa approach.

7. Standard preoperative bloodwork including a coagulation profile.

8. Discontinue anti-platelet and anti-coagulant therapy in consultation with the patient's Primary care physician (PCP) or cardiologist.

9. Consult the neurophysiology service for intraoperative monitoring.

Operative Period

Anesthesia

General: endotracheal intubation required, with nonparalyzing agents to allow for intraoperative cranial nerve monitoring.

Positioning

Transmastoid: supine with the head turned toward the contralateral ear.

Middle fossa: lateral decubitus or supine with a shoulder and hip bump, and Mayfield head holder (Fig. 144.2).

Perioperative Antibiotic Prophylaxis

Cephalosporin with adequate blood-brain barrier penetration; clindamycin and vancomycin are alternatives in patients who are allergic to penicillin.

Monitoring

Somatosensory evoked potentials (SSEP): this may be employed as per preference of the Neurosurgeon.

Electromyography (EMG): this is recommended with middle fossa or combined approaches, preferably administered by an electrophysiology service that is independent of the operating surgeon.

Facial nerve: this is recommended.

Auditory brainstem response (ABR): ipsi- and contralateral monitoring. This is recommended for complex or revision surgery, preferably administered by an electrophysiology service that is independent of the operating surgeon. If CSF is actively leaking through the ear, ipsilateral monitoring cannot be performed.

Instruments and Equipment to Have

Available

1. Microscope
2. Otologic drill with irrigation system
3. Middle ear and mastoidectomy set
4. Middle fossa dura retractor
5. Electrophysiology monitoring device, such as nerve integrity monitoring system (NIMS) monitor with a Prass or Kartush probe or similar stimulator
6. Synthetic bone cement
7. Dural tissue homograft substitute
8. Fibrin glue
9. Titanium plating system to close the craniotomy defect
10. Surgical navigation device (helpful but is not essential)

Key Anatomic Landmarks

1. Temporal bone anatomy:
   a. Tegmen tympani and tegmen mastoideum
   b. Sinodural angle
   c. Semicircular canals
   d. Ossicular chain
   e. Tympanic and mastoid segment of the intratemporal facial nerve
2. Middle fossa floor anatomy:
   a. Arcuate eminence
   b. Greater superficial petrosal nerve (GSPN)
   c. Meatal plane over the internal auditory canal
   d. Middle meningeal artery
   e. Vein of Labbé

f. Root of the zygoma noting the floor of the middle fossa.

Prerequisite Skills

1. Proficiency in temporal bone anatomy and tympanomastoidectomy

2. Proficiency in middle fossa anatomy, surgical approach, and techniques of repair.

Operative Risks

1. Intraoperative injury to the facial nerve

2. Intraoperative injury to the GSPN

3. Sensorineural hearing loss or deafness

4. Vertigo or disequilibrium

5. Conductive hearing loss from ossicular disruption or compression

6. Iatrogenic injury to the semicircular canals

7. Epidural or subdural hemorrhage

8. Iatrogenic CSF leak

9. Meningitis

10. Stroke

Surgical Technique

- Transmastoid approach is preferred for small lateral tegmen mastoideum defects:

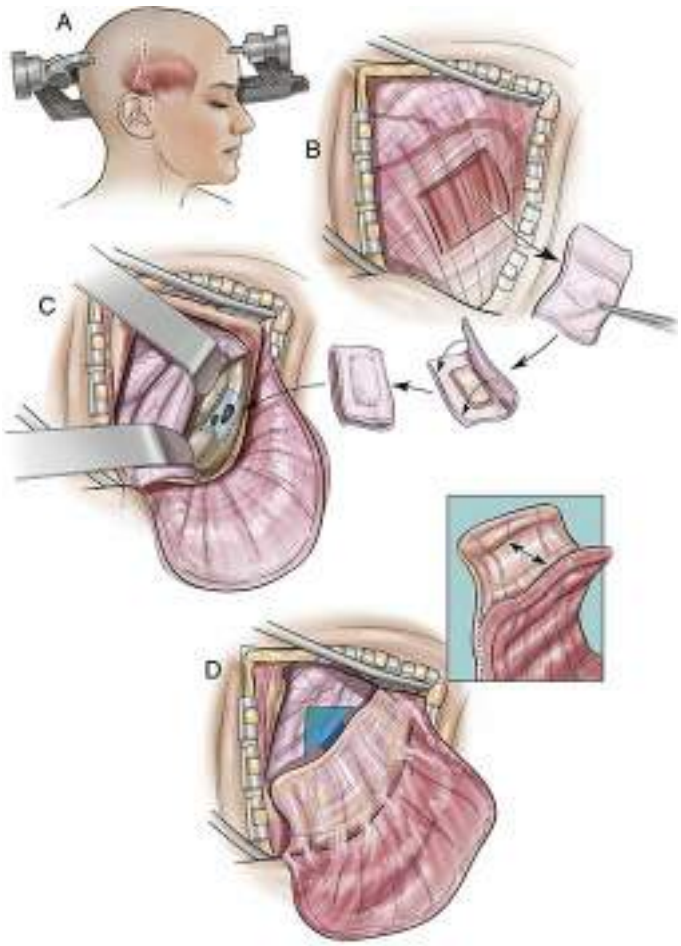

FIG. 144.2 Middle fossa surgical technique.

Middle fossa craniotomy approach for reconstruction of tegmen defects with CSF otorrhea, including vascularized deep temporalis fascia-periosteal flap for multilayer closure. Once skin incisions **(A)** are made and the galea transected, a large piece of superficial temporalis fascia is harvested **(B)**. The temporalis muscle is carefully dissected in a subperiosteal fashion from an anterior to posterior direction, disconnecting it from the skull as far as possible posteriorly and superiorly. This maneuver preserves the temporalis muscle fibers and the blood supply to the periosteal layer of the deep temporal fascia. The temporalis muscle is then retracted inferiorly and anteriorly out of the field for later use. A middle fossa craniotomy and the dura of the inferior temporal lobe is dissected away from the middle fossa floor until the tegmen defect(s) are identified.

Dissection is routinely done posterior to anterior along the tegmen floor, taking caution to preserve the greater superficial petrosal nerve, thereby avoiding traction on the geniculate ganglion. The locations of the defects are identified based on the preoperative studies and examination of the field, and are confirmed with image guidance, if available. Primary repair of the dura is dictated by the size, location, and integrity of the surrounding tissue. A thin piece of calvarial bone is harvested from the inner table of the craniotomy bone flap, wrapped in the superficial temporalis fascia, and draped directly over the bony defect(s) **(C)**. The final layer involves onlay of the vascularized deep temporalis fascia-periosteal flap. The flap is tucked medially as far as possible, and is splayed out over the surface area of the middle fossa bony floor covering the free superficial temporalis fascia and the bone graft **(D)**. The flap is sandwiched between the dura (and dural repair) of the temporal lobe and the bony repair. Finally, the craniotomy bone flap is replaced and secured, allowing adequate room anteroinferiorly to accommodate the vascular pedicle of the deep temporalis fascial flap. With permission from Vivas EX, McCall A, Raz Y, et al: ICP, BMI, surgical repair, and CSF diversion in patients presenting with spontaneous CSF otorrhea. Otol Neurotol, 2014 35:344-347.

- Prep and drape the patient for a standard postauricular approach.
- Inject the postauricular region, incisura, and tragus with xylocaine and epinephrine.
- Harvest the fascia of the temporalis muscle and allow it to air dry.
- Perform a complete mastoidectomy.
- Identify the tegmen mastoideum, sinodural angle, sigmoid sinus, incus, and horizontal semicircular canal.
- Identify and preserve the facial nerve.
- Completely expose the tegmen defect(s).
- Perform a multilayer repair using a combination of autologous

tissue, such as bone graft or bone pate, cartilage, and temporalis fascia.

- Surgicel can be placed over the completed repair.
- Fibrin glue can be used for reinforcement.

- Middle fossa approach is preferred when there are large or multiple defects along the tegmen mastoideum or if the tegmen tympani is involved. Large meningoencephaloceles are best managed through the middle fossa. It is also used in the presence of canal wall down cavities. This should be a team effort in conjunction with neurosurgical colleagues:
  - An LD should be placed and ICP measured in patients with spontaneous leaks.
  - Prep and drape the patient for a middle fossa craniotomy.
  - Preserve the temporalis muscle and underlying fibro-periosteal layer.
  - Dissect the muscle off of the bone and retract anteriorly making sure to preserve the vascular pedicle.
  - Perform a craniotomy saving the bone for replacement with rigid plate fixation.
  - Expose the floor of the middle fossa with careful dissection using a posterior to anterior technique when elevating the dura.
  - Identify anatomic landmarks, such as GSPN and arcuate eminence.
  - The arcuate eminence/superior semicircular canal (SSC) is typically oriented perpendicular to the petrous ridge and 60 degrees from the internal auditory canal.
  - Maintain a high level of suspicion for SSC dehiscence in patients with numerous osseous defects and avoid direct suction over the area of the arcuate eminence.
  - Completely expose all osseous defects.
  - Reduce existing encephalocele(s) and perform appropriate repair of the dura.
  - Perform a multilayer repair of the tegmen plate using a combination of autologous tissue, such as bone graft or bone pate, cartilage, and

temporalis fascia.

- Vascularized tissue also can be used to create a pedicled deep temporalis fibroperiosteal flap.
- Synthetic materials, such as bone cement, can be an adjunct to the repair, but should not be used independently.
- Fibrin glue can be used for reinforcement.
- A J-P drain under the temporalis muscle informs of a seroma or hematoma.

- Combined approaches may be required for complex defects and will require all or a combination of the techniques described above.
- Obliteration of the middle ear requires plugging of the Eustachian tube, removal of the middle ear contents, tympanic membrane, and ear canal skin. The meatus is oversewn and the middle ear cavity is filled with an abdominal adipose tissue graft.

Common Errors in Technique

1. Inadequate exposure of all osseous defects resulting in a persistent CSF leak.

2. Inadequate repair of defect(s), such as when performed with a single layer closure.

3. Lack of CSF diversion in the perioperative period in patients with spontaneous leaks and elevated ICP.

4. Aggressive elevation of dura resulting in iatrogenic tears, GSPN/facial nerve injury, trauma to the temporal lobe, or vascular injury.

Postoperative Period

Postoperative Management

1. Patients who undergo transmastoid approaches may be discharged the same day of surgery or after a night of observation, depending on medical comorbidities and the extent of the procedure.

2. Patients who undergo a middle fossa or combined approach should be observed in a monitored postoperative setting.

3. Neuro-checks should be performed routinely the first 24 hours and weaned as appropriate.

4. Postoperative CT of the head should be obtained to evaluate for subdural or epidural hemorrhage after middle fossa, or combined approaches if intraoperative bleeding was encountered or if an altered mental status develops.

5. If an LD was placed, it should remain open for 48 to 72 hours.

6. Bed rest while the LD is open.

7. The collection system of the LD should be maintained at shoulder level.

8. Patients should be instructed to avoid Valsalva maneuvers for 2 weeks after surgery.

9. Stool softeners may be used to help reduce Valsalva forces when needed.

10. Once the LD is clamped, the patient should be assessed for the presence of a persistent leak.

11. Transient aphasia may be present in patients who undergo the left middle fossa approach.

12. A high suspicion for seizures should be maintained after temporal lobe manipulation.

13. Seizure prophylaxis may be required.

14. Postoperative headache is common while the LD is open.

15. Following successful repair, consider repeating the lumbar puncture in a few weeks to assess for the return of increased intracranial pressure in those patients with spontaneous CSF leaks.

Complications

1. Persistent CSF leak

a. This may develop from inadequate repair of the primary leak site, or alternatively from an unrecognized secondary defect. Wide exposure of the osseous defect(s) with multi-layer repair is the best way to prevent persistent leaks. Revision surgery may be required if an LD does not stop CSF egress.

b. Persistent leaks raise suspicion for elevated intracranial pressures and may ultimately require CSF diversion.

2. Hearing loss

a. Conductive hearing loss may occur from postoperative hemotympanum and undergo spontaneous resolution within weeks. Inadvertent dislocation of the ossicles can occur during surgical dissection and would require ossicular reconstruction. Ossicular fixation can occur if bone cement migrates into the middle ear and will require revision surgery. A hearing aid is a nonsurgical option for hearing rehabilitation of conductive hearing loss. A bone anchored hearing device (BAHA) is another option to address a conductive hearing loss. sensorineural hearing loss (SNHL) can result from iatrogenic injury to the SSC. This can be prevented by maintaining a high level of suspicion for a dehiscent SSC during dissection of the floor of the middle fossa and avoidance of direct suctioning over the area of the arcuate eminence. SNHL can also be sequelae of excessive manipulation or drilling of the ossicular chain. SNHL should be initially treated with an oral steroid taper for 7 to 10 days. Persistent hearing loss may be amenable to standard amplification.

3. Facial paresis/paralysis

a. This may be secondary to inflammation, traction, or thermal injury. During middle fossa exploration, gentle dissection over the GSPN can reduce traction injury to the nerve. Thermal injury may also occur when using high-powered drills. Copious irrigation is the best prevention. Treat with 7 to 10 days of high dose oral steroids. Nerve transection requires immediate surgical repair. Invasive facial reanimation procedures should be postponed for 12 months in the context of an anatomically intact nerve in order to wait for spontaneous recovery. Facial rehabilitation therapy is beneficial in the presence of synkinesis and hypertonicity.

4. Epidural or subdural hemorrhage; this may require evacuation

    a. Postoperative neurological checks in the immediate postoperative period is the best way to diagnose an evolving hemorrhage. Meticulous hemostasis during surgery is essential. Anticoagulants and aspirin products should be discontinued in the immediate pre- and postoperative period. Neurosurgical management is required if this complication occurs.

5. Meningitis

    a. Perioperative antibiotics and sterile techniques are the best preventative measures. If an active otitis is encountered the day of surgery, consider postponing the procedure. Keep the patient on antibiotic therapy postoperatively for 10 days if an active otitis is inadvertently encountered and the procedure cannot be aborted. If meningitis develops in the postoperative period, CSF culture should be obtained and broad spectrum antibiotics started until culture results are available. Neurological management is required if this complication occurs.

6. Brain abscess

    a. Perioperative antibiotics and sterile techniques are the best preventative measures. Immediate evacuation of the brain abscess is necessary. Fluid should be sent for culture and sensitivities, and broad-spectrum antibiotics started until the results are available. Neurosurgical management is required.

7. Stroke and aphasia

    a. Gentle manipulation with minimal traction of the temporal lobe is essential in preventing a stroke and aphasia. Neurological management is required if this complication occurs.

8. Seizures

    a. These may result from manipulation of the temporal lobe. Anticonvulsant therapy is required with slow taper. Neurological management is required if this complication occurs.

Alternative Management Plan

1. Patients who cannot undergo surgical repair should be treated with a diuretic, such as acetazolamide. Long-term management in this manner may not be successful.

2. Patients with persistent, recurrent, or new CSF leaks need to be evaluated for the presence of elevated ICP. If present, there may be a need for permanent CSF diversion with a shunt.

3. Recurrent temporal bone CSF leak following repair may require obliteration of the middle ear and mastoid.

4. Repair of a temporal bone CSF leak may unmask a CSF leak in the anterior or contralateral skull base, which will require a separate procedure.

Discussion

The etiology of CSF leaks from the temporal bone differs between the pediatric and adult populations. In children, CSF leaks are more likely to be secondary to congenital malformations of the temporal bone, whereas adults are more likely to have suffered traumatic head injuries or the sequelae of chronic otitis or iatrogenic injury. Spontaneous CSF leaks from the temporal bone are rare in both populations. In adults they are associated with elevated BMI and benign intracranial hypertension. The treatment algorithm for CSF leaks involves surgical management, except for traumatic injuries because of the high rate of spontaneous resolution. Surgical management should be undertaken by those with proficient knowledge of temporal bone anatomy and who are comfortable with transtemporal and middle cranial fossa approaches. Optimal repairs include multilayer closure preferably with autologous tissue. Patients who are diagnosed with concurrent elevated intracranial pressures need to have the hypertension treated medically or with CSF diversion. Persistent intracranial hypertension poses a risk for recurrent leak or the development of a new leak at another site. Recent reports in the adult literature have highlighted an overall lower incidence of meningitis with spontaneous CSF temporal bone leak than previously thought.

Evidence-Based Medicine Question

Do adult patients with a spontaneous CSF leak have a higher incidence of developing meningitis? The authors cited below performed a retrospective review of patients who presented with spontaneous CSF leak or encephalocele over an 11-year period. They identified 12 adult patients (15 ears) with a documented duration of CSF leak ranging from 4 months to 11 years. None of the patients presented with meningitis during this time, except for one patient who developed meningitis secondary to a subarachnoid hemorrhage. This report is in contrast to the incidence of meningitis in the pediatric population, where spontaneous CSF leaks are likely from congenital malformations of the inner ear and present as recurrent episodes of meningitis. *Rao N, Redleaf M: Spontaneous middle cranial fossa cerebrospinal fluid otorrhea in adults.* Laryngoscope *126(2):464-468, 2016.*[10]

Editorial Comment

Recognition of CSF otorrhea or rhinorrhea sets the otolaryngologist on a path to identify the source of the leak and to plan an efficacious and safe means of repair. The most common etiology of CSF otorrhea is temporal bone trauma. Fortunately, we rarely see iatrogenic cases of CSF leak following mastoid surgery. Spontaneous leaks are often identified following myringotomy tube placement for presumed serous otitis media. Once this has occurred, efforts are made to quickly evaluate patients and ideally obtain fluid for beta-2 transferrin assay. The relatively low incidence of subsequent infection (suppurative otitis media or meningitis) allows time for obtaining optimal imaging, consulting with other services (neurosurgery, ophthalmology), and planning for elective repair.

The author emphasized that the surgical technique should be comprised of a multilayer closure. Defects in the floor of the middle fossa can be reinforced with a bone graft taken from the temporal squamosal craniotomy and secured with temporalis fascia. If possible, a pedicled flap of fibro periosteum from the medial aspect of the temporalis muscle can be rotated into the defect to provide a vascularized covering of the compromised dura covering the temporal lobe.

Patients found to have increased intracranial pressure identified by a lumbar puncture obtained weeks after surgery require close surveillance.

Acetazolamide may control borderline elevated pressures. A ventriculoperitoneal shunt may be necessary to avoid sequela of increased ICP, such as headaches, papilledema, and the development of a CSF leak from another location.

Barry Hirsch

Review Questions

1. Surgical landmarks for the middle fossa approach include all of the following *except*:

   a. Meckel's cave

   b. Middle meningeal artery

   c. Vein of Labbé

   d. Arcuate eminence

   e. GSPN

   f. **IAC**

2. Complications from transmastoid CSF otorrhea repair include all *except*:

   a. Sensorineural hearing loss

   b. Conductive hearing loss

   c. Facial paralysis

   d. Persistent CSF leak

   e. **Aphasia**

   f. Meningitis

   g. Sigmoid sinus thrombosis

3. Spontaneous CSF leaks are:

   a. Most commonly seen in children

   b. Likely secondary to congenital malformations of the temporal bone in adults

c. Resolve with conservative management

d. **Most commonly diagnosed in obese middle-aged women**

e. Most likely to present with meningitis in adults

4. Large or multiple osseous defects of the tegmen plate are best addressed with:

a. Middle ear and mastoid obliteration

b. **Middle fossa approach with multilayer repair**

c. Transmastoid approach with multilayer repair

d. Fibrin glue alone

5. Dehiscence(s) of the tegmen plate should always be repaired regardless of the presence of encephalocele or CSF leak:

a. True

b. **False**

Temporal Bone Trauma

C.Y. Joseph Chang

Introduction

Major head injuries can cause a variety of craniofacial fractures. Temporal bone trauma may occur as a result of blunt or nonpenetrating injury or a penetrating injury, such as gunshot wounds. The temporal bone contains several important structures, including the facial nerve, cochleovestibular nerve, labyrinth, ossicles, tympanic membrane, and internal carotid artery, that may be injured as a result of temporal bone trauma. If the force of trauma is strong enough, a fracture of the temporal bone may occur, which can injure these important structures, resulting in various functional deficits, including facial nerve dysfunction, hearing loss, dizziness, and cerebrovascular ischemic injury. Other associated sequelae include intracranial injuries such as hematoma, brain contusion, injury to the abducens nerve, and violation of the dura resulting in cerebrospinal fluid (CSF) leakage with increased risk of bacterial meningitis.

The management of trauma to the temporal bone typically occurs after initiation of trauma resuscitation for acute associated injuries, such as intracranial injury, vascular injury, thoracoabdominal injury, hemorrhage, shock, and other morbid events that require immediate medical or surgical attention. Injuries to the ossicular chain may require surgical management but are typically re-evaluated after several months using techniques described in Chapter 132 (Ossicular Chain Reconstruction). Sensorineural hearing loss and dizziness do not require acute surgical intervention unless there is a significant perilymphatic fistula. Lacerations of the ear canal usually heal spontaneously, but there is a risk of stenosis of the ear canal when severe damage is present in the skin of the ear canal. These cases are typically treated with placement of a wick or stent and steroid/antibiotic ear drops. The few cases that may

result in stenosis or atresia of the ear canal can be managed surgically as described in Chapter on Ear Canal Stenosis Repair. The surgical management of CSF leak is described in Chapter 144 (Cerebrospinal Fluid Otorrhea and Encephalocele Repair).

This chapter will discuss in further detail the medical and surgical management of facial nerve injury. The management considerations will be based on a theory of disease based on limited data available at this time.

Key Operative Learning Points

1. The bone overlying the facial nerve should be thinned and then gently fractured to remove the loosened bony fragments for atraumatic decompression of the facial nerve.

2. The labyrinthine segment of the facial nerve is located at the anterior-superior portion of the fundus of the internal auditory canal, which bisects the angle between the greater superficial petrosal nerve (GSPN) and superior semicircular canal (SSCC).

3. Granulation tissue along the facial nerve fracture site should not be dissected aggressively in order to avoid iatrogenic injury to the facial nerve.

Preoperative PERIOD

History

1. History of present illness

   a. Penetrating versus nonpenetrating injury

   b. Onset and status of facial nerve dysfunction: This information helps in the stratification of patients' prognosis for recovery and helps determine who may benefit from surgical intervention.

      1) Normal after injury with delayed palsy or paralysis

      2) Immediate onset palsy or paralysis

      3) Progression of palsy or paralysis over time

c. Presence of other craniofacial and intracranial injuries

2. Past medical history

a. Prior facial nerve dysfunction such as Bell's palsy. There may be fewer neurons functioning, even if the facial function returned to normal and lead to poorer prognosis for recovery after the current injury.

b. Prior ear or mastoid surgeries

c. Prior intracranial procedures

d. Diabetes

Physical Examination

1. Facial nerve evaluation: House-Brackmann grading scale is typically used

2. Otologic evaluation

a. Tympanic membrane

1) Perforation

2) Hemotympanum

3) CSF otorrhea

b. Ear canal

1) Laceration

2) Hemorrhage

c. Surrounding soft tissue

1) Battle's sign—Postauricular ecchymosis

d. Tuning fork

e. Balance evaluation

1) Gait

2) Tandem gait

3) Romberg test

3. Rhinologic evaluation

a. CSF rhinorrhea

4. Audiologic evaluation

a. Pure tones

b. Speech discrimination scores

c. Tympanogram

5. Electrophysiological studies

a. Electroneuronography (ENoG)

b. Electromyography (EMG)

Imaging

Computed tomography (CT) temporal bone—The presence of temporal bone fracture can be confirmed. The locations of probable Fallopian canal fracture sites can also be determined.

Indications for Decompression Surgery

1. Patients with a poor prognosis for good facial nerve functional recovery. This includes patients with the clinical findings of immediate onset facial paralysis, immediate onset facial palsy with progression to paralysis, or those with unclear facial function at onset with progression to paralysis, in addition to ENoG showing greater than 95% denervation and EMG showing no voluntary motor potentials.

2. Timing—As early as possible, within 12 to 14 days of injury

3. Patient has no contraindication to surgery based on medical status and coexisting injuries.

4. Some physicians may consider CT findings regarding indication for surgery, but the main indication for surgery remains prognosis for facial nerve recovery based on clinical course and electrical testing.

5. Patients who remain unconscious after injury during the 12- to 14-day window for possible facial nerve decompression surgery represent a significant dilemma, as the degree of facial nerve injury cannot be adequately determined. It may be that most of these patients are not

good candidates for facial nerve surgery due to the severity of their intracranial injuries. As there are no data correlating the CT findings to the probability of spontaneous facial nerve recovery, it may be prudent not to consider facial nerve surgery in these patients during the acute postinjury period.

Indications for Decompression Surgery

1. Evidence of facial nerve transection based on poor facial nerve recovery over 6 to 8 months or high likelihood of facial nerve transection based on clinical presentation

2. Timing—Facial nerve repair may be contemplated as early as the traumatic acute inflammatory changes have subsided, typically 4 weeks after injury, if the presence of facial nerve transection has been established.

Contraindications

1. Medical comorbidities and/or injuries with increased risk for general anesthesia

Preoperative Preparation

1. Ensure that any brain injury has not progressed.

2. Confirm status of hearing.

3. Obtain and review facial nerve electrical tests to confirm that there is no volitional movement.

Operative Period

Anesthesia

- General: This procedure requires general anesthesia; no paralytic agents if direct facial nerve stimulation is anticipated

Positioning

- Supine: The patient is positioned the same as for any otologic procedure, with the head turned away from the surgeon. If a middle fossa craniotomy is performed, the vertex of the head will also need to be accessed. A shoulder roll and hip bump may be necessary if neck rotation is limited.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin: The antibiotic regimen is the standard perioperative regimen for clean, noncontaminated surgery.
- Clindamycin or vancomycin if patient is allergic to penicillin

Monitoring

- Auditory brainstem response (ABR)—For intracranial procedure
- Somatosensory evoked potential (SSEP)—For intracranial procedure
- A lumbar drain can be placed at the time of middle fossa surgery to relax the temporal lobe prior to retracting it. The drain is removed at the end of surgery.
- An alternative or supplement is to administer mannitol 1 g/kg and furosemide 40 mg given 30 minutes prior to temporal lobe retraction.
- Dexamethasone 12 mg is given for nausea prophylaxis and reduction of intracranial edema.

Instruments and Equipment to Have Available

1. Standard otologic surgery set
2. Otologic drill
3. Standard craniotomy set with standard retractors for middle fossa cases

4. Operating microscope

Key Anatomic Landmarks

1. Standard mastoidectomy landmarks
   a. Horizontal semicircular canal (HSCC)
   b. Tegmen tympani
   c. Facial recess
   d. Stylomastoid foramen
   e. Cochleariform process
   f. Oval window niche
2. Standard middle fossa landmarks
   a. SSCC
   b. GSPN
   c. Meatal plane leading to the internal auditory canal

Prerequisite Skills

1. Tympanoplasty with mastoidectomy, facial recess
2. Middle fossa craniotomy
3. Knowledge of the anatomy of the floor of the middle fossa

Operative Risks

1. Intracranial and extradural hemorrhage
2. Dysphasia related to temporal lobe retraction
3. Seizures related to retraction of the temporal lobe
4. Injury to the inner ear related to unplanned fenestration or ossicular injury
   a. Conductive hearing loss

b. Sensorineural hearing loss

c. Dizziness

5. CSF leak due to injury of the dura

Surgical Technique

Total facial nerve decompression can be performed using one of two approaches: the combined middle fossa craniotomy and transmastoid approach and the translabyrinthine approach. The middle fossa craniotomy typically results in preserved hearing, so it is indicated for patients who have usable sensorineural hearing function and those who are medically fit to undergo middle fossa craniotomy. The translabyrinthine approach violates the otic capsule, which results in complete deafness on the ipsilateral side. Therefore this approach is appropriate for patients with no usable ipsilateral hearing function and adequate contralateral vestibular function. The advantage of this approach is that it avoids any intracranial brain retraction.

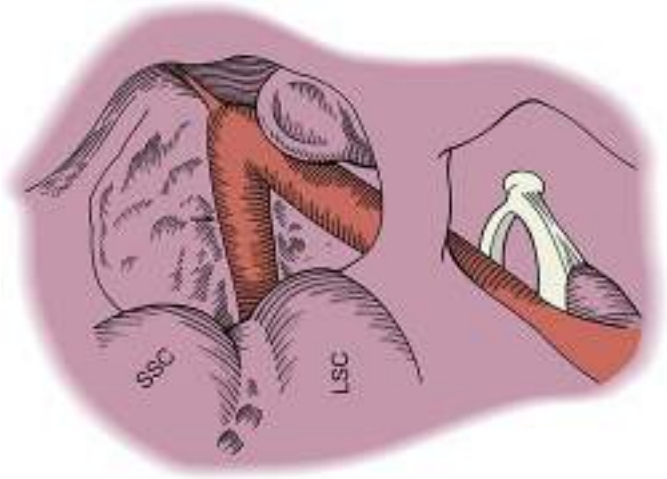

FIG. 145.1 Transmastoid approach for total facial nerve decompression, right side. The incus has been removed in this case. *SSC,* Superior semicircular canal; *LSC,* lateral semicircular canal.

Transmastoid, Middle Fossa Craniotomy Approach—Hearing Preservation

- Standard mastoidectomy with facial recess dissection is performed (Chapter 134: Mastoid Surgery). The incus may need to be dislocated temporarily after separation of the incudostapedial joint, or the incus may have to be removed for access. The incus buttress may be left intact in most cases (Fig. 145.1).
- The facial nerve is skeletonized from the second genu to the stylomastoid foramen. Care is taken to leave a very thin "eggshell" layer of bone over the facial nerve.
- The thin bone overlying the nerve is gently fractured using a curved pick (Rosen needle), and the bone fragments are removed.
- The epineurium of the nerve is not disturbed.
- Standard middle fossa craniotomy approach (Chapter on Acoustic Neuroma). A cranial flap is turned to expose the middle fossa dura (Fig. 145.2).
- The middle fossa dura is elevated to the level of the meatal plane over the internal auditory canal (IAC). Care is taken to dissect from posterior to anterior to prevent injury to the geniculate portion of the facial nerve. Anterior to posterior dissection could result in inadvertent elevation of the GSPN with the dura to the geniculate resulting in a traction injury to the facial nerve.
- The SSCC and GSPN are identified. The SSCC may be blue-lined to confirm location of the canal lumen.
- The area medial to the SSCC and GSPN is drilled to the IAC dura, which is skeletonized using a diamond burr toward the meatal foramen and labyrinthine segments of the facial nerve.
- The labyrinthine segment and meatal foramen are skeletonized with the diamond bur using copious irrigation. It is technically challenging to leave a thin bone lining that can be fractured with a pick in this area.

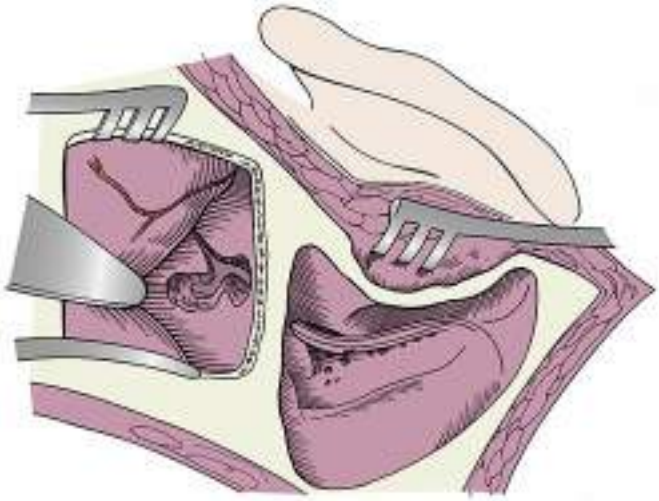

FIG. 145.2 Combined middle fossa and transmastoid approaches for total facial nerve decompression, right side.

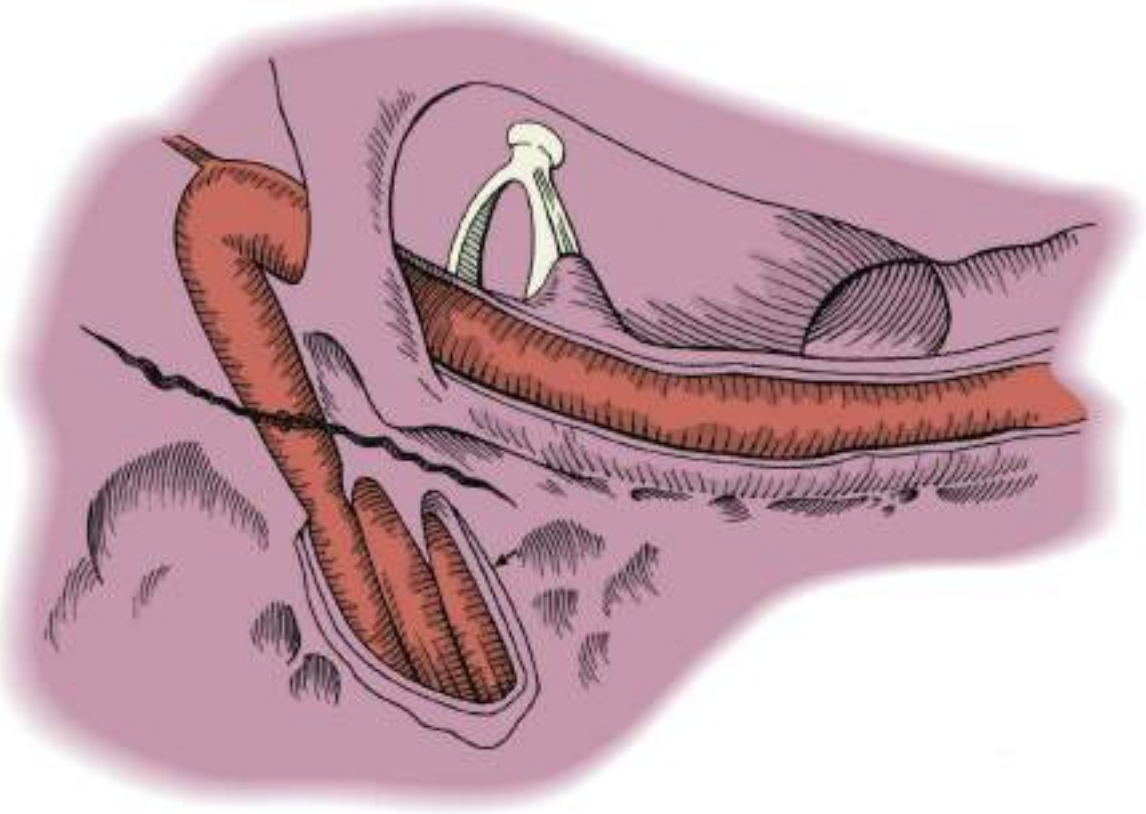

FIG. 145.3 Transmastoid translabyrinthine approach for total facial nerve decompression, right side.

- The basal turn of the cochlea is just medial to the labyrinthine and

geniculate segments of the facial nerve, so care is taken to avoid drilling into this area.

- The tegmen tympani is drilled open with the diamond bur and the malleus head, incus body, horizontal facial nerve, and anterior portion of the HSCC are identified.
- The geniculate and horizontal segments of the facial nerve are decompressed from this approach.
- If the incudostapedial joint was separated, the incus is replaced back in position with application of Gelfoam to stabilize its position as needed.
- The cranial bone flap is replaced and fixated with a cranial plate and screw system.
- Standard closure of the mastoid and craniotomy incisions

Translabyrinthine Approach—No Useful Hearing

- The standard translabyrinthine bony dissection is performed (Fig. 145.3; see Chapter 140).
- After skeletonizing the vertical segment of the facial nerve and drilling through the labyrinth, the labyrinthine segment of the facial nerve can be found just medial to the ampullated end of the superior semicircular canal.
- The meatal segment to the lateral IAC and the geniculate can be decompressed at this stage.
- The horizontal segment can be decompressed from the medial and superior side to the second genu and then down along the vertical segment in the standard fashion. Care should be taken to avoid CSF leak through the IAC dura.
- The closure is performed with application of a muscle plug in the aditus ad antrum, waxing of all exposed mastoid air cells, and placement of an adipose tissue graft into the mastoid.

Facial Nerve Grafting

- The surgical approach is similar to those used for the facial nerve

decompression.

- The facial nerve repair typically requires use of a nerve graft, since a significant segment of the injured facial nerve may be fibrosed and require resection. The greater auricular nerve is typically used. A sural nerve may also be used, but its diameter may be too large for use in the labyrinthine segment.
- A tension-free repair is critical for maximal axonal regrowth across the anastomoses. In most cases, the medial portion of the bony Fallopian canal can be preserved to allow for a suture-free repair by laying the nerve graft into the fallopian canal trough and stabilizing the repair with Gelfoam packing or tissue glue. The nerve graft should be made slightly longer than the length of the nerve defect to reduce the risk of separation at the anastomosis during the healing process.
- A standard suture repair may also be used to augment the repair, typically using 8-0 or 9-0 nylon or other monofilament suture for an epineurial anastomosis.
- An anastomosis of the facial nerve in the IAC is technically challenging. Usually only a single suture through the center of the nerve end is feasible.

Common Errors in Technique

1. If there are areas of inflammation and granulation along the course of the facial nerve where the fallopian canal has been disrupted, aggressive dissection in these areas should be avoided in order to minimize iatrogenic injury to the facial nerve. Visualization is very difficult in these areas so an iatrogenic facial nerve transection can occur.

2. Inadequate decompression of the labyrinthine segment and meatal foramen portions of the facial nerve if a middle fossa craniotomy is not performed

3. Failure to separate the incudostapedial joint in cases where the horizontal facial nerve cannot be decompressed without trauma to the incus

4. In facial nerve repair, the use of an inadequate length nerve graft or technical failure of repair may cause failure of the repair due to tension at

the anastomosis.

5. Fenestration of the cochlea or superior semicircular canal during facial nerve decompression through the middle fossa approach

6. Injury to the middle fossa or IAC dura with CSF leak

Postoperative Period

Postoperative Management

1. Standard neurosurgery intensive care monitoring overnight

2. Monitor for intracranial complications and CSF leak.

3. Apply eye lubricating drops and ointments for patients with lagophthalmos.

4. Audiogram at 1 month postoperatively

5. Oral steroids may be given for 2 weeks: prednisone 60 mg per day for 10 to 14 days; then a 6-day taper.

6. Monitor facial nerve function over the next year.

Complications

1. Intracranial hemorrhage: The patient requires an immediate CT with possible placement of ventricular drain and return to the operating room for evacuation of hematoma if necessary.

2. CSF leak: Lumbar drainage for 3 days. If there is persistent leak, the patient will need a surgical repair as described in Chapter 144 (CSF Otorrhea).

3. Dizziness: Most patients will recover without treatment, but some may need vestibular physical therapy for prolonged imbalance. Acute vertigo may be managed with vestibular suppression with benzodiazepines or meclizine and antiemetic medications.

4. Persistent conductive hearing loss may be managed with ossicular reconstruction or a hearing aid.

5. Persistent sensorineural hearing loss may be managed with a hearing aid.

6. Severe to profound hearing loss may be managed with contralateral routing of signals (CROS) aid or osseointegrated implant (bone anchored hearing aid (BAHA) or Ponto).

Alternative Management Plan

1. Observation: Some patients have medical contraindications for surgery or decline surgery. Some patients are not evaluated for surgical facial nerve decompression until after the time window for decompression has passed. The efficacy of the facial nerve decompression is not fully understood, as discussed in a later section.

2. Delayed facial nerve decompression has been done, but its true efficacy and theoretical efficacy remain in doubt, as discussed in a later section.

3. Steroid treatment: High-dose treatment with steroids typically causes generalized reduction in inflammation and edema, so it could be considered as a noninvasive treatment option, although there are no data regarding efficacy.

Discussion

Temporal Bone Fracture Classification

There has been an evolution in the classification of temporal bone fractures. In the past, the fractures were classified as either longitudinal or transverse. In practice, many fractures are comminuted and cannot often be classified well into one or the other category. A more modern classification divides fractures into otic capsule sparing and otic capsule penetrating injuries (Fig. 145.4A and B).[4] Most fractures can be classified as one or the other. In addition, there is a higher risk of sensorineural hearing loss, facial nerve injury, and CSF leak with otic capsule penetrating injuries, so there is some clinical utility to the use of this classification system. Penetrating fractures can also be classified using this classification, although the risk of facial nerve injury is high regardless of the classification of these injuries.

Evidence-Based Medicine Question

How effective is the combination of ENoG and EMG in predicting facial nerve recovery in patients with facial nerve paralysis due to temporal bone trauma?

The data regarding the prognostic value of ENoG for temporal bone trauma are extremely limited and are mostly extrapolated from data regarding Bell's palsy. Limited data suggest that less than half of patients with poor ENoG findings within 14 days of injury will have poor recovery of facial nerve functions.[5] The addition of poor EMG findings could increase the odds of poor facial nerve outcome, but the degree to which this is true remains unknown.

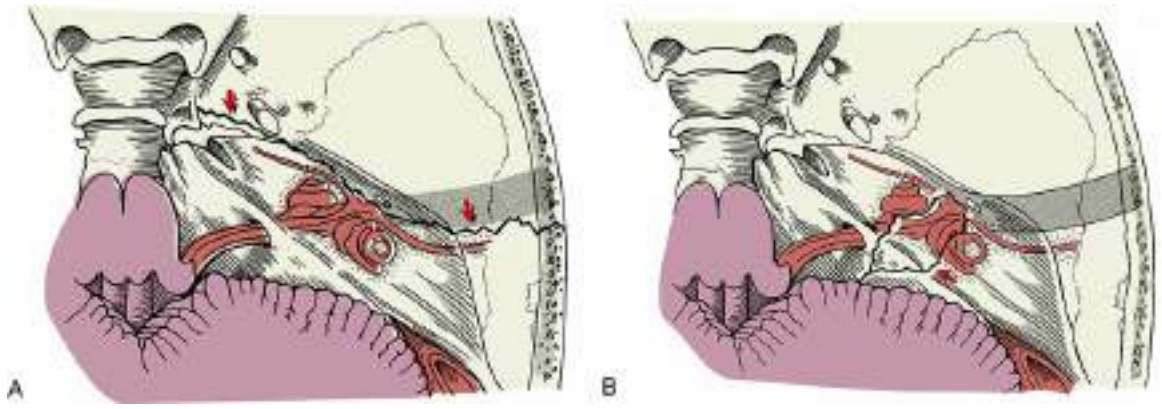

FIG. 145.4 **A,** Figure showing otic capsule sparing temporal bone fracture. *Red arrows* point to fracture line. **B,** Figure showing otic capsule penetrating temporal bone fracture. *Red arrow* points to fracture line.

What is the efficacy of surgical facial nerve decompression?

The data regarding outcomes after facial nerve decompression surgery are difficult to determine, but roughly 50% or slightly more have a good outcome with HB 1 to 2 function.[1] It is unclear how much better these results would be if a similar cohort underwent non-surgical treatment.

What is the efficacy of steroid treatment?

There are no substantial published data regarding the effect of steroid treatment for traumatic facial nerve injury.

Editorial Comment

The evaluation and management of temporal bone trauma encompasses signs and symptoms related to hearing, balance and facial nerve function and assessing the integrity of the dura. CT imaging of the temporal bone should be obtained to assess the status of the otic capsule, pneumatized regions of the middle ear and mastoid, intracranial space and carotid artery. Identification of conductive hearing loss is managed expectantly since the loss from blood or other secretions in the middle ear typically resorb resulting in resolution. Immediate onset sensorineural hearing loss is often permanent. Imaging may show penetrating fracture going through the otic capsule or, rarely, air in the vestibule. Acute vestibular insult often improves within a few weeks due to central compensation. Persistent clear otorrhea raises suspicion of a cerebrospinal fluid leak which can be confirmed by testing for the beta-2 transferrin protein. Most traumatic leaks stop within a week suggesting conservative observation initially be followed.

This chapter focuses on the controversial management of injury to the facial nerve. There is limited substantiated scientific basis for the definitive medical or surgical intervention. In the presence of complete paralysis the electrical status of the facial nerve is assessed by electroneuronography and electromyography. The interpretation of the electrical test results have been correlated with management recommendations in place for idiopathic facial paralysis (Bell's palsy). The indications for facial nerve intervention in temporal bone trauma have been extrapolated from those ascribed for management of the facial nerve in surgical decompression in Bell's palsy. Experience over time has demonstrated that delayed onset facial paralysis following temporal bone trauma typically results in good to excellent recovery. Patients with unknown timing or immediate onset facial paralysis, if neurologically and medically stable, should undergo temporal bone imaging and electrical testing to identify the possible site of trauma and the electrical status of the degree of injury. This electrical test may need to be done serially to identify possible deterioration of neural function raising consideration for exploration and repair or decompression. At minimum, the results of electrical testing should provide prognosis for anticipated recovery.

Barry Hirsch

General Considerations

The facial nerve can be injured as a result of penetrating or nonpenetrating temporal bone trauma. Penetrating temporal bone trauma with facial nerve paralysis, such as those due to gunshot wounds, has a high incidence of facial nerve transection. In these patients, surgical intervention to repair the facial nerve is typically performed soon after the injury. Facial nerve injury due to nonpenetrating temporal bone trauma is typically due to edema of the facial nerve in response to the trauma. As the nerve becomes edematous within the Fallopian canal, ischemic nerve injury occurs. In theory, surgical decompression and removal of the bone of the Fallopian canal overlying the facial nerve should be helpful in reducing the level of injury. Based upon limited human histopathology data in temporal bone trauma cases, the edema and ischemia of the facial nerve extend throughout the fallopian canal and appear to be most severe at the narrowest areas of the canal, specifically the labyrinthine segment and meatal foramen, regardless of the site of the fracture. If this is indeed the case, facial nerve decompression must include not only the primary site of injury but also the entire length of the fallopian canal.[1]

The goal then becomes reduction of the progressive ischemic injury to minimize facial nerve fibrosis and allow the injured facial nerve axons to regenerate. If facial nerve decompression is contemplated, it must be done over in a timely fashion. Based on limited data from surgical decompression performed for the treatment of Bell's palsy and limited data on temporal bone trauma,[2] the time window may be as short as 12 days, after which the injury becomes irreversible and refractory to further treatments. One must also keep in mind that there are no definitive studies that show that facial nerve decompression has any efficacy in these cases for temporal bone trauma.[3]

Review Questions

1. Possible sequelae of temporal bone trauma do not include

a. Facial nerve injury

b. Hearing loss

c. Dizziness

d. Cerebrospinal fluid

e. **Hypoglossal nerve injury**

2. Evaluation of facial nerve injury does not include

a. Facial nerve grading

b. ENoG

c. EMG

d. CT

e. **Magnetic resonance imaging (MRI)**

3. The area of the facial nerve at most risk of ischemic injury is

a. **Labyrinthine**

b. Geniculate

c. Horizontal

d. Vertical

e. Extratemporal

4. Which of the following surgical approaches can preserve the ossicular chain?

a. Transmastoid approach

b. Transmastoid transfacial recess approach with temporary packing of the middle ear and eustachian tube

c. Temporal bone obliteration with closure of the ear canal and eustachian tube

d. **a and b**

e. a and c

Surgery for Vertigo

Peter Weber, and Elizabeth Toh

Introduction

Surgery for vertigo is typically a treatment of last resort, whether due to a peripheral or central etiology. The vast majority of patients may be managed conservatively with medical treatment and/or vestibular rehabilitation therapy. Critical to the management of patients with vertigo is the correct diagnosis of the underlying pathology. The small percentage of patients who fail maximal medical management may benefit from surgery. It is imperative that the correct side is also identified. Surgical options include those that address the specific pathology of the disease, as well as those that ablate the peripheral vestibule or organ. This chapter describes operative techniques for posterior semicircular canal (PSC) occlusion; endolymphatic sac decompression, with or without shunting; labyrinthectomy; vestibular nerve section; and vascular loop decompression. Repair of superior canal dehiscence (SSCD) and treatment for acoustic neuroma are discussed in Chapters 149 and 142, respectively.

Key Operative Learning Points

1. Surgery is indicated only for control of disabling vestibular symptoms in patients with peripheral or central vestibulopathy with failed maximal medical treatment and vestibular rehabilitation.

2. Vestibular ablation is typically contraindicated in those patients with bilateral peripheral or central vestibulopathy.

3. The retro sigmoid and retromastoid are the preferred approaches for vestibular nerve section in patients with aidable hearing in the affected ear.

4. The PSC should be fenestrated midway between the ampulla and the common crus for PSC occlusion to minimize the risk of violating the vestibule and causing sensorineural hearing loss (Fig. 146.1).

5. Ablation of the vestibular inner ear in the presence of bilateral peripheral vestibulopathy may result in disabling oscillopsia.

6. Suctioning in the vicinity of a fenestrated or dehiscent semicircular canal may result in disruption of the membranous labyrinth and cause postoperative sensorineural hearing loss.

7. Incomplete removal of the sensorineural epithelium within the PSC ampulla is the most common cause of persistent vertigo following labyrinthectomy.

Preoperative Period

History

- Determine the frequency, duration, sidedness, symptoms, and length of time affecting the patient to help make the diagnosis.
- History of migraines, motion intolerance, family history, and visual disturbances should be elicited.
- History of seizures should be asked as well as cardiovascular disease.
- History of trauma should be assessed.
- Current and past medications should be assessed.
- Tinnitus is non-specific unless characterized as being pulsatile. The evaluation should include glomus tumor, dural AV arteriovenous malformations, meningoceles, SSCD superior semicircular canal dehiscence, aneurysms, vascular loops, and dehiscent high riding jugular bulb.

Physical Examination

- Office vestibular testing can usually evaluate benign positional vertigo (BPPV), hypoactive systems, vestibular ocular reflex (VOR) pathology, perilymph fistula, and acute vertiginous attacks.

- Postural hypotension may be important to eliminate.
- Pneumotoscopy should not cause vertigo or nystagmus. If present, consider perilymphatic fistula (PLF) or possibly SSCD.

Audiogram

- Early Meniere syndrome typically manifests low-frequency sensorineural hearing loss on the affected side. Progression of disease results in a greater flat SNHL sensorineural hearing loss.
- SSCD may demonstrate a conductive loss due to the third window effect, and loud noise may cause "dizziness" (Tullio phenomenon).
- Labyrinthectomy may be offered to those with severe to profound SNHL. Caution and informed consent should be provided to patients with functional hearing who are offered intratympanic gentamicin therapy. Up to 30% of patients may experience further hearing loss following gentamicin injections.

Vestibular Testing

- Videonystagmography (VNG) can be useful in identifying the "weak" side or bilateral weakness. Identifying bilateral weakness is important as it may preclude vestibular ablation surgery.
- Vestibular evoked myogenic potential (VEMP) testing can be useful in identifying SSCD or indicate the side of the lesion.
- Dix-Hallpike maneuver is used to make the diagnosis of BPPV.

Imaging

- Magnetic resonance imaging (MRI) with gadolinium is important to assess for central lesions or inflammation of the vestibular nerve(s) or cranial nerves.
- Computed tomography (CT) of the temporal bone in the coronal plane best highlights the SSCD (see Chapter 149).

Consultation With

- Cardiology may be indicated to evaluate for arrhythmias (Holter monitoring), autonomic dysfunction (tilt table testing), or other abnormalities.
- Neurology may be indicated for evaluation for a central etiology including headaches, seizures, and TIAs transient ischemic attacks.
- Psychiatry may be especially beneficial as many of these patients may suffer from depression or anxiety.

Indications

BPPV–Posterior Canal Plugging

- Offer surgery only after particle repositioning maneuvers by trained therapists or MDs Meniere's disease fail to control symptoms that significantly affect the life of the patient. Less than 1% of patients require surgical intervention.[1]
- Surgical success rates are over 90%.
- Must ensure the proper canal has been identified prior to surgery

Contraindications

Surgery in the elderly carries the potential development of vestibulitis, which can incur the unintended consequence of severe disequilibrium. This more chronic disorder is worse than the BPPV. The elderly with dysfunction of the inner ear are more prone to repeated falls and fractures.

Do not operate if the affected ear is the only hearing ear.

Preoperative Preparation

Verify that the planned operative procedure is being done on the identified malfunctioning semicircular canal.

Document hearing levels.

Document that a VNG was performed and rotary chair testing, if

available, is obtained.

Explain the risks and ensure realistic expectations, including that disequilibrium may occur after the surgery.

Review imaging to ensure that no other pathology is present as the source for unrelenting positional vertigo.

Operative Period

Anesthesia

General anesthesia is preferred, and the patient should not be paralyzed during the operative procedure so that cranial nerve 7, as well as other cranial nerves, can be monitored if the need arises.

Positioning

- The patient is turned 180 degrees from anesthesia so that the surgeon is on the side of ear to be operated and the scrub nurse on the opposite side with the microscope at the head of the table.
- For the suboccipital or retrosigmoid approach the patient is typically put in neurosurgical pins and a Mayfield holder. Depending on the ability to turn the neck, an ipsilateral shoulder and hip bolster may help in providing access.

Perioperative Antibiotic Prophylaxis

IV cefazolin; clindamycin for patients who are allergic to penicillin

Steroids

Typically 10 mg IV of Decadron for adults is given, which helps reduce postoperative vertigo and nausea.

Monitoring

Neurophysiology monitoring usually includes the facial nerve. For hearing preservation procedures the cochlear nerve is monitored. Somatosensory potentials are observed for intracranial procedures.

Instruments and Equipment to Have Available

- Microscope
- Mastoidectomy instrument set
- Neurosurgical instruments for intracranial procedures
- Otologic drill
- Facial nerve dissector and stimulator

Key Anatomic Landmarks

The lateral semicircular canal (LSC) is key. It is also important to understand the relationship of the facial nerve to the PSC and the sigmoid sinus.

Prerequisite Skills

Knowledge of temporal bone anatomy and experience, not only operating in this area but managing the potential complications

Operative Risks

- Pain
- Bleeding (including the sigmoid sinus)
- Infection (including meningitis)
- Hearing loss in the operated ear that can be partial or total; sensorineural loss is more common but conductive loss could also occur
- Facial paresis and paralysis

- Loss of taste sensation on the tongue
- Tinnitus
- Vertigo or disequilibrium that can be temporary or permanent
- CSF (leak cerebrospinal fluid leak)
- Seizure, stroke, death

Surgical Technique

BPPV—Posterior Canal Plugging

- The patient is prepped and draped as for standard mastoid surgery.
- A cortical mastoidectomy using a postauricular incision is done followed by identifying the LSC, incus, tegmen, and, typically, the sigmoid sinus.
- Saline-soaked Gelfoam pledget can be placed in the antrum to reduce the amount of blood and bone dust entering the middle ear space.
- The PSC lies directly posterior and perpendicular to the LSC.
- A diamond bur is used to skeletonize and blue-line the PSC so that a 1 × 3-mm oval window of bone over the mid-portion of the PSC is opened to expose, but not violate, the membranous labyrinth within the opened SCC (Fig. 146.1).
- The opened semicircular canal can be plugged with bone wax, bone dust, or connective tissue and then covered with fascia.
- If the membrane is violated, the canal is still packed.
- Suction should be avoided.
- Closure is per surgeon's choice.

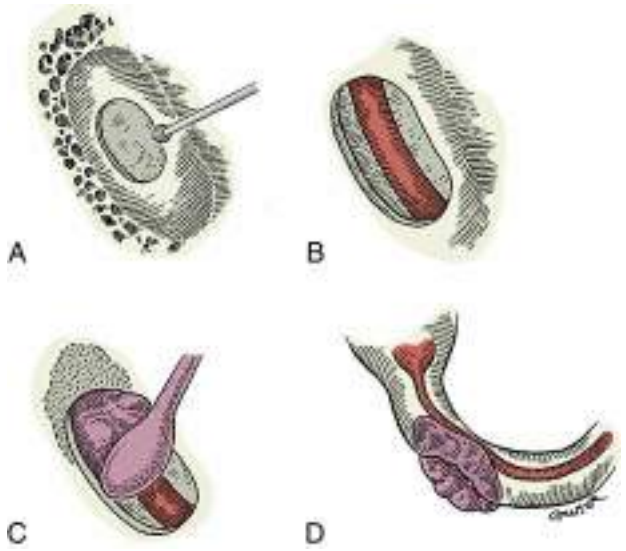

FIG. 146.1 Technique for posterior semicircular canal.

A, Skeletonization of mid-portion of posterior semicircular canal (PSC) using small diamond bur. **B,** PSC fenestrated without violating membranous labyrinth. **C,** Bone wax, bone paste, or soft tissue is applied to the fenestrated portion of the PSC using a duckbill elevator. **D,** The membranous labyrinth within the PSC is compressed and occluded.

Surgery: Meniere

Endolymphatic Sac Decompression Shunt

- Offered only when the patient fails maximal medical therapy, including intratympanic steroid injections
- Maximal medical therapy includes treatment of identified vertiginous triggers such as migraine, allergy, stress, and diet.
- This remains an excellent choice of surgical options since it spares the vestibular system (important to many who have jobs or hobbies that require good balance), typically spares hearing, and postoperative recovery time is often brief.
- Vertigo symptoms are typically relieved in approximately 60% of patients.[2-4]

- As with all surgery for Meniere disease, fluctuating and progressive hearing loss, aural fullness, and tinnitus may persist.
- The patient is prepped and draped as for standard mastoid surgery.
- A standard postauricular incision is made followed by a cortical mastoidectomy, identifying the LSC, incus, tegmen, and sigmoid sinus.
- Saline-soaked Gelfoam pledgets can be placed in the aditus ad antrum to reduce the amount of blood and bone dust entering the middle ear space.
- The endolymphatic sac lies on the dura between the PSC and the sigmoid sinus and is consistently inferior to "Donaldson's Line"—an imaginary line extending posteriorly from the parallel plane along the LSC.
- The facial nerve is identified in the vertical segment.
- The sigmoid sinus is skeletonized and decompressed as necessary.
- The posterior fossa dural plate between the PSC and sigmoid sinus is removed and then followed up to and medial to the facial nerve as necessary (Fig. 146.2).
- The endolymphatic sac appears as thickened dura in a fan shape and can be followed anteriorly under the PSC to identify the operculum and endolymphatic duct.
- Decompression is now complete.

FIG. 146.2 The dura of the posterior fossa is widely

exposed. The endolymphatic sac is visible as a thickening of the dura fanning out from the posterior semicircular canal to the sigmoid sinus.

- The dura can be elevated and the sac remain tented away from the bone of the posterior fossa by placement of Surgicel superior and inferior to the sac.
- To place a shunt, a small narrow piece of 0.005 inch-Silastic sheeting is cut to size. The sac is opened with a Beaver blade of choice, and the lateral walls are separated and the shunt is positioned.
- Closure is per surgeon's choice.

Labyrinthectomy

- Reliably controls the vertigo associated with Meniere greater than 95% of time[5]
- Destroys all the hearing, thus not recommended for patients with functional aided hearing
- Can be combined with a cochlear implant if indicated
- Patients require vestibular rehabilitation postoperative to aid in balance compensation.
- Patients should know that this may preclude them from functioning at heights, climbing ladders, or other activities that require critical balance.
- Elderly patients typically have a more difficult time compensating.
- All five sensory epithelia end organs have to be removed to achieve success.
- The patient is prepped and draped per standard mastoidectomy protocol.
- The LSC, incus, tegmen, and sigmoid sinus are identified.
- Perilabyrinthine air cells are removed to further expose the PSC and SSC.

- Identify the horizontal and vertical portions of the facial nerve.
- The LSC is first opened from superiorly to inferiorly in order to protect the facial nerve. It is opened posteriorly to the PSC (Fig. 146.3).
- The PSC is then opened and followed anteriorly and inferiorly taking care to protect the medial portion of the vertical segment of the facial nerve.
- Keeping the inferior wall of the PSC intact can protect a high riding jugular bulb.
- The PSC is followed superiorly to the common crus where it joins the non-ampullated end of the SSC.
- The SSC is then followed superiorly and anteriorly taking care to leave the superior wall intact to protect the tegmen.
- The vestibule is then opened, exposing the neurosensory epithelium of the superior and lateral ampullae.

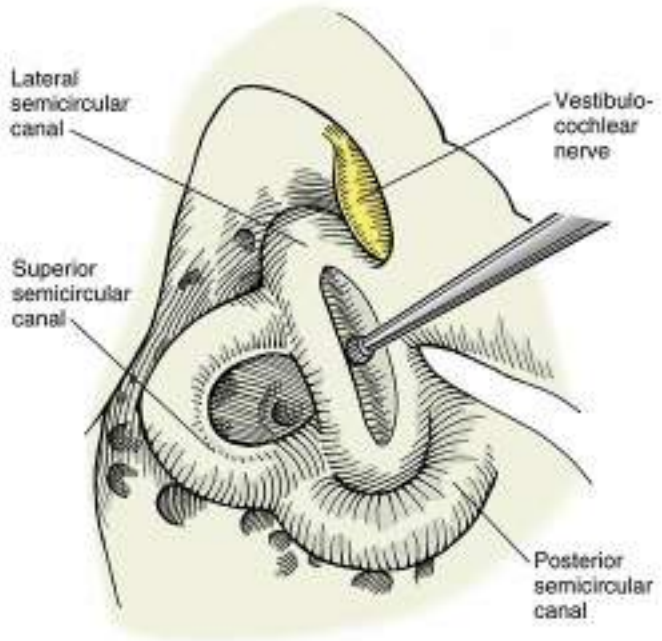

FIG. 146.3 The superior wall of the lateral semicircular canal is removed. The inferior wall is left intact to protect the facial nerve.

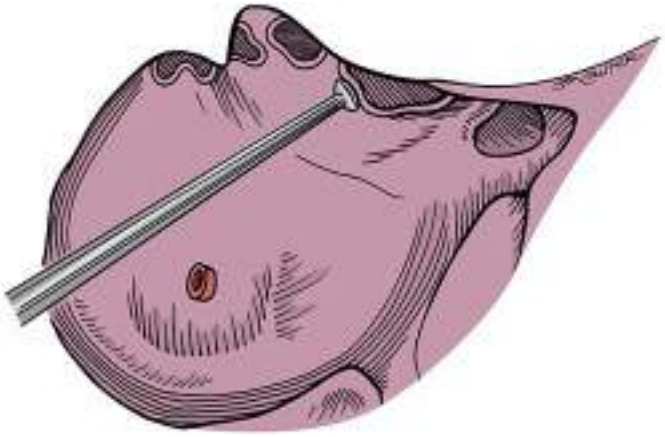

FIG. 146.4 The five areas of neurosensory epithelium are exposed and removed systematically using a round knife or microcurette.

- The neuroepithelium of the ampulla of the PSC lies medial to the vertical (mastoid) segment of the facial nerve. Specific efforts are needed to ensure removal. The medial wall of the vestibule is left intact to protect the internal auditory canal (IAC) and prevent CSF leaks.
- The neuroepithelium is removed from all five vestibular end organs (Fig. 146.4).
- Closure is per surgeon's choice.

Vestibular Nerve Section—Retrolabyrinthine

- Patients should know that this may preclude them from functioning at heights, climbing ladders, or other activities that require critical balance. Elderly patients typically have a more difficult time with vestibular compensation.
- Vestibular nerve section reliably controls the vertigo associated with Meniere greater than 95% of time.[5,6]
- Patients require vestibular rehabilitation postoperatively to aid in central compensation.

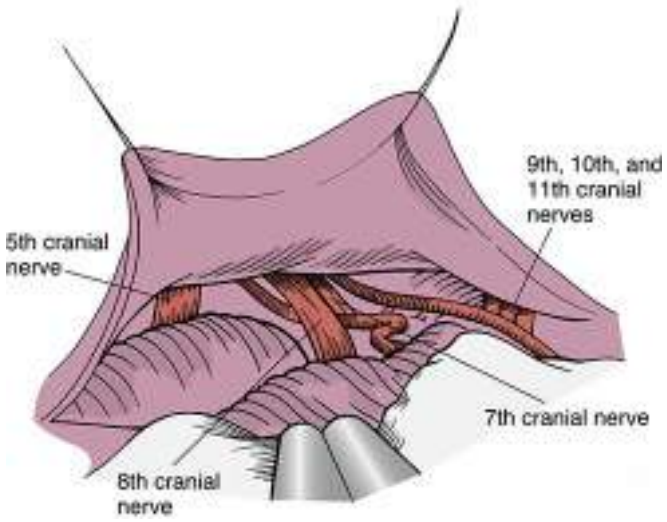

FIG. 146.5 Retrolabyrinthine exposure of the posterior fossa.

- The hearing preservation rate is greater than 95%.[6]
- The patient is prepped and draped for the standard mastoidectomy surgery.
- The incision is placed 2 to 3 cm posterior to the ear crease from the area above the temporal line to the mastoid tip.
- An anterior skin flap is elevated, and then a large Palva flap or T-based flap is elevated.
- A complete mastoidectomy is performed exposing the LSC, incus, tegmen, sigmoid sinus, PSC, and SSC.
- A Gelfoam-soaked pledget can be placed in the antrum.
- Bone over the posterior cerebellar dura, sinodural angle, and tegmen is removed with drill and/or bony elevators and bone biting forceps.
- The endolymphatic sac is preserved.
- The dura is then opened, anterior to the sigmoid sinus and posterior to the PSC via a C- or U-shaped flap.
- The cerebellum is protected with a ½ by 3-cm neuropatty, and the cerebellopontine cistern is opened to drain CSF.
- As the cerebellum falls away, the CP cerebellarpontine angle is opened,

exposing the seventh and eighth cranial nerve complex (Fig. 146.5).

- The location of CN VII is confirmed with electrical stimulation.
- The cleavage plane between the auditory and vestibular portions of CN cranial nerve VIII is identified, typically demarcated by a small vessel and a subtle difference in color (the auditory portion is whiter) (Fig. 146.6).
- The vestibular portion is also superior to the auditory portion in the CP angle and then rotates within the IAC such that the auditory portion is anterior to the vestibular nerve and inferior to the facial nerve. The inferior and superior vestibular nerves lie posterior to the facial and auditory nerves in the IAC.
- Using a blunt dissector like a ball dissector or Rhoton the two portions are separated (Fig. 146.7).
- Typically a curved bayonet microscissors or nerve knife is used to cut the vestibular nerve, exposing the nervus intermedius (Fig. 146.8).
- Finally, a small portion of the nerve is removed so that the ends do not reapproximate and lead to recurrence of vertigo/disequilibrium.
- Hemostasis is assured, the neuropatty removed, and the dura reapproximated and covered with Tisseal to prevent CSF leak. If the dura cannot be closed, homograft substitution dura can be used as well.
- Fascia can be used to seal off the antrum, and the mastoid can be packed with abdominal adipose tissue.

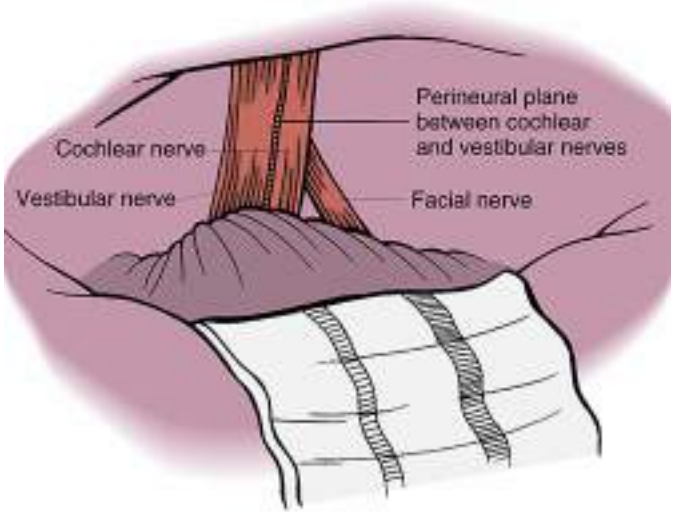

FIG. 146.6 A perineural plane between the cochlear and vestibular nerves is frequently demonstrated by a small vessel or a slight depression in the nerve running longitudinally on the dorsal surface of the nerve.

FIG. 146.7 Separation of the cochlear and vestibular nerves.

FIG. 146.8 The vestibular nerve is divided, starting from the superior-dorsal surface of the eighth cranial nerve.

FIG. 146.9 The skin incision for a retrosigmoid vestibular nerve section.

- Closure is per surgeon's choice.
- Patients typically are hospitalized until the severe vertigo subsides.

Retrosigmoid Vestibular Nerve Section

- Patients should know that this may preclude them from functioning at heights, climbing ladders, or other activities that require critical

balance. Elderly patients typically have a more difficult time with vestibular compensation.

- Nerve section reliably controls the vertigo associated with Meniere greater than 95% of time.[5]
- Patients require vestibular rehabilitation postoperatively to aid in compensation.
- The hearing preservation rate is greater than 95%.[6]
- The patient is typically placed in the supine position with the head secured with pins and a Mayfield head holder.
- A soft roll may be placed under the shoulder to help position the head flexed about 45 degrees down and rotated away to expose the surgical site.
- Some neurosurgeons may infuse mannitol to lower intracranial pressure.
- The incision is made obliquely from the posterior superior position toward the mastoid tip. The site of the incision is planned over the location of the sigmoid sinus, which can be determined by neural navigation systems (Fig. 146.9).
- These incisions and subsequent craniotomies have decreased in size over time.
- The incision is carried down to the periosteum, and the anterior and posterior flaps are elevated making sure to occlude the mastoid emissary vein if encountered.
- The courses of the sigmoid and transverse sinuses are either estimated or marked out with the use of neural navigation systems (Fig. 146.10).
- The small craniotomy is then made (1.5 to 2 cm), sometimes exposing the posterior portion of the sigmoid sinus.
- Hemostasis is obtained. Exposed mastoid air cells are occluded with bone wax. The C- or U-shaped flap in the dura is opened.
- From this point, the steps are the same as outlined in the retrolabyrinthine approach.
- To minimize postoperative headaches, the small craniotomy can be

filled with a plug of bone dust and chips wrapped in Surgicel or by replacing the craniotomy bone flap.

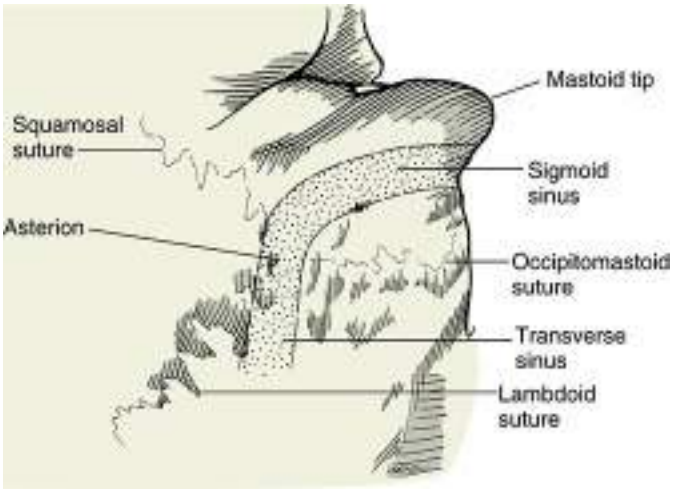

FIG. 146.10 The surface anatomy of the mastoid and retrosigmoid cranium and the estimated course of the transverse and sigmoid sinuses.

- Some surgeons use surgical plates or hydroxyapatite cement.
- The incision is closed per surgeon's choice.
- The patient is admitted until the severe vertigo subsides.

Middle Fossa Approach for Vestibular Nerve Section

- Patients should know that this may preclude them from functioning at heights, climbing ladders, or other activities that require critical balance. Elderly patients typically have a more difficult time with vestibular compensation.
- Reliably controls the vertigo associated with Meniere greater than 95% of time
- Patients require vestibular rehabilitation postoperatively to aid in compensation.
- The hearing preservation rate is greater than 95%.

- The reported advantage of this approach is that the superior, inferior, and singular portions of the nerve can be identified to increase complete nerve section.
- The disadvantages of this approach include significant temporal lobe retraction and increased risk to auditory and facial nerves, as well as headaches, compared to the other two approaches.
- The patient is supine with the head turned to expose the side to be operated on.
- Mannitol may be used to decrease intracranial pressure.
- Many incisions can be used to expose the needed cranium. I prefer an anteriorly based skin flap and a posteriorly based temporalis flap. However, the most common incision is a vertical incision extending superiorly from a pretragal skin crease inferior to the zygoma to the temporal line. Once the cranium is exposed, the craniotomy is marked out to be 4 × 5 cm such that two-thirds of the opening is anterior to the EAC and one-third is posterior (Fig. 146.11).
- The craniotomy is accomplished with a ball bur on a surgical drill or with craniotomy bur holes connected with a straight bit used with a footplate attachment.
- The bone flap is removed and saved in antibiotic solution to be replaced when closing the surgical exposure.
- Bipolar cautery is used to control bleeding.
- The dura is then elevated off of the floor of the middle fossa (Fig. 146.12), such that the middle meningeal artery is seen anteriorly, the tip of the petrous ridge medially, and the arcuate eminence posteriorly.

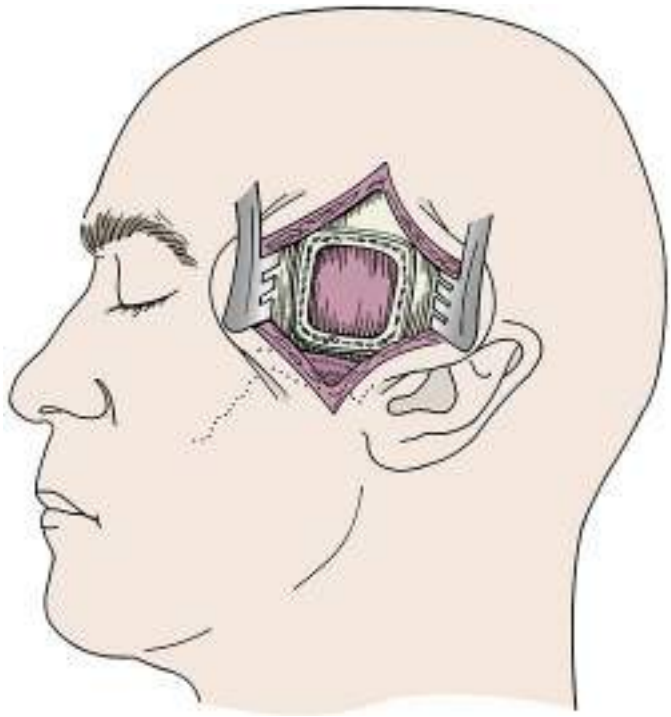

FIG. 146.11 Middle fossa craniotomy.

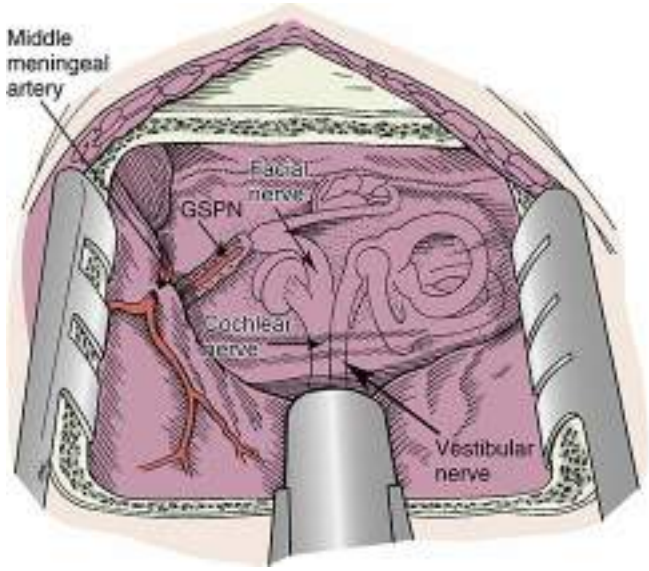

FIG. 146.12 Anatomy of the middle fossa floor. *GSPN*, Greater superficial petrosal nerve.

- Care is taken not to stretch or traumatize the greater superior petrosal nerve (GSPN) during elevation as this is the most common way to injure the facial nerve.

- A self-retaining middle fossa retractor is placed, and the location of the IAC is estimated by bisecting the angle formed by the GSPN and the arcuate eminence. In addition, neural navigation can readily pinpoint the IAC.
- The IAC is then exposed by drilling off the surrounding bone starting medially and working laterally, taking care not to injure the basal turn of the cochlea (Fig. 146.13).
- Bill's bar, which separates the facial nerve anteriorly from the superior vestibular nerve posteriorly, is exposed at the fundus.
- The dura of the IAC is opened, exposing the nerves within the IAC. The superior nerve is sectioned and reflected medially to expose the inferior vestibular nerve, which is sectioned along with the singular nerve.

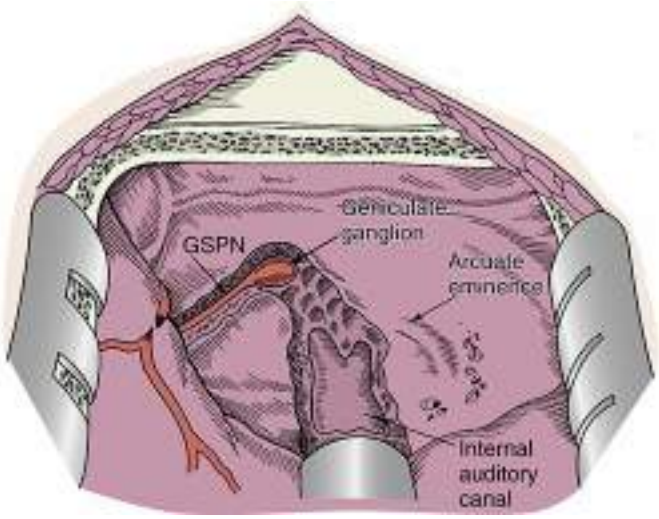

FIG. 146.13 Exposure of the internal auditory canal.
GSPN, Greater superficial petrosal nerve.

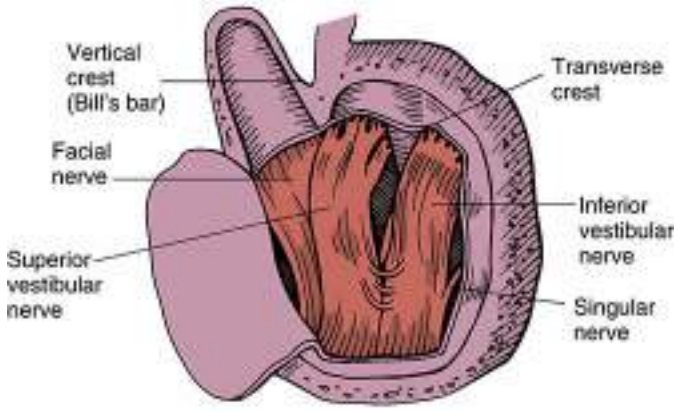

FIG. 146.14 The transverse crest and Bill's bar are exposed at the fundus of the internal auditory canal. The dura of the internal auditory canal is opened. The facial, superior vestibular, inferior vestibular, and singular nerves are identified.

- Scarpa's ganglion is also removed.
- The dural flaps are reapproximated, and a free muscle plug is placed, the temporal lobe is allowed to re-expand, and the craniotomy bone flap is plated into place.
- Closure per surgeon's choice

Translabyrinthine Vestibular Nerve Section

- This is a very rare approach and only considered if a traditional labyrinthectomy fails.
- The goal is to remove Scarpa's ganglion, which could also be done via a middle cranial fossa approach.
- This additional entry into the IAC carries an increased risk of facial nerve injury and CSF leak.
- The initial surgery is the same as with labyrinthectomy as that provides the surgical approach. The lateral portion of the IAC is then exposed by drilling the bone covering the IAC away in a 270-degree fashion.
- The superior limit is the ampulla of the SSC. The transverse crest separating the superior and inferior vestibular nerves is identified.

- The dura is opened, and the nerves exposed (Fig. 146.14).
- The superior nerve is separated from the facial nerve in a lateral to medial fashion and a small section removed. The same is done with the inferior and singular nerves.
- The dura is reapproximated, and the incus is removed. A large fascia graft is placed to isolate the epitympanum from the antrum, and the mastoid cavity is packed with an abdominal adipose tissue graft.
- Closure per surgeon's choice

Surgery for Uncompensated Peripheral VestibulopAthy

- These are patients who typically have an uncompensated unilateral hypofunctioning vestibular system.
- They have failed extensive vestibular rehabilitation and medical management.
- Treatment options include chemical ablation with gentamicin with the possibility of hearing loss, vestibular nerve section, or labyrinthectomy.

Postoperative Period

Postoperative Management

- For non-intracranial and cranial procedures, the patient is discharged when he or she is no longer vertiginous and is able to safely ambulate and maintain nutrition.
- Patients undergoing intracranial procedures are monitored in a neurosurgical ICU until medically stable to transfer to a surgical floor.
- Vertigo is typically managed with medications such as Phenergan, Valium, Ativan—interestingly, Zofran and meclizine do not seem to be as effective.

- Postoperative antibiotics are usually given for 7 days, although some surgeons elect to only administer perioperative antibiotics.
- Vestibular rehabilitation is important in any ablative vestibular procedure.

Complications

These mirror those of the operative risks:

CSF Leak

Early leaks may respond to lumbar drain and pressure dressings. For those that do not respond, reoperation may be required to seal the defect causing the leak.

Vertigo/Disequilibrium

This is not uncommon in the immediate postoperative period. However, vestibular rehabilitation is invaluable in assisting with disequilibrium and positional vertigo. Medications such as Ativan do have a role for acute vertigo management.

Meningitis

Intravenous antibiotics are essential for treating this bacterially induced disease. However, steroids may be useful if the disease is not bacterial.

Partial/Total Hearing Loss

This may be treated with hearing aids, osseointegrated implants, or cochlear implants.

Dysguesia/Loss of Taste

May occur if the chorda tympani is stretched or sacrificed. The taste typically compensates over a 1- to 9-month window, but about 2% of the time patients may continue to experience a metallic-like taste on half the

tongue.

Facial Nerve Paralysis

Usually due to stretching of the nerve, however direct injury or cutting of the nerve can occur. High-dose steroids for 7 to 10 days is indicated, and repair of the nerve is done at time of injury if noticed. If the nerve does not recover, facial reanimation surgery may provide some benefit.

Intracranial Bleeding

Neurosurgery is consulted, and evacuation of clot and/or control of bleeding vessel may be indicated.

Pneumocephalus

May cause headaches or other intracranial complaints. Consult with neurosurgery to determine whether to observe, since air will resolve over time, or if evacuation is indicated.

Headache

This is not uncommon, depending on the surgery. Typical analgesics such as ibuprofen and acetaminophen normally help. For more chronic or complex cases, pain management or neurology may be consulted.

Alternative Management Plan

There are limited options for those patients who have failed optimal medical and physical therapy interventions. A transcanal labyrinthectomy is a quicker means of removing the neuroepithelium, allowing the patient a brief time under anesthesia if deemed safe by the patient's PCP or medical specialist.

Patients may opt not to consider perceived invasive procedures or are medically not safe to undergo general anesthesia and the ablative procedures described. Efforts should again be directed to use of vestibular suppressants and the possibility of intratympanic steroids or

gentamicin. Physical therapy to ensure safety with ambulation should be revisited.

Discussion

Evidence-Based Medicine Question

Is there a reliable surgical treatment algorithm for Meniere disease?

This is a difficult question to answer since so many variables play a role; however, the one overlying variable is "do no harm." Thus, the procedure that has the most chance of success while having minimal chance of complications wins out. A new study from England demonstrates 90% success 1 year following steroid injections, just a little bit better than gentamicin, which has the side effect of possible sensorineural hearing loss.[6] All the other procedures require anesthesia. When steroid injections fail, then one has to weigh the risks of using anesthesia with no significant risk to hearing and the vestibular system and a 65% success rate of endolymphatic sac surgery versus the office procedure of gentamicin with up to 30% hearing loss rates.[4] If the endolymphatic sac surgery is not successful and the goal is still to preserve hearing, then a vestibular nerve section may be a better treatment option (less than 5% chance of significant hearing loss) than gentamicin; however, the risk of an intracranial procedure must be factored in. The labyrinthectomy is typically the last option of surgical choice since it destroys hearing and balance.

Editorial Comment

Treatment of vestibular disorders is one of the more difficult challenges facing Otolaryngologists. It is critical to define the side of the pathology. Equally important is to understand the status of vestibular function on the contralateral side. BPPV of the PSC can be readily diagnosed. It is rare that the Epley repositioning maneuver fails to achieve satisfactory control. In the past, sectioning of the singular nerve was the recommended surgical approach for medical failure. Occlusion of the posterior canal is safer toward hearing preservation and more directed at the involved end organ.

Intratympanic gentamicin therapy is also very successful when delivered in the appropriate patient. This technique should be avoided in people with chronic ongoing vestibulopathy as it may aggravate the underlying symptom complex. It does incur the risk of sensorineural hearing loss. It should be used cautiously and with informed consent in patients with good hearing.

It is important to have an excellent understanding of the anatomy of the contents in the internal auditory canal. The seventh and eighth cranial nerves have a specific orientation that must be critically recognized in order to safely ablate vestibular dysfunction and preserve hearing and facial motor function. This pertains to the three approaches to vestibular nerve section.

The decision for labyrinthectomy is based on verification of the side of disease that is strengthened by the presence of unilateral hearing loss. As mentioned, the contralateral side should have good residual vestibular function in anticipation of rehabilitation from central compensation.

The use of postoperative vestibular rehabilitation therapy is strongly recommended to promote quicker recovery from any ablative procedure. The patient may require short-term disability as he or she regains the ability and confidence to function normally.

Barry Hirsch

Review Questions

1. To surgically treat BPPV of the PSC it is important to:

   a. Suction out the offending otolith from the canal to prevent recurrence.

   b. Open the membranous labyrinth to plug the canal, thus providing the best seal to prevent recurrence.

   c. Drill through the canal in order to plug both ends to ensure no recurrence.

   d. **Keep the membrane intact when plugging the canal.**

2. When performing a vestibular nerve section from the retrosigmoid approach and visualizing the four nerves in the CPA, the inferior and

superior vestibular nerve bundles are located:

a. Directly posterior to the facial and cochlear nerve

b. Directly inferior to the facial and cochlear nerve

c. Directly anterior to the facial and cochlear nerve

d. **Directly superior to the facial and cochlear nerve**

3. In a middle fossa craniotomy for vestibular nerve section, the superior and inferior vestibular nerves in the IAC are located:

a. **Directly posterior to the facial and cochlear nerve**

b. Directly inferior to the facial and cochlear nerve

c. Directly anterior to the facial and cochlear nerve

d. Directly superior to the facial and cochlear nerve

Superior Semicircular Canal Dehiscence

Andrew A. McCall

Introduction

Superior semicircular canal dehiscence (SCD) syndrome was first described by Minor et al. in 1998; it consists of anatomic dehiscence of the superior semicircular canal accompanied by symptoms including dizziness, autophony, and hearing loss.[1] The prototypical dizziness symptoms associated with SCD syndrome include sound- and/or pressure-induced vertigo. Autophony indicates the hearing of internal body sounds, such as hearing the heartbeat or hearing the eyes move. Hearing loss due to SCD typically presents as a low-frequency conductive hearing loss with an air-bone gap that commonly closes in the high frequencies.[2] The treatment of SCD syndrome consists of plugging the affected superior semicircular canal.

Key Operative Learning Points

1. Dehiscence of the superior semicircular canal in SCD usually involves the floor of the middle cranial fossa.

2. Plugging the superior semicircular canal is the most efficacious treatment for SCD syndrome.

3. SCD is commonly associated with other bony defects in the floor of the middle fossa, which are usually addressed in the same setting.

Preoperative Period

History

1. History of present illness

   a. Does the patient experience dizziness?

   Two types of elicited dizziness are commonly associated with SCD syndrome: sound- and pressure-induced dizziness. Sound-induced dizziness occurs in response to exposure of the affected ear to loud noise, such as that from loud machinery, music, or crowd noise. Pressure-induced dizziness in SCD syndrome occurs in response to the transient elevation of intracranial pressure, as occurs with heavy lifting or bearing down. The dizziness that occurs in response to these inciting events is usually transient. Dizziness may be elicited by positive pressure in the external meatus, as with finger manipulation. Some patients with SCD syndrome have nonspecific chronic dizziness with or without elicited dizziness.

   b. Does the patient have autophony?

   Autophony is the hearing of internal body sounds. Examples of common sounds heard by patients with SCD syndrome include hearing one's eyes move, the sound of one's heels hitting the floor, hearing one's heartbeat, the sound of chewing, or hearing one's voice reverberate within one's head. Note that autophony of breathing is not expected in SCD; if this is present, alternative diagnoses such as patulous Eustachian tube should be considered.[3]

   c. Does the patient have hearing loss?

   Hearing loss is common in SCD syndrome. The dehiscence of the superior canal results in a third mobile window (the oval and round windows being the first and second) into the inner ear. This third mobile window allows for the shunting of air-conducted sound energy away from the cochlea and leads to hearing loss.[4]

   d. Is the patient asymptomatic?

   Superior canal dehiscence can present as an incidental finding discovered on imaging performed for another reason. Patients with asymptomatic SCD do not require surgery and should be observed.

2. Past medical history

a. Prior treatment: Has the patient had prior treatment for SCD syndrome or for dizziness thought to be from another etiology?

b. Medical illness

1) What is the hearing status in the contralateral ear?

2) What is the vestibular function of the contralateral ear?

3) Is there a history of migraine? Migraine may interfere with or prolong compensation following a vestibular insult, such as that which occurs following plugging of the semicircular canal.

4) Is the patient's overall medical health sufficient to tolerate a craniotomy?

c. Surgery

d. Family history

1) Some cases of familial SCD syndrome have been described. Most cases, however, appear to be sporadic.

e. Medications

1) Is the patient currently on anticoagulation therapy that would interfere with the performance of a craniotomy?

2) Is the patient currently taking vestibular suppressant medication? Vestibular suppressants can interfere with vestibular compensation following surgery.

Physical Examination

1. Otoscopy

a. Otoscopic examination in SCD syndrome is normal.

2. Tuning fork examination

a. Weber lateralizes to the affected ear and Rinne can be negative (bone conduction perceived louder than air conduction). (Note: Not all patients with SCD have demonstrable hearing loss or an air-bone gap. Therefore the findings of tuning fork examination are variable in SCD and are often in line with audiometric findings.)

b. When the vibrating tuning fork is placed on the lateral malleolus of

the ankle, it can often be perceived in the affected ear.

3. Tullio phenomenon

   a. Presentation of a loud sound (as with a Barany noise box or delivered with an audiometer) to the affected ear results in dizziness.

4. Hennebert sign

   a. Pneumatic otoscopy or tragal pressure to the affected ear results in a vertical-torsional nystagmus with associated dizziness. Note that this nystagmus is likely to be difficult to perceive without the assistance of Frenzel lenses.

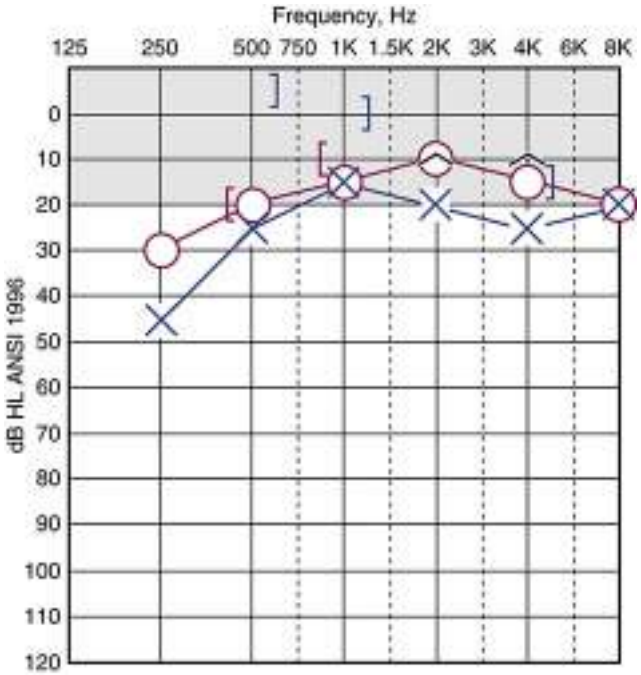

FIG. 147.1 Audiometric findings in dehiscence of the semicircular canal.

This audiogram, from a patient with left superior semicircular canal dehiscence syndrome, demonstrates a supranormal bone conduction threshold at 500 Hz and an air-bone gap that is larger in the low frequencies.

Audiometric Findings and Other Testing

1. Audiogram
    a. The characteristic audiometric findings of SCD include supranormal bone conduction thresholds and a predominantly low-frequency air-bone gap (Fig. 147.1).
2. Acoustic reflex testing
    a. The audiometric findings in SCD may mimic those seen in otosclerosis. Acoustic reflex testing can be used to distinguish between these diagnoses. In SCD, acoustic reflexes are present. In contrast, in otosclerosis, acoustic reflexes are absent because the stapes is immobilized.
3. Vestibular evoked myogenic potential (VEMP)
    a. Presentation of a loud tone (or click) to the ear and evaluating for an inhibitory response in the ipsilateral sternocleidomastoid muscle is the cervical VEMP test. Reduced thresholds or increased amplitude on the test is consistent with SCD.
    b. The ocular VEMP test (excitatory response measured in the contralateral inferior rectus muscle) has been suggested to be a more sensitive and specific test for SCD than the cervical VEMP test.[5]

Imaging

Computed tomography (CT) of the temporal bone with fine cuts should be obtained when SCD syndrome is suspected. Multiple planes should be evaluated to confirm the diagnosis (Fig. 147.2). An image guidance study should be performed if the use of image guidance is planned for surgery.

Indications

1. SCD syndrome—Patients should make the final decision as to when they want to intervene based on their perceived severity and disability.

Contraindications

1. Anatomic SCD without symptomatology

2. An active coplanar semicircular canal problem (e.g., contralateral posterior semicircular canal benign paroxysmal positional vertigo [BPPV]) should be treated prior to proceeding with surgery.

3. SCD syndrome in an only one hearing ear: Very strong consideration should be given to alternatives to surgery owing to the risk of hearing loss in the operative ear.

4. Medical conditions that would preclude a craniotomy

Preoperative Preparation

1. Obtain preoperative medical clearance for craniotomy surgery.

2. Stop anticoagulation therapy (Note: this should be done with the guidance of the patient's medical provider).

Operative Period

Anesthesia: General

Positioning

The patient is placed supine with the head turned and the ear to be operated facing upward. If image guidance is to be employed, the patient's head is fixed within a Mayfield head holder to fix it in position and permit placement of the image guidance system. The operating surgeon works at the head of the operating table; therefore the table must be positioned to accommodate the surgeon, the microscope, and the image guidance setup.

Perioperative Antibiotic Prophylaxis and Administration of Medication

First-generation cephalosporin

Steroids are given pre- and perioperatively to lessen the chances of sensorineural hearing loss (SNHL).

Mannitol is given near the time of craniotomy to provide brain relaxation.

Monitoring

Facial nerve electromyography (EMG), brainstem auditory evoked responses, somatosensory evoked potentials (SSEPs)

The anesthesia team should be notified that facial nerve monitoring will take place during the surgical procedure and that therefore long-acting neuromuscular blockade should be avoided.

Instruments and Equipment to Have Available

1. Binocular microscope

2. Craniotomy set and drill/craniotome

3. Brackmann-tipped suction irrigation setup

4. Facial nerve stimulator

5. Bone wax: Bone wax is placed in a warming bath to make it malleable and thus easy to mold into the contour of the dehiscence.

6. Image guidance: Image guidance can be a useful adjunct for locating and confirming the site of dehiscence of the superior canal or for orientation along the floor of the middle fossa. Its use may be particularly helpful in cases where there are numerous focal tegmental dehiscences that may be confused with the site of the SCD.

7. Middle fossa retractor

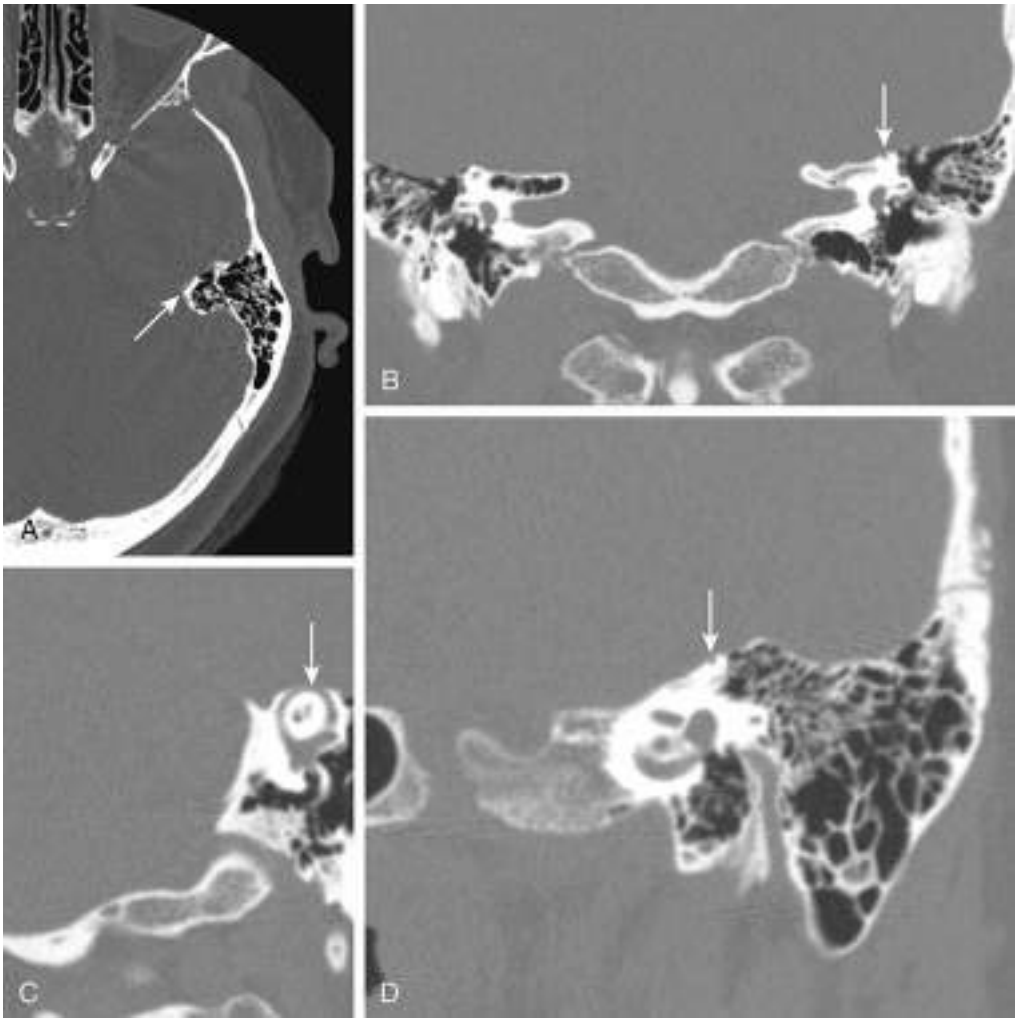

FIG. 147.2 Computed tomography findings in semicircular canal dehiscence.

A, Axial, **B**, coronal, **C**, Pöschl, and **D**, Stenvers projections show dehiscence of bone overlying the left superior semicircular canal *(arrows)*.

Key Anatomic Landmarks

1. External auditory canal (EAC): The EAC and root of the zygoma are the surface landmarks useful for approximating the expected location of the internal auditory canal (IAC). The superior semicircular canal is located immediately posterior to the IAC near the petrous ridge.

2. Arcuate eminence/labyrinthine bone: The arcuate eminence is often distinguishable along the floor of the middle cranial fossa because the surrounding labyrinthine bone is denser and yellower in color than the

surrounding tegmental bone. Furthermore, the arcuate eminence is typically raised in comparison with the surrounding tegmental bone. In SCD, a linear slit representing the dehiscence is centered within the arcuate eminence.

3. Greater superficial petrosal nerve (GSPN): The GSPN courses anteriorly across the floor of the middle cranial fossa. Its location can be confirmed by retrograde stimulation of the facial nerve by passing current with the facial nerve stimulator. The angle between the GSPN and the superior semicircular canal is approximately 120 degrees, bisected by the internal auditory canal.

4. Since the landmarks along the floor of the middle cranial fossa can be variable in their prominence, image guidance can sometimes be useful for purposes of orientation.

Prerequisite Skills

1. Knowledge of the anatomy of the floor of the middle fossa

2. Experience with image guidance if it is to be employed

3. Otomicrosurgical skills

Operative Risks

1. Sensorineural hearing loss

SNHL can occur as a result of an intraoperative injury to the membranous labyrinth, from removal of too much perilymph, or from serous labyrinthitis following surgery. Great care should be taken in operating in the vicinity of the SCD to avoid suctioning perilymph and risking damage to the endolymphatic membrane.

2. Facial nerve injury

The facial nerve may be dehiscent at the site of the geniculate ganglion and manipulation or traction of the facial nerve during elevation of the dura can result in facial paresis or paralysis. Although dehiscence of the facial nerve at the geniculate ganglion is more common in SCD patients than in the general population,[6] facial paresis/paralysis is rare following SCD surgery when proper operative technique is employed.

3. Inadequate plugging of the dehiscence resulting in persistent symptoms postoperatively

4. Epidural hematoma

5. Dural tear/cerebrospinal fluid (CSF) leak

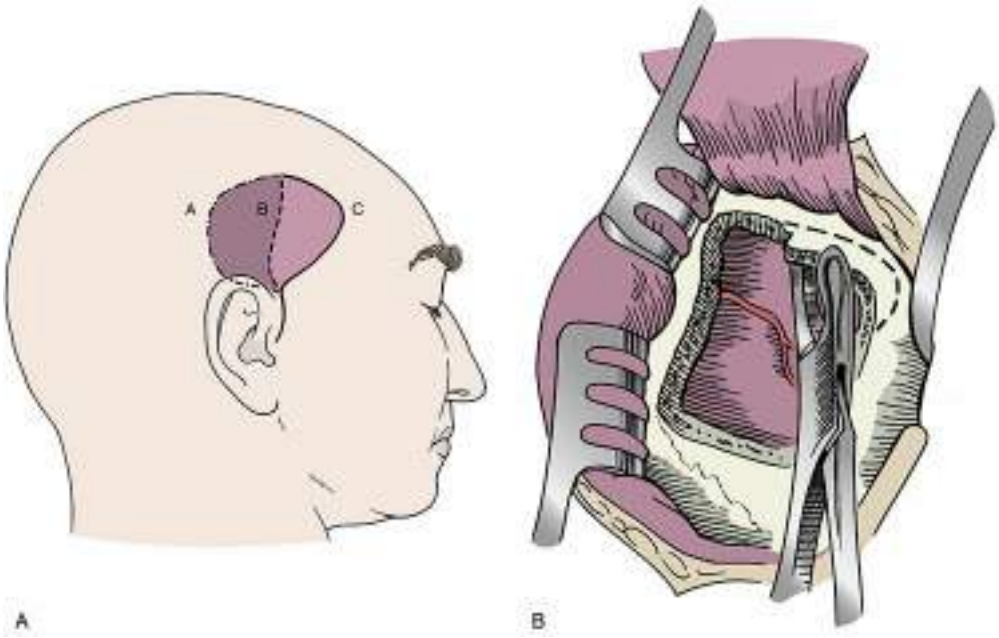

FIG. 147.3 **A**, Skin incisions for middle fossa approach to SCD. Our preference is that marked by line B. **B**,The craniotomy is taken down to the floor of the middle cranial fossa.

Surgical Technique

1. Skin incision and elevation of the soft tissues

There are several types of skin incisions that can be used to approach the middle cranial fossa; the incision we most commonly employ extends from the preauricular crease to the temporal region (Fig. 147.3A). The temporalis muscle is then rotated anteroinferiorly toward the zygoma to allow for exposure of the bony cranium. A cuff of fascia is left posteriorly to facilitate reapproximation of this muscle during closure.

2. Craniotomy of the middle fossa

Craniotomy of the middle fossa (see Fig. 147.3B) can be performed by either making burr holes and using a craniotome or using a standard otologic drill. With the otologic drill, a diamond burr is used to remove the inner cortex and avoid a dural tear. The craniotomy should be centered over or biased slightly anterior to the EAC and be approximately 4 by 5 cm. Rongeurs or a drill can be used to remove excess bone and make the inferior extent of the craniotomy flush with the floor of the middle fossa. If the middle fossa retractor is to be used, it is especially important to ensure that the vertical bony cuts parallel each other to permit retention of the retractor. Care must be taken, regardless of the instruments used, to keep the underlying dura intact for maintaining an extradural plane of dissection. In removing the bone flap, blunt dissection should be used to ensure that the dura is elevated off of the inner bony cortex (and thus does not tear). The bone flap should be set aside in a marked container for replacement during closure.

3. Dural elevation and identification of dehiscence of the superior canal

The dura underlying the temporal lobe is then elevated off the floor of the middle cranial fossa. Instruments should be directed in a sweeping motion from posterior to anterior to avoid subluxing a dehiscent facial nerve at the geniculate ganglion. Venous oozing is commonly encountered during dural elevation anteriorly and can readily be controlled using hemostatic agents (such as Surgifoam or Surgicel packing). Dissection continues medially until the SCD is identified within the arcuate eminence near the petrous ridge. Identifying the GSPN anteriorly in the operative field (visually and augmented with facial nerve stimulation) can sometimes be helpful with orientation, especially in cases where identification of the SCD is challenging. Bipolar electrocautery can be used on the dura of the elevated temporal lobe to render it taut and thus help to lessen the need for manual retraction. Once the dehiscence is located (Fig. 147.4A), great care should be taken with the use of suction because of the risk of inducing sensorineural hearing loss with inadvertent suctioning of the perilymph or membranous labyrinth. A useful instrument to employ during exposure of the dehiscence is a small Brackmann-tipped suction irrigator; the continuous irrigation is useful for sweeping blood out of the field and keeping the field moist, while the small suction ports make it less likely that perilymph will be suctioned or inadvertent damage done to the endolymphatic membrane.

4. Plugging dehiscence of the superior canal

Once the dehiscence has been adequately exposed, the canal is plugged. Placement of a middle fossa retractor can be used for exposure during plugging, but that is often unnecessary. Rather, the side of the suction irrigator can be broadly applied to the temporal lobe dura to provide retraction during plugging. Bone wax is placed directly onto the dehiscence and a small neurosurgical patty is used to gently force bone wax into the site of the dehiscence, thus plugging the canal (see Fig. 147.4B-D). Pressure is directed inferiorly (toward the floor of the middle fossa and into the dehiscence) while the neurosurgical patty is removed to leave the bone wax in the site of dehiscence rather than allowing the wax to stick to the patty and be removed, risking damage to the endolymphatic membrane. Alternative materials that can be used for plugging include a mixture of bone wax and bone dust harvested during the craniotomy or a plug made up of fascia and bone chips. Care should be taken to make sure that both the ampullated and nonampullated ends of the canal are plugged. If additional skull base defects are identified, those should also be addressed (see Chapter 144).

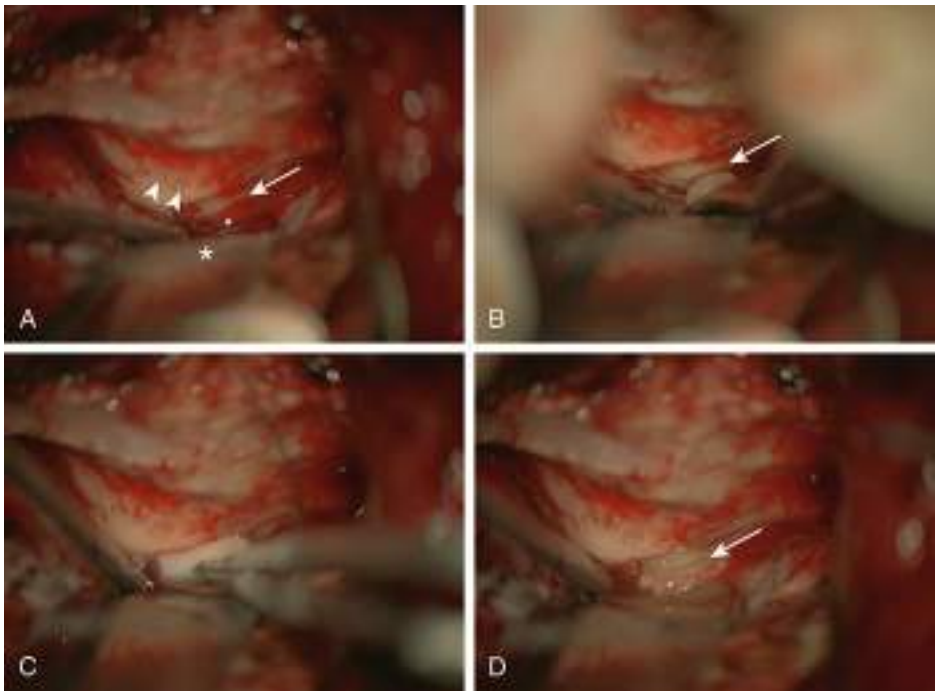

FIG. 147.4 Plugging of semicircular canal dehiscence.

These panels show intraoperative photographs of the

plugging of a left superior semicircular canal dehiscence (corresponding computed tomography shown in Fig. 147.2). In **A**, a middle fossa retractor is in position *(asterisk)*, elevating the temporal lobe dura for visualization of the left semicircular canal dehiscence *(arrow)*. Also note the thin bone of the tegmen mastoideum overlying mastoid air cells *(arrowheads)* and contrast that bone with the dense labyrinthine bone of the arcuate eminence surrounding the site of superior semicircular canal dehiscence (best shown in panel **B**. Bone wax is placed onto the area of dehiscence, **B,** and a neurosurgical patty is used, **C,** to put inferior pressure on the wax such that it occludes the dehiscence, **D**.

5. Closure

Hemostasis before closure is imperative. The craniotomy bone flap is secured with a plating system and a Jackson-Pratt (JP) drain is placed if there is concern for accumulation of blood. The temporalis muscle is sutured into position and the skin is closed.

Common Errors in Technique

1. Craniotomy not properly executed

Missteps during the craniotomy can result in inadequate exposure. Particular attention should be paid to centering the craniotomy on the EAC or biasing it slightly anterior to the EAC and to ensure that it is made to come flush with the floor of the middle fossa. Furthermore, the procedure is designed to take place in the extradural plane. If a dural tear occurs, the dural defect should be repaired. Failure to recognize or properly repair a dural defect places the patient at risk for CSF leak and intracranial infection.

2. Adequate intracranial hemostasis is not maintained

Venous oozing from the anterior aspect of the operative field in the vicinity of the GSPN is common during middle fossa craniotomy. Failure to control this bleeding will cause blood to obscure the operative field, thus placing the dehiscence at risk for accidental manipulation. The use of suction is of particular concern because suctioning to remove blood, if

performed directly on the site of the dehiscence, risks rupturing the endolymphatic membrane or removing excessive perilymph, leading to sensorineural hearing loss.

3. Failure to fully occlude the superior semicircular canal

Irrespective of the material used to plug the dehiscence, the surgeon must ensure that both ends of the superior semicircular canal are plugged. If the surgeon fails to fully plug the canal, a third window will remain and symptoms may persist following surgery.

Postoperative Period

Postoperative Management

1. Patients are admitted to the intensive care unit (ICU) or a monitored ward following surgery and their neurologic status is monitored.

2. Pain management: Oral or parenteral opiate analgesia is commonly required for several days following surgery.

3. Physical activity: Patients should be expected to experience a lack of normal balance following surgery, since the plugged canal is rendered nonfunctional and central compensation takes time to develop. Patients should be assessed by physical therapy while they are in the hospital; outpatient vestibular rehabilitation should be recommended.

Complications

1. Hearing loss

Profound deafness is a risk with SCD surgery. Standard treatments for unilateral sensorineural hearing loss can be considered if this complication were to occur (see Chapter 135). Transient sensorineural hearing loss is detected in some patients in the postoperative period but usually recovers when mild. If there is a significant change in hearing, steroid therapy should be considered.

2. Facial paralysis

Facial paralysis is possible if a dehiscent geniculate ganglion is not

recognized and is injured or the GSPN is accidentally stretched during dural elevation. This complication is rare. In cases where preoperative imaging is suggestive of a dehiscent geniculate ganglion, extra care should be taken to avoid this complication. Treatment is as with other causes of acute facial paralysis (see Chapter 138).

3. Epidural hematoma

Although uncommon, an epidural hematoma can appear following middle fossa craniotomy. Treatment involves urgent craniotomy for evacuation of the hematoma.

Alternative Management Plan

1. Observation

Observation is chosen by some patients with symptoms related to SCD syndrome—that is, those patients whose symptoms are not particularly bothersome and do not undermine their quality of life. Furthermore, observation is all that is necessary for asymptomatic patients with anatomic SCD.

2. Transmastoid SCD plugging

As an alternative to middle fossa craniotomy, the superior semicircular canal can be plugged through a transmastoid route.[7,8]

Discussion

Evidence-Based Medicine Questions

Is canal resurfacing an efficacious alternative to canal plugging for SCD syndrome?

1. Resurfacing of a dehiscent superior semicircular is associated with a higher rate of symptom recurrence than plugging of the affected canal. Dr. Minor, in reporting a series of patients (2005), found that four of 11 patients who underwent canal resurfacing without plugging developed recurrent symptoms within 3 to 6 months after surgery. On the other hand, of nine patient who underwent plugging, eight had complete resolution of symptoms and the ninth was "90% better."[9]

2. In cases of “near dehiscence,” where a patient presents with findings consistent with SCD syndrome but the affected superior semicircular canal is found, at surgery, to have a very thin layer of bone overlying it, both plugging and resurfacing have been used with benefit.[10] Additional data are needed to determine which method is better for cases of “near dehiscence.”

Editorial Comment

Superior semicircular canal dehiscence (SSCD) is a relatively new radiographic diagnosis that encompasses a host of unusual signs and symptoms that can now be explained by the third window effect of a defect in the otic capsule covering the canal. In the past, hearing a patient indicate they hear themselves breathe, their eyes move or their heels hit a hard surface when walking were thought to carry a functional diagnosis. Patients would report symptoms of Tullio’s phenomenon or show Hennebert’s sign were evaluated for syphilis or thought to have a perilymphatic fistula. It is now recognized these and many other symptoms are consistent with SCD. Failed stapes surgery for otosclerosis was deemed to be from an inner ear conductive disorder attributed to stiffness of the basilar membrane. It is now recognized that the third window effect provides a tangible explanation for this other source of conductive hearing loss.

A thin cut bone algorithm CT scan in the coronal plane is needed to demonstrate the dehiscent semicircular canal. This imaging is necessary to demonstrate the presence and location of the bony defect and the surrounding anatomy of the temporal bone. Cervical or ocular vestibular evoked myogenic potential (VEMP) show the reflex arc from auditory stimulation to muscle responses in the neck or inferior rectus muscles. The threshold for eliciting these responses is lower in SSCD pathology.

The next controversy which is still debated is how best to repair the defect. The two schools of thought are capping (covering over the defect) and plugging (filling the defect with soft tissue, bone dust or bone wax). The approach for repair has also evolved. Initially a middle fossa approach was recommended to provide direct visualization of the dehiscence. Currently, if the amount of aeration in the antrum and tegmen are sufficient, a transmastoid approach can be executed. This

usually entails covering of the bony defect with cartilage placed between the overlying dura and above the arcuate eminence. The canal can also be plugged isolating and unroofing its proximal and distal ends and occluding the membranous canal with soft tissue or bone wax. These repairs can be offered for signs and symptoms related to hearing loss and/or vertigo.

Patients should be counseled about the risks of benefits of the procedure. People may experience low grade vestibulopathy problems related to motion intolerance. Partial or complete sensorineural hearing loss can occur due to manipulation of part of the inner ear. It is the disabling nature of the disorder that promotes patients toward having it repaired. Successful elimination of these life changing symptoms can be most rewarding to both the patient and surgeon.

Review Questions

1. When the dura is elevated off the floor of the middle cranial fossa to expose a dehiscent superior semicircular canal, which of the following techniques should be used?

   a. Bipolar electrocautery along the floor of the middle fossa

   b. **Posterior-to-anterior dissection along the floor of the middle fossa**

   c. Incision of the dura to gain exposure

   d. Identifying the middle meningeal artery and then dissecting in a posterior direction until the dehiscence is located

2. Complications of superior semicircular canal plugging include all of the following except

   a. Hearing loss

   b. Facial paresis/paralysis

   c. Epidural hematoma

   d. **Jugular bulb injury**

3. All of the following structures are useful for identifying the location of a dehiscent superior semicircular canal except the

   a. **Cochleariform process**

   b. External auditory canal

   c. Arcuate eminence

   d. Greater superficial petrosal nerve

Stereotactic Radiosurgery

C.Y. Joseph Chang, and Stephen Cass

Introduction

Acoustic neuroma, also known as vestibular schwannoma, is a benign neoplasm arising from the vestibular portion of the cochleovestibular nerve. This tumor can cause a variety of sequelae, most common among which are hearing loss, tinnitus, and dizziness/imbalance. The tumor can grow to a large size and cause additional symptoms related to brain-stem compression, hydrocephalus, and effects on other cranial nerves (CNs). Extremely large tumors can be life threatening. Advances in magnetic resonance imaging (MRI) and audiologic evaluation have led more of these tumors to be detected even when there are few symptoms and the tumors are typically small. This has created a greater need for the management of these tumors over time. The main goal in this endeavor is to prevent the tumor from growing to a large size, thus decreasing the likelihood of morbidity, while also minimizing the deleterious effects of treatment. Secondary goals include the prevention of progressive CN dysfunction due to the tumor, such as loss of hearing and facial nerve dysfunction.

In order to determine the optimal treatment for a particular patient, it is necessary to understand the natural history of acoustic neuroma (growth rate and hearing changes over time) as well as the outcomes following intervention, whether that is surgery or stereotactic radiosurgery (SRS). Observation (watch and scan) has become more prevalent, adding another dimension to the decision making involved in treatment. What is the chance that a particular tumor will grow to a life-threatening size during the patient's natural life span and require treatment? On average these tumors grow slowly (2 mm per year), but the growth rate varies widely, with about 50% showing no growth during observation and others that grow an average of 2 to 4 mm per

year (up to 18 mm). Moreover, the growth rate is nonlinear over time, since some growing tumors can stop growing while other tumors that showed no growth for years may start growing again.

The advent of radiosurgery for the treatment of acoustic neuromas more than 40 years ago has significantly changed the contemporary management of acoustic neuroma. To date more than 100,000 patients with acoustic neuroma have been treated with radiosurgery, and the rate of radiosurgery treatment is growing. Currently about 50% of acoustic neuromas are treated with surgery, and the remainder are split between observation and radiosurgery. In addition to primary treatment for tumors, radiation offers a noninvasive treatment of residual tumor after microsurgery.

Stereotactic radiation treatments are available in two types. Single-fraction stereotaxy (SRS) is one and stereotactic radiotherapy, used for multifraction treatment, is the other. Both types use precise stereotactic localization of the lesion as well as conformal treatment plans that focus the radiation beam on the target tissue. The use of the Gamma Knife to treat acoustic neuroma was first reported in 1971 and, over time, this technology has been refined through several generations of devices to its current utilization of MRI for target localization and automated radiation delivery. The Gamma Knife uses numerous fixed Cobalt 60 sources and collimators (the Perfexion Unit has 192 sources and collimators) to send a focused radiation beam to the target (Fig. 148.1). Several linear accelerator (LINAC)–based radiosurgery delivery systems are also available. These use advanced robotic technology, multileaf collimators, and radiographic verification of positioning, all of which are highly accurate and flexible.

This chapter discusses in further detail the management of acoustic neuroma with stereotactic radiosurgery. The management considerations are based on the limited data available at the time of writing.

Key Operative Learning Points

1. Patient selection is complex owing to the lack of reliable information on long-term tumor control rates after radiotherapy.

2. The planning of tumor treatment must produce a highly conformal

radiation field comprising the volume of the tumor and minimizing radiation to areas that are sensitive to radiation damage, including the cochlea and brain-stem.

Preoperative Period

History

1. History of present illness
   a. Age and family history of longevity. The length of time during which tumor control will be needed is important.
   b. Hearing loss. The presence of usable hearing will be important in patient counseling.
   c. Dizziness. The patient may have imbalance, a floating sensation, and vertigo; all of these may be affected by treatment.
   d. Facial numbness—Large tumors may cause trigeminal nerve dysfunction.
   e. Headache
   f. Facial nerve weakness or facial spasms. These may indicate a possible facial nerve schwannoma or a vascular tumor involving the facial nerve.
   g. The presence and nature of tinnitus
2. Past medical history
   a. History or family history of neurofibromatosis II (NF2)
   b. History of prior intracranial surgery or radiation to the area
   c. Chronic serious medical conditions including coronary artery disease, chronic lung disease, chronic anticoagulation, or other conditions that may make the patient a poor surgical candidate

Physical Examination

1. Otologic evaluation

a. Tympanic membrane

b. Tuning fork

2. Neurologic evaluation

a. Facial nerve evaluation—The House-Brackmann grading scale is typically used.

b. Other CNs

1) Trigeminal nerve

a) Facial sensation

b) Corneal reflexes

c. Cerebellar evaluation—dysmetria

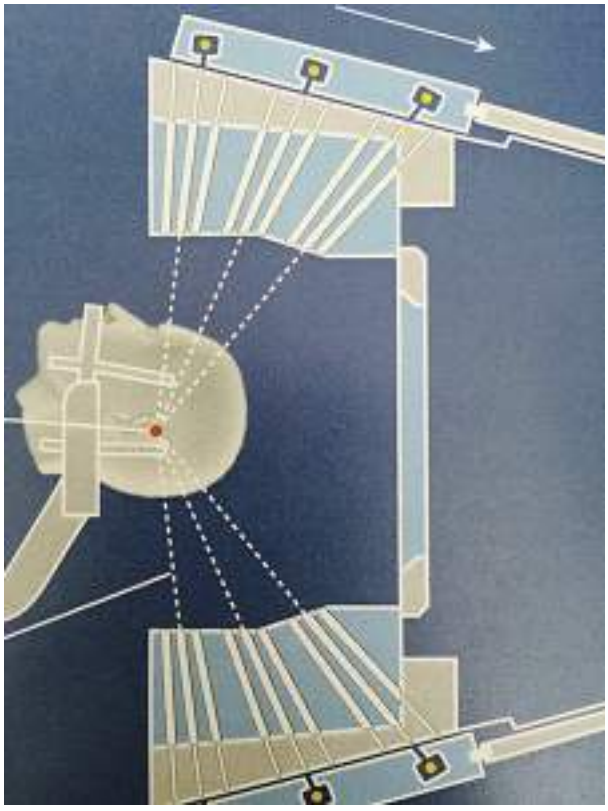

FIG. 148.1 Conceptual diagram of focused beam radiation.

d. Balance evaluation

1) Gait and tandem gait

2) Romberg test

3. Audiologic evaluation
   a. Pure tones
   b. Speech discrimination scores
   c. Tympanogram
4. Vestibular evaluation
   a. Search for pathologic nystagmus
   b. Bedside testing of the vestibuloocular reflex (VOR)—head impulse test
   c. Videonystagmogram—This test may be performed if there are concerns regarding the status of contralateral vestibular function or the presence of other vestibular disorders.

Imaging

- MRI with gadolinium including high-resolution images through the internal auditory canals (IACs). Alternatively, MRI without gadolinium with high-resolution submillimeter images through the IAC (fast imaging employing steady-state acquisition (FIESTA)/constructive interference steady state (CISS) sequences) can image the IACs and cerebellopontine angle adequately but may miss other intracranial lesions.
- Computed tomography (CT) of the brain with contrast may be used if MRI cannot be performed due to metal implants or other issues, but its sensitivity is much lower than that of MRI.

Indications for Radiation

1. The considerations regarding the need to provide treatment for acoustic neuroma with radiation or surgery include tumor size, tumor growth rate, patient's symptoms, patient's age, and medical comorbidities. Because there is considerable uncertainty as to the optimal treatment for any given situation, the patient's and the treating physician's preferences and biases may play a major role in determining whether to treat and how.

FIG. 148.2 Leksell head frame.

2. Most tumors that have been determined to need active treatment

   a. SRS is ideally suited for small to medium-size tumors.

   b. Surgery is generally preferred in younger patients, since the rate of long-term (20 to 30 years) tumor control following SRS is not established and the chance of developing a radiation-induced complication is theoretically greater in a young versus an older person.

3. Patients who are medically unfit for surgery

4. Patients who are fit for surgery but choose stereotactic radiation

5. Tumors that have recurred after prior surgery

6. Some tumors that have recurred after prior stereotactic radiation have been retreated with stereotactic radiation.

7. Patients with bilateral acoustic neuromas associated with NF2 may also choose the radiation option, although tumor recurrence rates are higher and hearing preservation rates lower than those associated with sporadic tumors.

Contraindications

1. Many centers may consider tumors with an axial dimension larger than 3 cm as too large for radiation, but there are reports of a few centers

treating such large tumors.

2. The presence of significant symptomatic brainstem compression usually requires surgical decompression with various degrees of tumor removal.

3. Patients in their thirties or younger will have to consider the issue of very long term tumor control with radiotherapy and long-term radiation-induced complications.

Preoperative Preparation

1. The head frame (fixator) must be applied.

   a. Gamma Knife system—The Leksell head frame is put in place via head stabilization pins applied under local anesthesia (Fig. 148.2). This technique is characterized by high-resolution targeting and registration of the lesion and very stable head/target positioning (1-mm accuracy).

   b. LINAC system—The face mask is custom-made for the patient (Fig. 148.3). In LINAC, the head is registered to the frame through a mask/frame system imaged together with a CT scan (2-mm cuts) followed by fusion of an MRI to the CT to target the lesion. During treatment the head is stabilized by the mask and radiographs are taken after each table and gantry movement to adjust for any movement of the head within the mask system.

FIG. 148.3 Linear accelerator face mask with reference frame.

c. The Gamma Knife system is the most accurate, and is preferred when the greatest accuracy is required (i.e., high dose to a small target). For most other lesions, there is no practical difference between these approaches.

2. The MRI or CT is performed with the head frame or mask in position to allow the image to be referenced to the fixator.

a. The imaging data are imported into the targeting system for use in treatment planning.

Operative Period

Anesthesia

- None

Positioning

- Supine: The patient is positioned in the radiotherapy bay and the head frame or face mask is fixed to the system.

Perioperative Antibiotic Prophylaxis

- None

Monitoring

- Video and audio systems to communicate with patient.

Instruments and Equipment to Have Available

See "Preoperative Preparation," above.

Key Anatomic Landmarks

Tumor targeting takes into consideration the tumor's volume, shape, and location as well as important surrounding structures.

1. The structures that should receive as little radiation as possible include the following:

   a. The inner ear, including the modiolus

   b. The brainstem.

   c. CN 5

   d. Lower CN

Prerequisite Skills

1. Radiation biology

2. Radiation targeting

Operative Risks

1. Anxiety episode. If necessary, the patient may be sedated.

Surgical Technique

Source of Radiation

The Gamma Knife uses decaying Cobalt 60, which releases gamma radiation with an average energy of 1.25 meV. LINAC creates high-energy photons with various levels of energy; a maximum of 6 meV is most commonly used in SRS. The energy of the radiation affects the relationship of dose versus depth of tissue penetration. For 1.25 meV, the maximum dose is at 0.5 cm. For 6 meV, the maximum dose is 1.5 cm. These differences are taken into account by the treatment planning software associated with each type of device.

The main task of the treatment team is to formulate the radiation planning.

- The essential features of tumor targeting are similar among the various platforms. Conceptually, a device providing targeted treatment directs radiation from an external source at various angles to focus the dose on a central target. This geometry results in a radiation field with the highest dose at the center (isocenter) and a dose that decreases as a function of distance away from the isocenter (see Fig. 148.1).
- The percent isodose is the reduced dose that occurs at any circumferential distance away from the isocenter. The lower the isodose line used, the greater the decline in dosage at the margin but also the greater the difference between the minimum and maximum doses to the tumor. For example, when treatment is directed to the 50% isodose line, the maximum dose will be double the marginal dose, creating a "hot spot" at the center of the tumor.
- With a single shot of focal radiation, the shape of the isodose distribution field is spherical or elliptical, depending on the configuration of the treatment device.
- If multiple shots are targeted at different locations, the shape of the

isodose distribution field can be made in a diversity of 3-dimensional shapes. An irregularly shaped isodose field can be created that conforms to the shape of the tumor to be treated.

- The prescription isodose is the radiation field created for the treatment of a particular tumor, and the prescription isodose line is the border of the treatment volume (Figs. 148.4 and 148.5).

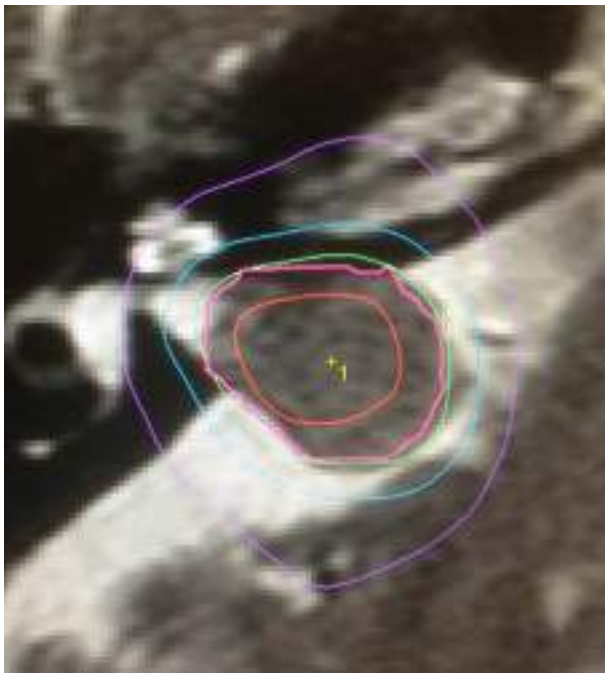

FIG. 148.4 Gamma Knife prescription isodose plan. +1 - Isocenter.

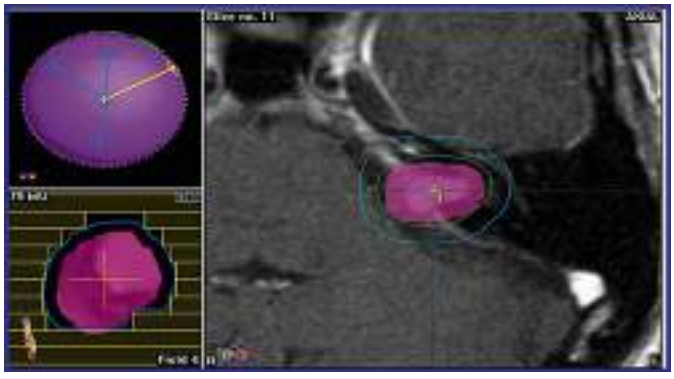

FIG. 148.5 Linear accelerator prescription isodose plan. +1 - Isocenter.

- The degree to which this prescription isodose covers the tumor volume is termed *conformity.* There are various indices indicating how good this conformity is, such as the conformity index, which is the ratio of the prescription isodose volume divided by the tumor volume.
- Targeting with the Gamma Knife is achieved by the use of 192 collimators (each with a single radiation source) at the same time. Fixed-diameter collimators are able to deliver very precise radiation beams with a very narrow penumbra to a single isocenter. The use of a single isocenter is ideal for creating a very precise, very small lesion in the trigeminal nerve for trigeminal neuralgia or a small eighth-nerve schwannoma near the cochlea.
- Target conformity is achieved in larger tumors using overlapping isocenters (multiple shots). Sector blocking can be used to further shape the radiation and shield critical structures. In LINAC, target conformity is achieved through the use of cones or multiple-leaf collimators and static beams or dynamic arcs created via table and gantry movements aimed at a single isocenter. The ability to create conformal treatment plans is likely no different between the two types of systems.
- Gamma Knife has been most commonly prescribed in the range of the 50% isodose line (an apparent trade-off between dose fall-off and creation of hot spots). For any given isodose reference, LINAC systems will generally create a more homogeneous dose of radiation compared with the Gamma Knife. The importance of differences in dose heterogeneity and isodose reference is not known.
- In both Gamma Knife and LINAC SRS, the radiation dose is referenced to an isodose line, which is a way of specifying the target dose. There is no difference in the ability to set this parameter.
- The radiation dose to the tumor is typically reported as the marginal dose applied at the 50% isodose line. The commonly used dose at this time is typically around 12 to 13 Gy at the 50% isodose line for Gamma Knife and 50% to 90% for LINAC systems. In the past, marginal doses of 25 to 50 Gy were used and resulted in significant rates of facial nerve dysfunction, trigeminal nerve dysfunction, edema of the brainstem, and hydrocephalus. These side effects have been reduced to very low levels with the currently used low doses.

- In addition to targeting the tumor adequately, structures outside the tumor that are sensitive to radiation damage must also be considered. There is still a radiation dose field outside the prescription isodose volume that extends to the radiation source. The radiation dose to structures such as the inner ear and brainstem should be minimized in designing the prescription isodose volume and is termed *blocking the area.*
- Hearing loss after targeted radiation has been associated with a higher dose to the cochlea in some studies, but this is likely not the only factor in hearing preservation. A high dose to the cochlear nucleus may also contribute to increased hearing loss, so this area as well should also be identified in targeting.

Common Errors in Technique

1. Poor conformity of treatment planning

2. Inadequate blocking of structures that are sensitive to radiation effects

Postoperative Period

Postoperative Management

1. Patients are discharged the same day and resume regular activities and diet.

2. Patients with very good hearing are treated with oral steroids for 10 days after treatment.

3. A small percentage of patients may develop headache, nausea, and swelling at the pin sites. These issues may be treated conservatively with medical management.

   a. Acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and narcotics may be prescribed for headache.

   b. Vestibular suppressants may be given for vertigo.

   c. Topical wound care may be offered for pin-site issues.

4. Rarely, acute CN dysfunction can occur; this should be treated with

corticosteroids and supportive care as necessary.

Complications

1. There is a very low rate of hydrocephalus after treatment that may require ventriculoperitoneal (VP) shunting.

2. Facial nerve dysfunction. Most cases of facial nerve dysfunction are delayed in onset, partial, and transient and should be treated with oral steroids. If there is severe facial dysfunction, various treatment options for lagophthalmos and facial reanimation are available (see Chapters 179 and 180).

3. Trigeminal nerve dysfunction. It can be permanent but is transient in most instances. This complication is typically treated with oral steroids.

4. Hearing loss and tinnitus. There may be progressive hearing loss.

   a. A hearing aid may be required to ensure usable hearing.

   b. Contralateral routing of signals (CROS) device or an osseointegrated implant may be needed to correct unusable hearing (see Chapter 135).

5. Dizziness. In most patients, this will improve with vestibular physical therapy.

Alternative Management Plan

1. Observation with serial MRI. A significant percentage of tumors may not grow after initial diagnosis.

2. Microsurgical removal (see Chapter 140)

Discussion

Outcomes, Prognosis, Complications

Tumor Control

It is critically important to understand the long-term outcome after stereotactic radiation because the treatment leaves tumor cells in place; control of tumor growth depends on damaging these cells and supporting vascular cells sufficiently that the tumor will fail to grow over a span of many years. Evaluation of the literature is hampered by the variable definitions of tumor control used in various studies. In the short term, over the first year after treatment, a significant number of tumors will enlarge temporarily, possibly due to inflammatory changes and edema, followed by involution to a baseline size or less.

A number of studies offer retrospective evidence that the treatment does significantly decrease the rate of tumor growth over 10 years versus observation without treatment. There is currently good observational evidence that, with current dosing strategies, tumor control rates over 10 years are greater than 80%.[1] The main factors that portend poor tumor control include failure of treatment conformity,[2] decreased radiation dose, large tumor size, and tumors that show active growth just prior to treatment.[3] Tumor control rates with any treatment modality should also be considered in view of the finding that about 50% of acoustic neuromas may not grow over a 5-year period of observation.

The tumor control rate after radiosurgery is established in the short term (90%). However, tumor control beyond 10 years is not definitively understood. The tumor control rate after surgical resection beyond 10 years is also poorly documented.

Facial Nerve Results

Rates of House-Brackmann I and II results after treatment are approximately 95% to 99%.[1,4] The facial nerve dysfunction typically occurs 6 to 9 months after treatment, is partial, and recovers. Facial nerve dysfunction is correlated with a higher dose at the treatment isodose line and target volume.

Hearing Loss

Diagnosis of a small acoustic neuroma when hearing is normal or near normal presents a special dilemma, since it is not clear whether early radiation treatment changes the natural history of hearing preservation

seen in observed (untreated) patients. Hearing preservation is also possible with microsurgery (50% to 70%) in the case of small tumors, but the remaining patients will incur total loss of hearing. Additionally, the rate of serviceable hearing preservation over time may not differ from that following stereotactic radiation. The hearing loss related to radiation typically occurs slowly over time; therefore it is rare to have a patient experience sudden hearing loss after radiation.

On average, hearing function decreases over time, whether or not the tumor is observed or treated with stereotactic radiation. There are centers that advocate for the early treatment of tumors in patients with serviceable hearing because some data point to good hearing preservation for at least a few years. However, on long-term follow-up there may not be a significant advantage to radiation, as actuarial rates of long-term serviceable hearing in patients with serviceable hearing prior to treatment may be less than 30%.[5] Hearing preservation rates appear to correlate best with better pretreatment hearing function. Other issues may include radiation dose to the cochlea, marginal dose, and tumor size. There are conflicting reports as to whether the results of radiation are superior, similar, or worse as compared with hearing monitored simply by observation.

Vestibular Function

There is a significant incidence of vestibular dysfunction in patients with acoustic neuromas prior to any treatment, and there is a significant rate of imbalance after treatment of any type. Long-term dizziness may be seen in some 50% of patients after radiotherapy, microsurgery, and observation. It is not clear whether management of the tumor has, on average, a long-term effect on dizziness. The radiation dose to the vestibule does not appear to correlate with the degree of dizziness.

Neurofibromatosis 2

The tumor control rate in tumors associated with NF2 is known to be significantly poorer than that in sporadic tumors. Based on various studies from 2013 and 2014, these tumor control rates ranged from 84% at a median follow-up of 109 months, 93% at a median follow-up of 36 months, and 87.5% at 2 years. In a study from 2008, based on actuarial

methods, the tumor control rate was 80.2% at 5 years and 80% at 3 years.

Hearing preservation rates are also poorer for tumors associated with NF. One study from 2014 reported actuarial hearing preservation rates of 44% at 5 years and 17% at 10 years. Another study from 2008 reported a usable hearing rate of 80% at 3 years.

Other Outcomes

Hydrocephalus requiring a VP shunt may occur in 0.8% to 6% of patients. The rate of trigeminal nerve dysfunction may vary between 0.2% and 21% depending on tumor size and radiation dose. Chronic headache may occur in some 50% of patients with acoustic neuromas and may not be affected by the treatment modality, including observation, microsurgery, or radiation. Radiation-induced malignancy is possible, but its true incidence following radiosurgery is not known. The available data suggest that the rate is low: 0.04% at 15 years in a study from 2014 (which included no acoustic neuroma neoplasms) and, in another study from 2013, 0.05% in 5000 patients treated with SRS. The corresponding rate in another study including only acoustic neuromas was 0.3% at 12.5 years.

Editorial Comment

The role of stereotactic radiation therapy has evolved over the past 30 years to become an accepted alternative means for treatment of acoustic neuroma. The initial controversy regarding its use centered on the long term control of tumor growth. Despite reduction in the prescribed dose the rate of tumor control has remained very good while the incidence of complications has significantly diminished. Microsurgery has a long term track record for efficacy. The outcomes following radiation, including the rare risk of development of malignancy, has been reported only for the past few decades. Greater confidence in relying on this modality stems from the consistent results demonstrating control over prolonged intervals.

The prevalence of radiation energy sources are delivered by either gamma radiation or linear accelerator. The literature is replete with studies lauding the beneficial outcomes of that particular method of

treatment. It is challenging to both physicians and patients to decipher if one form of treatment is better than the other. At present, the success achieved with both techniques of radiation treatment is reassuring there is no one correct modality.

Experience over time has demonstrated that radiated tumors can and do show expansion over the first one to two years following treatment. When it occurs, the increase in size should stabilize or diminish due to contraction. Continued enlargement is deemed treatment failure and further intervention is warranted.

As is detailed in this chapter, the decision for initial intervention is based on numerous factors including tumor size, location in the IAC, the patient's symptoms, chronological age, hearing status, and medical comorbidities. The physician's bias may influence what treatment should occur but the final decision rests with the patient's preference. As with many relatively new management options, reported outcomes over longer periods of time will help determine how to prioritize where stereotactic radiation fits into the treatment paradigm.

Dacryocystorhinostomy

Tonya Stefko

Introduction

- External dacryocystorhinostomy (DCR) was first described by Toti in the early 20th century. The technique is applicable to patients complaining of tearing and demonstrating obstruction of the lacrimal outflow system. The procedure consists of creating a fistula for egress of tears directly from the lacrimal sac into the nose and bypassing the nasolacrimal duct (Fig. 149.1). Description of endonasal DCR took place even before a report of external DCR.

Key Operative Learning Points

- For external DCR, the skin incision should be made in one stroke to the bone to minimize damage to the tissue planes.
- Silicon intubation of the lacrimal system must be performed gently and is used in this procedure both to minimize any scarring of the delicate canaliculi from postoperative inflammation and to help with identification and marsupialization of the lacrimal sac.
- It may be necessary to perform a septoplasty in cases where the septum is deviated toward the side of obstruction.

Preoperative Period

History

- Congenital or within the first few months of life?

- In newborns and infants, the most common site of obstruction is distally at the valve of Hasner, where canalization is often incomplete at the time of birth. In most patients, congenital nasolacrimal duct obstruction will resolve by the age of 6 to 12 months, so probing of the lacrimal system should be delayed until the end of the first year of life. Probing of the lacrimal system is most often curative at this age.[1]

- Complete medical history
  - Bleeding/clotting disorders
  - Hypertension-related pathology
  - If the patient will be under general anesthesia, evaluation by the primary physician is frequently necessary.
- In 8% to 14% of DCR surgeries, dacryoliths composed of precipitated organic material will be found.[2,3]
  - Affected patients may complain of intermittent tearing and pain and demonstrate a distended, tender lacrimal sacs but minimal or no inflammation.
  - Alternatively, the dacryolith may mimic complete obstruction and occasionally cause acute dacryocystitis.

Physical Examination

- Patients may complain of tearing for one of three reasons:
  - Hypersecretion of tears
    - Primary hypersecretion of tears is uncommon.
    - Secondary hypersecretion is a frequent cause of tearing.
      - May be due to a variety of ocular surface disorders, some as benign in nature as seasonal allergy. Associated symptoms and signs will help in making these diagnoses, and their proper treatment should proceed before surgical repair.
  - Reflex hypersecretion in patients with ocular surface dryness (as in those with Graves disease) must be addressed by referral to an Ophthalmologist.

- Abnormal eyelid position can cause reflex tearing by rubbing of lashes against the cornea or by desiccation of the cornea as a result of inadequate blinking or closure.
    - Patients' complaints will assist in making the diagnosis inasmuch as those with surface disorders causing reflex hypersecretion will complain of burning and a foreign body sensation.
    - Fluorescein drops instilled into the conjunctival cul-de-sac will highlight defects in the corneal epithelium when viewed with a cobalt blue filter on a penlight in patients with dry eye.
- Impaired drainage of tears
    - In adults, tearing secondary to insufficient lacrimal drainage is common.
        - Functional obstruction includes poor function of the medial canthal lacrimal pump, usually secondary to eyelid malposition or aberrant anatomy.
        - Physical obstruction may occur at the level of the punctum, canaliculus, common canaliculus, lacrimal sac, or nasolacrimal duct. The latter two account for about 74% of lacrimal outflow obstructions and are treated with greater than 90% success by external DCR surgery.[4]
- Combination of both hypersecretion and underdrainage
    - Most patients referred to an Otolaryngologist with complaints of tearing will already have been evaluated by an Ophthalmologist and treated for ocular surface disorders causing hypersecretion. If not, ophthalmologic evaluation should proceed before any consideration of lacrimal surgery for correction of tearing.

- Complete endonasal examination, with particular attention paid to the distal end of the nasolacrimal duct beneath the inferior turbinate, should be performed in the office.
    - Occasionally, physical obstruction of the ostium is visible and readily treated.
    - Significant rhinitis should also be treated before surgical correction because it also rarely causes functional obstruction.

- Note of any septal defects or deviation is important, particularly if an endonasal approach is selected.

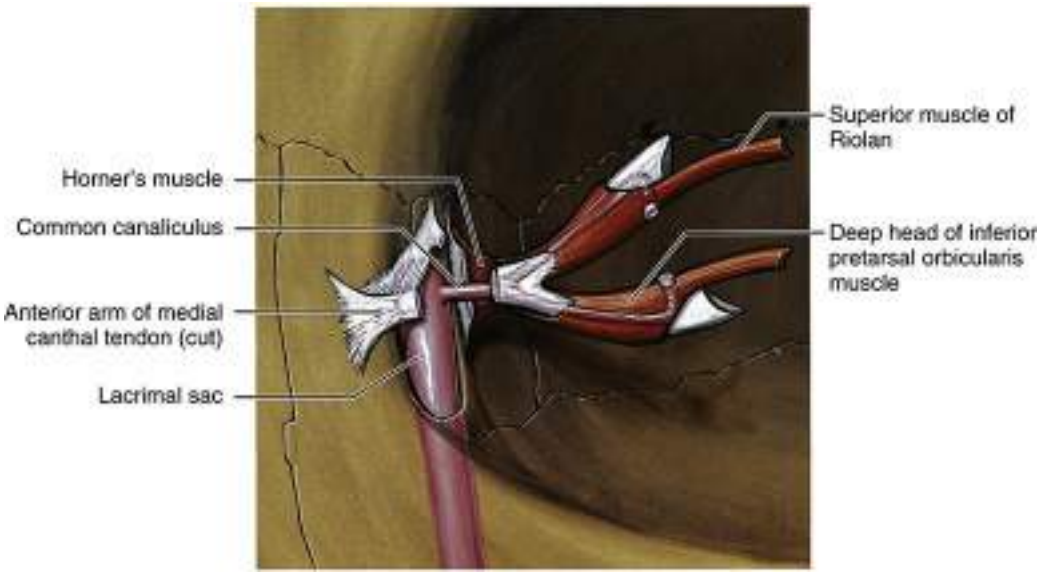

FIG. 149.1 Lacrimal drainage system, superficial anatomy. From Dutton JJ. Atlas of Clinical and Surgical Orbital Anatomy. Philadelphia: WB Saunders; 1994.

- Dilation and irrigation of the lacrimal system in the office can be used to localize the outflow blockage.
  - Probing of the lacrimal system, however, has no place in adult patients. This procedure is rarely if ever curative and will cause significant patient discomfort. In addition, there is a risk of trauma to the delicate mucosa-lined canalicular system, which is a considerably more difficult problem to treat than nasolacrimal duct obstruction.
  - Quick, easy passage of saline into the nasopharynx after topical anesthesia and gentle injection into the canaliculus may call into question the diagnosis of lacrimal obstruction.
    - However, this will often occur in the setting of a dacryolith because the liquid will drain around the object.
    - It is also sometimes possible to open the nasolacrimal duct with forceful injection, but resistance will be palpable and indicates that the system is probably functionally obstructed (i.e., not

functioning under the normal very low physiologic generation of negative pressure).

- The physician should note the speed and volume of flow, in addition to the presence of resistance or frank reflux of fluid.
  - Reflux in the presence of resistance to flow indicates obstruction.
  - If reflux occurs from the canaliculus being injected or if resistance to easy passage of a 22-gauge or smaller cannula is felt, canalicular obstruction is present, and DCR may not be appropriate.
  - Reflux of fluid from the opposite lid suggests obstruction distal to the common canaliculus, and DCR is likely to be curative.

Imaging

- May not be necessary in straightforward cases of lacrimal outflow obstruction
- Mandatory in children who develop tearing at some point after birth (i.e., acquired not congenital nasolacrimal duct obstruction) in the presence of normal eyelids; this suggests development of a mass
  - Magnetic resonance imaging (MRI) of the face with gadolinium
- Computed tomography (CT) of the orbits and sinuses may be ordered in some situations to evaluate sinus and nasal anatomy and whenever a mass is suspected. It is particularly helpful where there is a history of previous facial trauma.
  - CT of the face with or without intravenous (IV) contrast
- Dacryoscintigraphy may be useful to pinpoint the area of obstruction, but irrigation in the office can usually localize the point of obstruction.

Indications

- Acquired obstruction of the nasolacrimal duct
- Acute dacryocystitis with an abscess unresponsive to antibiotic therapy
  - Patients complain of tearing, discharge, swelling, and pain over the lacrimal sac.

- Some cases proceed to periorbital cellulitis before diagnosis, so a high index of suspicion in this setting must be maintained.
- Pressure over the sac produces purulent reflux from the punctum, which is often quite painful for the patient.
- Probing or irrigation at this time is useless and may complicate the situation.
- About two-thirds of acute infections grow gram-positive organisms in culture, and about 7% are anaerobic.[5] Treatment of acute infection consists of at least 3 weeks of oral antibiotic, antibiotic-steroid drops, and warm compresses.
- An abscess in the area requires prompt percutaneous drainage, often possible in the office under local anesthesia. The sac may then be irrigated with antibiotic solution. Occasionally, poor response to oral therapy will require intravenous antibiotic treatment and prompt surgery.
  - This may, however, lead to a lacrimal fistula draining to the skin.

- Endonasal DCR has enjoyed renewed interest since the 1980s but is less preferred because of lagging success rates and expense. Recent reports suggest that the technique is becoming more successful.[6]
- In the presence of any suspicion of a mass in the lacrimal system, external DCR with biopsy is mandatory.
  - The symptom of bloody tears is particularly worrisome for the presence of a tumor.
  - Palpation of a mass superior to the medial canthal tendon also suggests a lacrimal sac abnormality.

Contraindications

- If a mass is suspected or found at surgery, it may be possible to complete the DCR if the sections are benign, if intraoperative frozen sections are available. If malignancy is found, however, dacryocystectomy with appropriate margins should be performed and creation of an ostium into the nose avoided.
- Successful DCR requires a functional upper outflow system.

- Treatment of upper system (punctum, canaliculus, and common canaliculus) obstruction must be undertaken either separately or in the setting of surgical DCR.
  - Punctal stenosis may be treated by various punctoplasty techniques.
  - Canalicular stenosis may be treated with silicon intubation, generally only in the setting of incomplete obstruction.
  - Common canalicular stenosis may sometimes be treated in the setting of DCR by silicon intubation.
  - If intractable upper system obstruction is present, primary conjunctivodacryocystorhinostomy with placement of a Jones tube is necessary.

Preoperative Preparation

- Patients should discontinue anticoagulant medication if at all possible.
- Acute dacryocystitis should be treated medically as well as possible.

Operative Period

Anesthesia

- Local anesthesia with sedation
  - Cocaine is an excellent nasal decongestant and topical anesthetic.
- General endotracheal anesthesia is my preference for patient comfort and protection of the airway.
- The patient may be administered nasal decongestant before anesthesia, or cottonoids soaked in decongestant may be placed.

Positioning

- Supine on operating table

Perioperative Antibiotic Prophylaxis

- 2 G of cephalexin IV
- 600 mg of clindamycin IV if cephalosporin-allergic

Monitoring

- As per anesthesia

Instruments and Equipment to Have Available

- Suction (8 Frasier or similar)
- 0.5 × 3 neurosurgical cottonoids
- Nasal decongestant
- Small skin rakes
- Scalpel (#15 blade)
- Cottle elevator

FIG. 149.2 Anterior lacrimal crest (arrow). The incision will be hidden in the lower eyelid crease.

- Small and medium up-biting Kerrison bone punches
- Silicon intubation system (i.e., Crawford or Reitling style)
- Bipolar cautery
- Small Castroviejo needle drivers
- 6.0 Vicryl suture
- 6.0 Silk suture
- 7.0 or 8.0 absorbable or nonabsorbable suture for skin
- 12-French silicon straight catheter

Key Anatomic Landmarks

- The anterior lacrimal crest is the anteriormost border of the orbit and is part of the ascending process of the maxilla (Fig. 149.2).
- The nasal ostium should be made just anterior to the tip of the middle turbinate.

- Bone removal should not proceed more than 2 mm above the medial canthal tendon to ensure no violation of the skull base.

Prerequisite Skills

- Basic surgical tissue handling skills
- Intubation of the nasolacrimal system

Operative Risks

- Failure of surgery to alleviate epiphora
- Infection
- Bleeding
- External scar
- Compromised blink due to violation of some fibers of the zygomatic branch of the facial nerve

Surgical Technique

- A number 15 scalpel blade is used to create an approximately 1.5-cm skin incision over the anterior lacrimal crest by cutting in one stroke down to the periosteum (Fig. 149.3).

FIG. 149.3 Lacrimal sac elevated from the fossa (medial).

FIG. 149.4 Lacrimal sac reflected and bone partially removed from the fossa.

- A Cottle or similar instrument is used to elevate the periosteum over the maxillary bone. Elevation proceeds posteriorly and superiorly and includes the lacrimal sac fused to the periosteum (see Fig. 149.3).
- A small dehiscence of bone is often encountered at the junction of the maxillary and lacrimal bones and is useful for insertion of a Kerrison punch to begin bone removal.
  - If this dehiscence is not present, the bone may often be cut with a small osteotome.
  - Only rarely is it necessary to drill to gain access to the nose, although drilling is more frequent in patients with duct obstruction when dealing with inflammatory diseases such as sarcoid or Wegener granulomatosis.
  - If the anterior lacrimal crest obstructs visualization, it may be partially resected with the bone punch.
  - A wide area of bone removal facilitates working in the nose (Fig. 149.4).
- The patient's upper punctum is gently dilated, and a 0 or 00 Bowman or similar probe is inserted.
  - The probe is immediately turned medially, and gentle lateral traction is placed on the lid to straighten the canaliculus.

- When the probe is in the sac, it is rotated up over the medial aspect of the brow and visualized through the wound to be distending the sac.
- The sac is opened over the probe, and the incision is extended as completely superiorly and inferiorly as possible (Fig. 149.5).
  - The sac may be incised with an angled crescent blade, an angled needle-tipped cautery, or a radiofrequency dissector.

FIG. 149.5 Probe in the lacrimal punctum visible in the wound from the opened lacrimal sac.

  - Extension of the incision in the sac anteriorly at its upper and lower limits is helpful for inspection of the interior of the sac.
  - Any foreign bodies should be removed.
  - A low threshold for biopsy should be maintained.
  - The probe is removed from the lacrimal punctum.
- The nasal packing is now removed.
- A vertical straight or oval opening into the nasal mucosa is created with a needle-tipped cutting/cautery device.
- One probe of a silicon intubation system (such as a Guibor tube) is passed through the upper canaliculus, into the sac, and through the fistula and retrieved in the nose with the appropriate device (such as a grooved director).

- The second probe is passed through the lower canaliculus and retrieved in the same manner. Both tubes are then elevated from the lacrimal sac (through the skin incision) with a small blunt hook, and 6-0 silk suture is tied around both at about the level of the skin incision.
  - The suture should be tied in a single square knot to facilitate later removal via the punctum.
  - The hook should then be used to check tension of the tubes at the medial canthal angle: The loop should prolapse no farther than the medial limbus (Fig. 149.6). The ends of the suture are trimmed to 3 mm.
- Approximately 4 cm of a 12F straight catheter is cut. One end may be beveled with drape scissors if desired.
- It is passed, beveled end first, over both wire probes, into the nasal cavity, and up into the wound. The catheter is retrieved in the wound with sturdy forceps, such as Adson's.
- Double-armed 7-0 chromic gut suture is passed across the lumen of the tube approximately 4 mm from its end while taking care to not cut the silicone stents with the needle (Fig. 149.7).
- The tube is retracted into the nose, and both ends of the suture are passed through the anterior wall of the lacrimal sac. The tube is pulled up into the sac, the sutures are tied in a series of five or six overhand knots, and the ends are cut (Fig. 149.8).
- The lacrimal sac area is now irrigated with an antibiotic solution.
- The three tubes are cut together approximately 1 cm proximal to the naris.
- A 5-0 nylon loose stitch is fashioned to secure the catheter to the nasal mucosa.

FIG. 149.6 Silicon stents should be loose enough to prolapse only as far as the medial corneal limbus.

FIG. 149.7 Rubber catheter around the silicone stents and gut suture passed across the lumen (for fixation into the sac remnant).

- The ends are cut short and rotated into the lumen of the tube so that they do not irritate the patient.
- An alternative to the use of the silicon straight catheter is suturing of at least a posterior flap of the lacrimal sac to a posterior flap of nasal mucosa and, if possible, the two anterior flaps over the silicon lacrimal

tube, using 6.0 Vicryl.

- Skin is closed with running 8-0 nylon suture or interrupted 7-0 chromic suture, and antibiotic-steroid ointment is applied (Fig. 149.9). This may be followed by a pressure bandage if significant hematoma is expected.

Common Errors in Technique

- Twisting the bone punch when it is directed superiorly may propagate a fracture to the skull base and cause a cerebrospinal fluid (CSF) leak.
- A functional upper lacrimal drainage system must be present for dacryocystorhinostomy to be effective.
- The rubber catheter stent must be sewn securely up into the body of the lacrimal sac.
- Gentle handling of the puncta and canaliculi is essential to avoid injury.

FIG. 149.8 Rubber catheter sewn into the anterior of the sac remnant and tied to rest in the fistula.

FIG. 149.9 The closed incision will be hidden in the lower eyelid crease.

Postoperative Period

Postoperative Management

- Oral antibiotic (as long as the silicon straight catheter will be in place, if used, or if infection was present)
- Topical antibiotic-steroid drops
- Nasal steroid spray
- Topical antibiotic-steroid ointment is applied to the sutures until they are removed in 5 to 7 days.
- Patients are instructed to not blow or pick their noses for 3 weeks. The first three medications are maintained until removal of the silicon straight catheter 10 days to 3 weeks postoperatively.
  - At this time the drops are tapered from 4 times a day to twice a day

and then discontinued 1 week later.

- The nasal steroid is continued until removal of the silicon stents, 2 months postoperatively.

- The patient is seen in the office 1 week postoperatively for removal of the skin sutures.
- One week after this visit (10 days to 2 weeks after surgery) the nylon suture in the nasal cavity is cut, and the catheter is withdrawn from the nostril in the office.
- The chromic gut suture holding the proximal end will have dissolved by this time.
- Two months postoperatively, the silicon tubes are removed either from the naris after cutting at the medial canthal angle or from the punctum by rotating the tube until the silk suture emerges from one punctum, cutting between them, and pulling the end with three lengths of tubing from the punctum.

Complications

- Too much tension on the silicone stent (placing the silk suture too deep) will cause erosion of the lacrimal puncta.
- Failure to put lateral traction on the eyelid (i.e., straightening the canaliculus) while passing a lacrimal probe will cause damage to the canalicular mucosa.

Alternative Management Plan

- Cases of upper system obstruction should be treated with respective appropriate procedures.
- In cases of recurrent infection or discharge in a patient with a dry eye, it may be preferable to do a dacryocystectomy.
- In some cases of inflammatory disease (granulomatous polyangiitis is most notable) a dacryocystectomy is likely more appropriate.
- In cases without severe infection

Discussion

Evidence-Based Medicine Question

What is the success rate of DCR, external and endoscopic?

An analysis of 100 consecutive failed DCRs, about ¾ of them external and the remainder endoscopic, showed that the most common reasons for anatomic failure were inadequate bony ostium, incorrect marsupialization of the lacrimal sac, and closure of the mucosal fistula.[7] These reasons were not different between the two approaches. A recent report of more than 1000 consecutive cases of endoscopic DCR by one surgeon (employing silicon lacrimal stents) showed a success rate of 92.7%.[8] A meta-analysis of more than 2000 cases showed the same success rate for external and endoscopic DCR, 87%.[9] A report of four recently published studies examining the efficacy of both approaches found that when the previous study was removed, the reported success of external DCR was between 91% and 100% and that of endoscopic procedures ranged from 91% to 97%.[10]

Editorial Comment

The external approach to dacryocystorhinostomy is necessary to understand even though in the age of excellent instrumentation many people prefer an endoscopic procedure. In cases of acute infection, suspected mass, suspected dacryolith, and diverticulum of the sac, an external approach will be required. In children, endoscopic DCR has been reported with varying success, as has external DCR. When possible, it is preferable to work with the child's anatomy, by probing first, sometimes more than once, and then placement of silicon stents into the nasolacrimal duct, rather than bypassing normal anatomy entirely.

Review Questions

1. A patient with intractable tearing undergoes irrigation of the lacrimal

system, with resulting reflux from the canaliculus of the opposite lid. Possible sites of obstruction are

a. Common canaliculus

b. Punctum

c. Opposite canaliculus

d. **Nasolacrimal duct**

2. A possible reason for inability to retrieve the probe of the silicon lacrimal stent in the nose is (choose all that apply)

a. Deviated septum

b. Punctal obstruction

c. Eustachian tube dysfunction

d. **Ethmoid air cell medial to the lacrimal fossa**

3. Tearing in neonates should be treated with prompt DCR.

a. True

b. **False**

Optic Nerve Decompression

Eric W. Wang, and Timothy DeKlotz

Introduction

1. Visual compromise due to injury or compression of the optic nerve can be debilitating and lead to significant impairment in a patient's quality of life.

2. Transcranial and transfacial access for optic nerve decompression have been the classical approaches for surgical intervention, although endoscopic/transnasal approaches are playing a more common role in the management of pathology affecting the optic canal.

   a. Improvements in endoscopic instrumentation, understanding of the anatomy, and increased experience have enabled these advances.

3. Causes of optic nerve injury can be classified as traumatic or nontraumatic optic neuropathy (ON).

   a. Most early endoscopic experience was concerned with treatment of traumatic causes of ON; however, conflicting reports have failed to demonstrate a definite benefit of surgical intervention, which has led to this indication falling out of favor.

   b. Endoscopic decompression is now becoming a more common role in nontraumatic ON secondary to compressive lesions or fibro-osseous disease.

Key Operative Learning Points

1. The optic canal is typically identifiable as a prominence in the superior-lateral wall of the sphenoid sinus.

2. At least 180 degrees of bone must be removed circumferentially from

the canalicular segment of the optic nerve after carefully thinning the bone with a high-speed drill.

Preoperative Period

History

1. History of present illness
   a. Visual complaints: Decreased acuity or color vision, diplopia, periorbital pain, unilateral versus bilateral symptoms
      1) Time course is important to document: Although chronic compression is frequently believed to have a decreased response to decompression, studies fail to correlate the length of time from the onset of the disease and the likelihood of visual improvement.[1]
   b. Additional neurologic symptoms: These symptoms may provide insight into the extent of the disease.
   c. Any recent interventions
2. Past medical history
   a. Prior interventions
      1) Surgical decompressions: Verify type of approach (transnasal endoscopic, transcranial) and outcomes.
      2) Nonsurgical treatment of underlying pathology: This might include radiation for a tumor or high-dose steroids.
   b. Other medical problems, surgeries: Determine if underlying health status may preclude surgical intervention.

Physical Examination

1. Ophthalmologic examination (formal ophthalmology consultation is highly recommended)
   a. Visual acuity (VA)
   b. Afferent pupillary defect: This can be seen prior to any decline in

VA.

c. Color vision testing: Decline in red color vision is seen first and may be present prior to a decline in VA.

d. Extra-ocular motility

e. Visual fields testing

f. Optical coherence tomography: Noninvasive testing can determine the nerve fiber thickness of the retina (long-standing lesions with evidence of nerve atrophy may be less likely to recover function after decompression).[2]

2. Cranial nerves: Concurrent cranial neuropathies can help define the extent of lesions as well as other nerves that may require decompression.

3. Nasal endoscopy: Identify any barriers to an endoscopic approach that may need to be addressed preoperatively or intraoperatively (i.e., septal deviation requiring septoplasty, acute sinusitis requiring antibiotic therapy).

Imaging

1. Computed tomography (CT) with contrast of the sinus

a. Navigational protocol: 1-mm slice width

b. Contrast is important for defining the location of the internal carotid artery (ICA) in relation to the optic nerve.

2. ± Magnetic resonance imaging (MRI)

a. Depends on specific indications of optic nerve decompression (i.e., critical for evaluating extension of the tumor into the optic canal but less important for defining fibro-osseous disease)

Indications

1. Compression due to an extrinsic mass

a. Tuberculum and planum meningiomas with extension into the optic canal

b. Mucocele

c. Fibro-osseous lesion (Fig. 150.1)

d. Primary sinonasal malignancy (in the absence of nerve invasion)

e. Fungal ball

f. Primary tumors of the skull base: chordoma, chondrosarcoma

2. Primary tumor of optic nerve: glioma, meningioma, hemangioma

3. ±– Trauma: Controversial

a. International Optic Nerve Trauma Study[3]: There is no clear benefit of high-dose steroid therapy versus canal decompression versus observation alone.

b. Select patients may benefit and be determined on a case-by-case basis.

Contraindications

1. Medical comorbidities precluding safe administration of general anesthesia: May require further optimization of the patient's medical condition if possible versus alternative treatment methods (i.e., radiation, steroids)

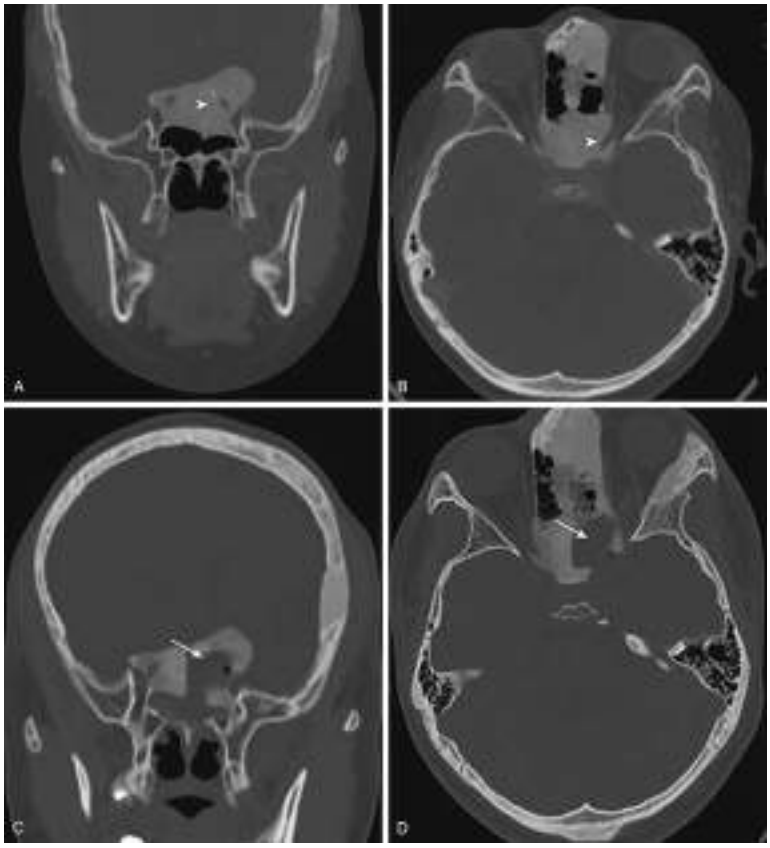

FIG. 150.1 Preoperative, **A, B,** and postoperative, **C, D,** computed tomography scans of a representative patient following endoscopic endonasal optic nerve decompression. Note symptomatic encasement of the left optic nerve *(arrowheads)* by fibrous dysplasia and wide bony decompression *(arrows)*. Right optic nerve with asymptomatic encasement (no prophylactic intervention performed).

2. Technical inexperience: Safe surgery requires significant experience in sinonasal surgery and should not be undertaken by a novice endoscopic sinus surgeon. Team surgery incorporating the skill set of an experienced otolaryngologist and neurosurgeon can be beneficial.

3. Trauma: See *Indications* above. Controversial indication and more recently has fallen out of favor

4. Optic nerve encasement, fibrous dysplasia: Surgical decompression of nerve encasement without visual compromise

a. Surgery in asymptomatic patients is associated with visual

deterioration.[4]

Preoperative Preparation

1. Documented formal ophthalmologic examination

2. Correct coagulopathy if present

3. Evaluate preoperative imaging for any variations in sphenoid pneumatization (i.e., an Onodi cell).

Operative Period

Anesthesia

1. General endotracheal anesthesia

Positioning

1. Head position: Mild extension and rotation toward surgeon

2. Rigid fixation with head pins (i.e., Mayfield head clamp): Ensures no accidental movements during dissection and drilling around critical neurovascular structures

3. Body position: Supine, reverse Trendelenburg decreases intraoperative bleeding.

Perioperative Antibiotic Prophylaxis

1. First-generation cephalosporin, although consider ceftriaxone given the potential risk for cerebrospinal fluid (CSF) leak

Monitoring

1. None

2. Somatosensory evoked potentials: Can be considered if ICA is at particular risk

3. Electromyogram (EMG): Monitoring of other cranial nerves is dependent upon the risk based on the extent of the tumor.

Instruments and Equipment to Have Available

1. Endoscopic sinus surgery instrument set
2. Endoscopic bipolar cautery
3. High-speed elongated drill with diamond bur
   a. Recommend having 4- and 2-mm burs available
   b. Self-irrigating system

Key Anatomic Landmarks

1. Sphenoid sinus
   a. Most posterior paranasal sinus, located immediately posterior to the posterior ethmoid sinuses
   b. Paired: Separated by an intersinus septation
   c. Natural sphenoid os is medial to the superior turbinate, approximately 1⁄3 to ½ of the height from its lower border.
   d. Multiple important landmarks within the sinus will guide safe surgery (Fig. 150.2).
      1) Lateral opticocarotid recess: Pneumatization of the optic strut, bordered by the optic nerve and ICA posteromedially
         a) Defines the extent of the osseous canalicular segment of the optic nerve
      2) ICA prominence: Be constantly aware of this critical landmark to prevent potential catastrophic complication; it may be dehiscent.
      3) Optic nerve prominence: Key area of planned decompression
2. Optic nerve

a. Travels in an anterolateral-to-posteromedial direction until reaching the chiasm

b. Divided into four segments[5]

1) Intraocular

2) Orbital

3) Canalicular

a) True canalicular: Complete osseous canal

b) Preforaminal: Under the falciform ligament

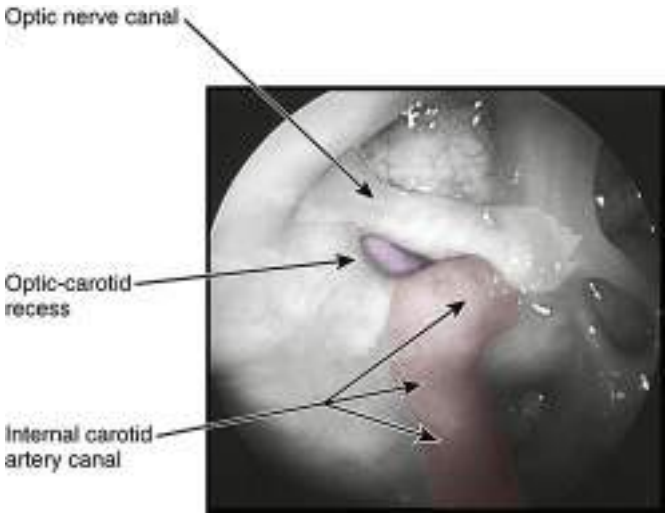

FIG. 150.2 Endoscopic view within the right sphenoid sinus demonstrating key anatomic landmarks; lateral opticocarotid recess, optic nerve prominence, internal carotid artery prominence. Pneumatization can vary and landmarks may be less visible in under-pneumatized sinuses.

4) Intracranial

c. CSF extends into the canal proximally and may lead to a CSF leak if the optic nerve sheath is injured or opened.

d. Ophthalmic artery (OA)

1) Compromise can lead to visual loss.

2) Typically arises from the ICA (although in a few patients, the OA can arise from a branch of the ICA or even the external

carotid artery)[6,7]

3) Within the canalicular segment, the OA lies inferior or inferomedial to the nerve.

a) Travels laterally: At the intraorbital os, it lies inferolaterally.

4) Runs within the optic canal sheath

a) In a small subset of patients, it may travel in a separate bony canal inferiorly.

3. Onodi cell: Posterior superior pneumatization of a posterior ethmoid cell

a. The previously discussed landmarks may be present within an Onodi cell instead of the sphenoid sinus depending on the extent of the cell.

Prerequisite Skills

1. Endoscopic ethmoidectomy (see Chapter 108, 3rd ed.)
2. Endoscopic sphenoidotomy (see Chapter 110, 3rd ed.)

Operative Risks

1. Optic nerve injury
   a. Thermal injury from high-speed drill
   b. Direct trauma during dissection
2. Hemorrhage
   a. Most commonly from cut mucosal edges
   b. Posterior septal branch of sphenopalatine artery can lead to brisk arterial bleeding.
   c. Catastrophic hemorrhage is possible if there is injury to the ICA.
3. Orbital injury
   a. Violation of the periorbita exposes the intraorbital contents to

possible harm.

4. CSF leak

   a. Violation of the optic nerve sheath or anterior clinoid dura can lead to a CSF leak.

Surgical Technique (, Video 150.1)

1. Nasal cavity decongestion: Topical oxymetazoline (0.05%) or epinephrine (1:1000) per surgeon preference

2. Uninarial approach

   a. Exceptions include (1) bilateral decompressions or (2) increased access required for tumor resection

3. Ipsilateral middle turbinate: Medialized or resected for access

   a. Preserve if possible, but do not hesitate to remove if limiting visualization.

4. Total ethmoidectomy

   a. Important to take down all septations, especially along the medial orbit and skull base to maximize visualization

5. ± Maxillary antrostomy

   a. May be performed for further delineation of the orbit if required

6. Wide sphenoidotomy

   a. The ipsilateral sphenoid sinus is maximally opened from planum sphenoidale to the floor of the sinus.

   b. Laterally, bone is removed flush with the orbital apex.

   c. The wide opening provides access for improved visualization and adequate freedom of mobility for dissection.

7. Identify key surface landmarks within the sphenoid sinus (see Fig. 150.2).

   a. In the absence of clear landmarks (i.e., fibrous dysplasia), stereotactic navigation can be helpful.

   b. Clear delineation of the medial orbit is imperative.

8. Posterior medial orbital decompression
    a. Thin posterior orbital bone can be dissected free after gently fracturing with a Cottle elevator.
    b. Thicker bone of the orbital apex will need to be thinned with a high-speed drill prior to dissecting free.
    c. Keep periorbita intact, otherwise orbital fat will herniate into the operative field and obstruct the surgeon's view.
        1) If a small amount of adipose tissue is obstructing an adequate view, judicious use of bipolar cautery can shrink the tissue. Do not attempt to resect this tissue.
9. Drilling and thinning of the orbital apex and optic canal (Fig. 150.3)
    a. A self-irrigating drill or copious handheld irrigation is used to prevent thermal injury to the underlying nerve.
    b. Bone is dissected free up to the tuberculum, optic strut, and paraclinoidal ICA (Figs. 150.4 and 150.5).
    c. At least 180 degrees of decompression is required to be considered adequate.
        1) Frequently up to 270 degrees of decompression can be achieved, especially if the anterior clinoid is well pneumatized.
    d. A 2-mm drill bit may be required when drilling the anterior clinoid, optic strut, and superior surface of the optic canal.
10. The optic nerve sheath is usually not opened.
11. The decompressed optic nerve can be covered with fibrin glue.
    a. Nasal packing is generally not employed given the potential for nerve compression and injury.
        1) The exception is following more complex cases requiring intradural dissection of the tumor and skull base reconstruction (in which optic nerve decompression is only a component of the overall procedure).
            a) Only gentle pressure with nasal tampon sponges is used to reinforce the reconstruction.

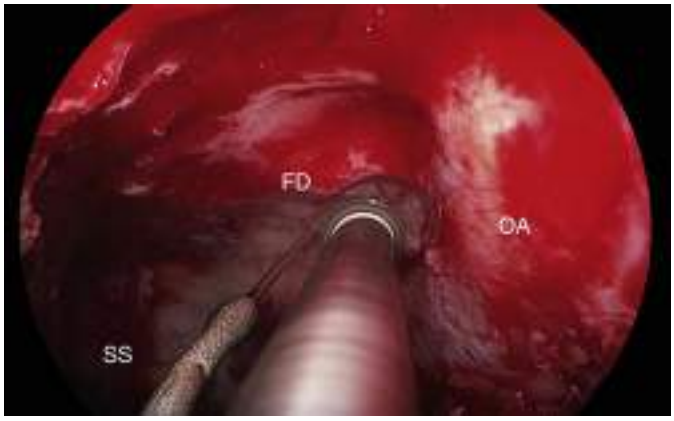

FIG. 150.3 Endoscopic view of the left sphenoid sinus and orbital apex. Abnormal bone overlying the orbital apex and optic nerve is drilled using a self-irrigating drill to prevent thermal injury. *FD,* Fibrous dysplasia; *OA,* orbital apex; *SS,* sphenoid sinus.

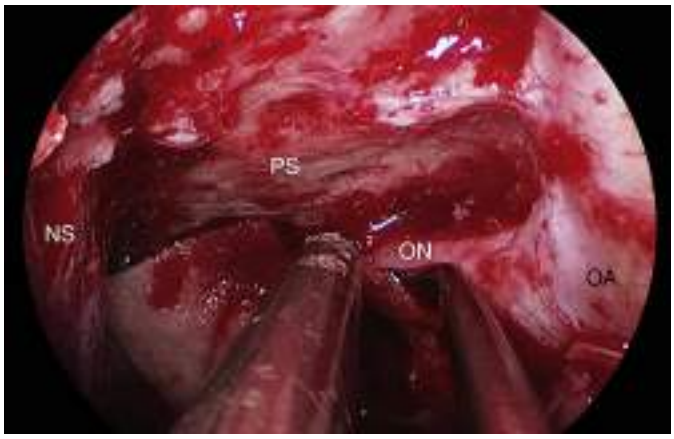

FIG. 150.4 Decompressed left orbital apex. Thinned bone overlying the left optic nerve is dissected free with a fine dissector. *NS,* Nasal septum; *OA,* orbital apex; *ON,* optic nerve; *PS,* planum sphenoidale.

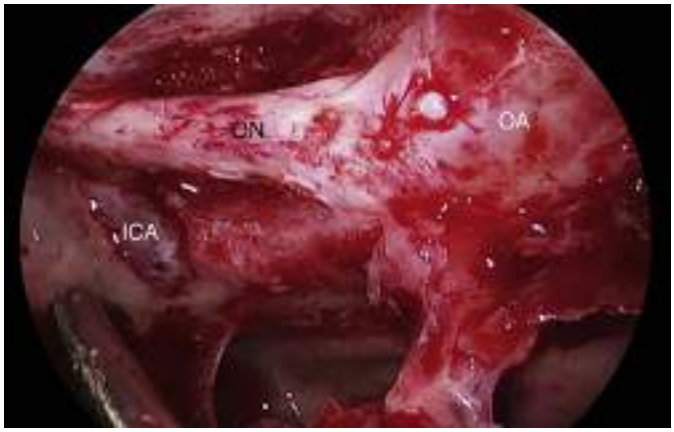

FIG. 150.5 Final decompression viewed with 45-degree endoscope demonstrating greater than 180 degrees of bony decompression of the optic nerve. The left internal carotid artery has been exposed without injury. *ICA,* Internal carotid artery; *OA,* orbital apex; *ON,* optic nerve.

Common Errors in Technique

1. Violation of periorbita can lead to an obstructed view.

2. Failure to use adequate irrigation can cause thermal injury of the optic nerve.

3. Placement of compressive nasal packing postoperatively can lead to nerve injury.

Postoperative Period

Postoperative Management

1. Nasal saline irrigation is started on postoperative day 1.

   a. Large-volume irrigations can be used immediately if an isolated nerve decompression procedure is performed.

   b. If part of a larger tumor resection procedure with intradural dissection (and requiring temporary packing for bolstering of a skull base reconstruction), then only nasal saline spray is used 4 times per day

2. Overnight admission is warranted to ensure no postoperative complications and for regular vision checks.

3. Antibiotics are generally not warranted postoperatively unless nasal packing is used.

4. Patient instructions are similar to those following standard sinus surgery.

   a. No nose blowing

   b. Avoid heavy lifting (<15 lbs) or strenuous activity for 1 to 2 weeks.

   c. Sneeze with an open mouth.

Complications

1. Epistaxis

   a. Minor oozing is common postoperatively and can typically be controlled with topical decongestant sprays.

   b. More significant bleeding is uncommon and the patient should be taken back to the operating room for exploration and control. The posterior septal branch of the sphenopalatine artery (as it crosses the anterior face of the sphenoid sinus) is the usual source of bleeding.

2. CSF leak

   a. Small risk during ethmoidectomy

   b. Superior decompression of the nerve may place the patient at particular risk of leak, notably if the corridor is narrow due to poor pneumatization of the anterior clinoid.

   c. Postoperative rhinorrhea can be collected and sent for confirmatory beta-2 transferrin testing if there is a high level of suspicion of a CSF leak.

   d. Head CT with any intracranial air is consistent with a dural defect.

   e. Immediate surgical repair is recommended rather than attempting conservative measures (i.e., lumbar drainage).

      1) A free graft (mucosal, adipose tissue) is likely all that would be required for repair.

3. Visual deterioration

   a. Inadequate irrigation while drilling over the nerve can lead to thermal injury.

   b. Vascular injury to the OA is possible.

   c. Compressive nasal packing can lead to neuropraxic injury and should be removed completely if possible or partially (if bolstering of skull base reconstruction is required).

Alternative Management Plan

1. Steroids

   a. Although steroids may temporize edema of the optic nerve, this is not a long-term solution to compressive pathology.

2. Radiation

   a. Can be used for select tumors, though use in close proximity to the optic nerve places vision at significant risk

3. Transcranial approach for optic nerve decompression

Discussion

Evidence-Based Medicine Question

Is transnasal endoscopic optic nerve decompression more effective than traditional open approaches for treatment of nontraumatic ON?

1. Current literature for endoscopic optic nerve decompression is limited to small retrospective case series with no direct comparison trials reported.

   a. Although results are promising for the endoscopic approach, this procedure cannot be considered the standard of care for compressive pathology given the relatively limited amount of outcomes data available.[8]

   b. Further research is required to support the regular use of the endoscopic approach over other approaches.

2. The favorable safety profile of the procedure has been demonstrated through larger case series performed for traumatic ON.[9]

Editorial Comment

Endoscopic optic nerve decompression can be a challenging procedure and should not be approached by a novice endoscopic sinus surgeon. Stereotactic navigation can be a useful aid in surgery, but anatomic landmarks are more reliable. Bony decompression of at least 180 degrees is necessary to be considered adequate. Avoid nasal packing unless absolutely necessary to prevent possible compression injury to the optic nerve.

Review Questions

1. At least _____ degrees of bony decompression must be accomplished to be considered an adequate optic nerve decompression.

   a. 90

   b. 120

   c. **180**

   d. 270

2. What segment of the optic nerve is particularly at risk due to circumferential bony encasement of the nerve?

   a. Intraocular

   b. Orbital

   c. **Canalicular**

   d. Intracranial

3. What is *not* an indication of optic nerve decompression?

   a. Tumor extension into the optic canal

b. Optic nerve glioma

c. **Fibrous dysplasia encasing the optic nerve without impaired nerve function**

d. Fibrous dysplasia encasing the optic nerve with impaired nerve function

4. The _____ defines the extent of the osseous canalicular segment of the optic nerve.

a. **Lateral opticocarotid recess**

b. Orbital apex

c. Internal carotid artery

d. Sella

5. Which option is *not* a potential cause of visual impairment following surgery?

a. Thermal injury due to inadequate use of irrigation

b. Injury to the ophthalmic artery

c. Compression from nasal packing

d. **Failure to perform a maxillary antrostomy**

Orbital Decompression

Tonya Stefko, and Carl H. Snyderman

Introduction

- Decompression of the orbit may be considered for the treatment of space-occupying lesions causing compromise of function as a result of expansion of the orbital contents or a decrease in the rigid orbital confines. The volume of the orbit averages about 30 mL, and it is only anteriorly that it is not bound by bone. By far, the most common indication for decompression is Graves orbitopathy, but similar surgical techniques are applied to infectious, traumatic, neoplastic, and iatrogenic etiologies (e.g., orbital hematoma after sinus surgery) (Figs. 151.1 and 151.2).
- The incidence of Graves disease in the general population is about 1% to 3%. Females are affected about 5 times as often as men, but older men who experience orbitopathy often have a more fulminant course. About one-third of patients with Graves disease will have orbitopathy, often asymmetrical and usually mild or moderate. Approximately 85% of patients evaluated primarily for orbitopathy will be found to have a dysthyroid state. In adults, Graves disease is the most common cause of unilateral and bilateral proptosis. The first report of decompression for this condition occurred in 1911.[1]
- The pathogenesis of Graves orbitopathy remains only partially understood. Serum levels of antibodies to the thyroid-stimulating hormone (TSH) receptor and collagen XIII seem to correlate with orbital disease activity.[2] TSH receptors are found on orbital fibroblasts, which may differentiate into adipocytes, and are more sensitive to TSH receptor antibodies than dermal fibrocytes. The proptosis is due to an increase in retrobulbar glycosaminoglycan deposition and edema and to a later increase in retrobulbar adipose tissue. Smoking is thought to

affect this by creating increased oxygen-reactive species or by causing local tissue hypoxia, both of which lead to increased chemokines recruiting T cells from the bloodstream. TH2 cells are the predominant type involved in the orbital disease.[3]

- The acute phase of the disease, which consists of orbital congestion, inflammatory cell infiltrate, and forward movement of the globe, generally lasts between 6 and 24 months. After this phase, the disease is characterized pathologically by increased fibrosis of the tissues. A second acute phase may occasionally affect the patient later in life. Asymmetrical involvement of the orbits occurs frequently.

FIG. 151.1 Patient with Graves orbitopathy preoperatively.

- The only external factor proven to affect Graves orbitopathy is cigarette smoking. Current smoking outweighs previous smoking as a predictor of disease severity. Patients in whom orbital disease develops are 4 times as likely to smoke, and discontinuation of smoking appears to lessen the severity and protect patients from the development of further symptoms.[4] Pretibial myxedema, thyroid acropachy (swelling of digits and toes), and female sex are also associated with more severe orbital disease.[5]
- Symptoms of Graves orbitopathy include eyelid retraction, proptosis, diplopia, dryness of the eyes, a sensation of pressure behind one or both eyes, and swelling of the eyelids and conjunctiva (chemosis). Signs consist of eyelid retraction more than 1 mm from the limbus, eyelid lag on downward gaze (failure of the upper eyelid to descend

properly when the patient looks down), unilateral or bilateral proptosis, restriction of extraocular movements (particularly upward gaze and abduction), hyperemia over the insertions of the horizontal rectus muscles, and corneal staining with fluorescein observed with a cobalt filter (Figs. 151.3 and 151.4).

- The courses of the orbital disease and any associated thyroid disease in Graves disease are independent. Euthyroid patients may have severe orbitopathy causing optic neuropathy or corneal perforation, whereas severely hyperthyroid patients may have no orbital signs or symptoms. Treating the thyroid abnormalities is essential to the patient's general health, but it is unlikely to help the eye disease. Exceptions are removal of a large goiter, which may lessen the orbital symptoms, and treatment with radioactive iodine, which sometimes acutely worsens the condition of the orbits (ameliorated by concurrent treatment with oral steroids).[6]
- Orbital decompression is sometimes undertaken for other causes of proptosis: infection with abscess, tumor, trauma to the optic nerve, or hematoma (such as might occur after endoscopic sinus surgery). Abscesses located along the lamina papyracea in the orbit or medially along the roof or floor are most amenable to endoscopic drainage. Occasionally, an orbital apex tumor causing compressive optic neuropathy (CON) may be successfully treated by decompression when resection of the tumor is inadvisable.[7]

FIG. 151.2 Patient with Graves orbitopathy 6 days after balanced decompression of both eyes.

Key Operative Learning Points

- Whenever possible, defer orbital decompression in Graves patients until the disease has been treated medically and is no longer active.
- In cases of poorly responding optic neuropathy or impending corneal perforation, it may be necessary to operate during the active phase of the disease.
- The number of walls decompressed correlates directly with the reduction in proptosis. The most reasonable approach appears to be the balanced decompression:[8] removal of the medial and lateral walls of the orbit. A recent meta-analysis suggests that the average reduction in proptosis is 4.5 mm regardless of the method used.[9] The roof is rarely decompressed, and decompressing the orbital floor gives a higher likelihood of new postoperative diplopia.[10]

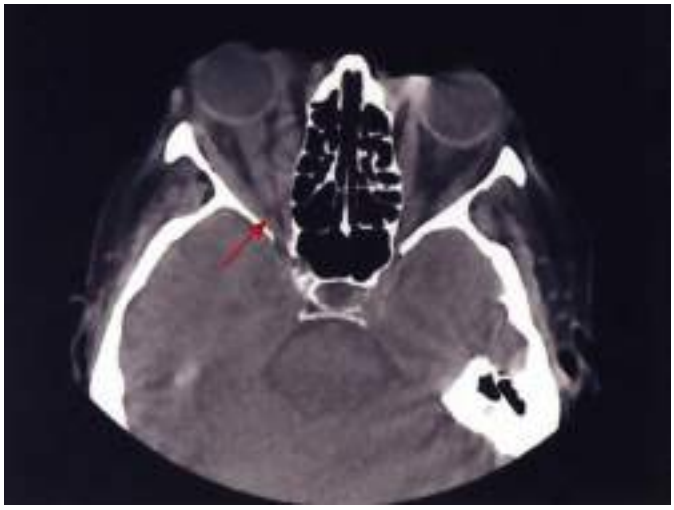

FIG. 151.3 Patient with Graves orbitopathy, optic neuropathy in the right eye, visual acuity of 20/50 in the right eye, and Ishihara color vision of 1.5 of 11 plates. Note the apical crowding *(arrow)*.

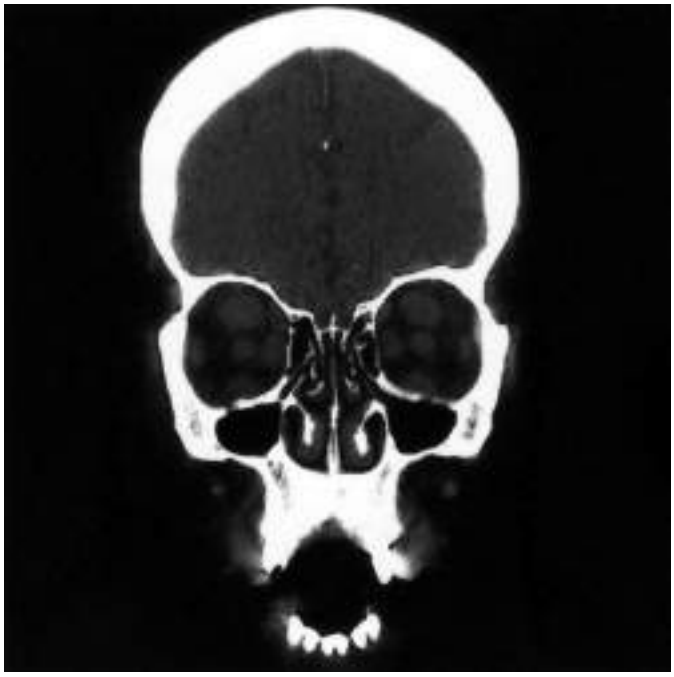

FIG. 151.4 Coronal view of the patient in Fig. 151.3.

Preoperative Period

History

- Smoking
- Thyroid status (euthyroid; previous treatments to render the patient euthyroid)
- Previous eye surgery
- Diplopia
  - In primary gaze
  - In other positions of gaze
- Previous sinus problems/surgeries

Physical Examination

- Complete eye examination by an Ophthalmologist
  - Best corrected visual acuity

    - Color vision
    - Extraocular movements
    - Pupillary responses
    - Intraocular pressure
    - Biomicroscopic examination of ocular surface and posterior segment
    - Hertel exophthalmometry (measures projection of each globe beyond the orbital rim)
- Nasal endoscopy. Endoscopic examination of the nasal cavity is performed to identify structural abnormalities that may interfere with surgery (septal deviation), coexistent disease that needs to be addressed at the time of surgery (nasal polyposis), and conditions that need to be treated prior to surgery (acute or chronic rhinosinusitis).

Imaging

- Computed tomography (CT) (no contrast) of maxillofacial structures to determine whether there is sinus disease or septal deviation and assess the relative size of the extraocular muscles and orbital adipose tissue compartments. Other anatomic variations that may pose a problem during surgery include a low cribriform plate, Onodi cells, Haller cells, or non-pneumatization of sinuses.
- Magnetic resonance imaging (MRI; particularly T2 sequence) of orbits if there is any question whether the disease is active (inflammatory phase)

Indications

- Urgent decompression during active phase of inflammation (for Graves):
    - Compressive optic neuropathy
    - Corneal ulceration
- Elective decompression after the disease is quiescent (for Graves):
    - Proptosis

- Sensation of pressure or pain
- Dryness of the eyes
- Subluxation of the globe

Contraindications

- Active sinus infection. Adequate medical or surgical management of sinus infection is necessary before orbital surgery due to the risk of infection spreading to the orbital tissues.
- Coagulopathy
- Unacceptable anesthesia risk

Preoperative Preparation

- CT scan
- Image-based navigation is optional and is not necessary unless there are anatomic variations or changes from prior surgery that obscure anatomic landmarks. If an optic nerve decompression is planned at the same time, navigation is helpful to identify the course of the optic canal and internal carotid artery.
- Preoperative counseling is particularly important so that the patient understands that this procedure, when performed for Graves disease, is likely to be the first in a series of surgeries. Strabismus surgery may be performed for unresolved diplopia, and eyelid surgery (either correction of retraction or blepharoplasty) may be required after that.
- Decide whether septoplasty or additional sinus surgery is necessary.
- Bilateral orbital decompression
  - Only rarely does it makes sense to stage this operation in a case of bilateral disease; however, there are a few patients in whom the orbitopathy is very asymmetrical and one orbit only may be decompressed.

Operative Period

Anesthesia

- General endotracheal anesthesia

Positioning

- Patient supine with head elevated >15 degrees to decrease bleeding

Perioperative Antibiotic Prophylaxis

- Two grams cephalexin IV

Monitoring

- As per anesthesia

Instruments and Equipment to Have Available

- Medial wall decompression
  - High-definition monitor
  - Zero- and 45-degree nasal endoscopes
  - Extended-tip bipolar cautery
  - Separate suction setup
  - Monopolar suction electrocautery
  - Standard endoscopic sinus surgery set
  - Kerrison bone punches
  - Cottle elevator
  - Ball probe
  - Extended disposable sickle knife (Beaver blade)
  - Endoscopic drill with 3- or 4-mm coarse diamond bit is optional.

    - Doyle silastic splints
- Lateral wall decompression
    - Needle-tip monopolar electrocautery
    - Curved blunt tenotomy scissors (such as Stevens)
    - Selection of brain ribbon retractors
    - Desmarres retractors, medium size
    - Reciprocating bone saw
    - Bone wax
    - Small bone rongeurs
    - High-speed drill with cutting burr
    - Toothed forceps
    - Blunt Westcott scissors
    - Fine-needle drivers
    - Penrose drain
    - 6.0 Vicryl and 7.0 absorbable or nonabsorbable sutures

Key Anatomic Landmarks

- Superiorly, bone is removed to within 2 mm of the skull base while being careful to not fracture the skull base.
- The anterior ethmoidal artery crosses the roof of the ethmoid sinus between the second and third lamellae, just posterior to the nasofrontal recess, and is susceptible to injury.
- Examination of the maxillary sinus with an angled endoscope usually reveals the neurovascular bundle of the infraorbital nerve running across the roof of the maxilla. This is the lateral limit of bone removal from the orbital floor.
- Landmarks within the sphenoid sinus are identified: the carotid canal, optic canal, and lateral optic-carotid recess. Drilling of bone should be along the axis of the optic canal to avoid injury to the carotid artery.
- In patients with compressive optic neuropathy, it is vital to perform

posterior medial wall decompression to relieve pressure on the optic nerve in the orbital apex.

Prerequisite Skills

- Endoscopic maxillary antrostomy, ethmoidectomy, and sphenoidotomy
- Nasal septoplasty
- Lateral orbitotomy

Operative Risks

- Violation of the skull base with cerebrospinal fluid (CSF) leak
- Bleeding from the anterior ethmoidal artery with orbital hematoma
- Traumatic injury of the optic nerve or internal carotid artery
- Hypesthesia from injury of the infraorbital nerve or descending palatine nerve
- Laceration of the medial rectus muscle

Surgical Technique

It does not matter whether the medial wall or lateral wall decompression is performed first. A relative advantage of performing the medial wall decompression first is that the orbital contents are under greater pressure and herniation of orbital adipose tissue into the sinus cavity is facilitated with external orbital massage.

Medial Wall Decompression

- A skin prep is optional.
- The nose is decongested with cottonoid pledgets soaked in 0.05% oxymetazoline.
- If a septoplasty is necessary for access, it is performed first.

- The inferior aspect of the middle turbinate is resected with curved sinus scissors to provide greater access and room for the orbital tissues to expand.
- The uncinate process is removed, and the antrostomy is maximally enlarged posteriorly and superiorly so that the junction of the medial and inferior walls of the orbit is exposed.
- The bulla ethmoidalis is opened for removal of ethmoid air cells in an anterior-to-posterior direction.
- The sphenoid sinus is opened, and the sphenoidotomy is maximally enlarged with Kerrison rongeurs. Residual septations are then removed in a posterior-to-anterior direction along the skull base. The nasofrontal recess is exposed, but further dissection of the frontal sinus is unnecessary and may predispose to stenosis.
- Bleeding from either the anterior ethmoidal artery or sphenopalatine artery is controlled with monopolar or bipolar electrocautery.
- The medial wall of the orbit is palpated and the thin bone of the lamina papyracea is fractured anteriorly with a Cottle elevator. Bone fragments are carefully elevated from the underlying periorbita with a Cottle elevator or ball-tipped probe.
- Removal of bone continues posteriorly to the anterior face of the sphenoid sinus, superiorly to the skull base, and inferiorly to the junction of the medial and inferior orbital walls.
- The floor of the orbit is then removed with angled Kerrison rongeurs to the medial aspect of the neurovascular bundle. The bone at the junction of the medial and inferior walls can be very thick and may require drilling. Removal of additional bone does not contribute to decompression and risks injury to the nerve and hypoglobus (vertical descent of the globe).
- If the decompression is being done for proptosis, decompression of the orbital apex beyond the anterior wall of the sphenoid sinus is not necessary. If the patient is undergoing decompression for visual loss, additional bone is removed posterior to the entrance of the optic canal.
- A sickle blade is used to incise the periorbita of the medial orbit, starting posteriorly and superiorly and proceeding anteriorly. A

disposable Beaver blade is preferred because it is sharper than reusable knives. The blade can be bent 30 degrees toward the orbit approximately 1 to 2 cm from the tip to provide a greater reach. The metal is brittle, however, and may snap if overbent. Multiple parallel horizontal incisions (at least three) are made from the ethmoid roof to the floor of the orbit. Each incision is superficial and parallel to the course of the medial rectus muscle so that the fibers of an enlarged muscle are not inadvertently transected. Intervening strands of periorbita are cut to allow complete herniation of the orbital contents. Gentle external pressure on the eyelids with the hand highlights remaining strands of periorbita and facilitates herniation of orbital adipose tissue into the ethmoid defect (Video 151.1).

- Hemostasis is obtained with warm saline irrigation.
- Silastic nasal splints are placed to prevent intranasal synechiae. Care must be taken not to catch the orbital tissues with the edge of the splint. Nasal packing is not used due to the risk of orbital hematoma.

Lateral Wall Decompression

- The skin is prepped with ophthalmic Betadine solution.
- The eyes are administered ointment and left unsutured during the procedure.
  - In patients with poor closure, it may be useful to temporarily suture the contralateral eye to protect it.
- The lateral wall of the orbit is approached through a lateral canthotomy incision. The incision is approximately 2 cm in length and extends posteriorly from the lateral canthal angle in a crow's foot crease. Stevens or similar scissors are used to cut the lateral canthal ligament and deepen the incision to bone. Bleeding is controlled with electrocautery. The periosteum is incised vertically along the apex of the rim with a scalpel or needle-tipped electrocautery. A Cottle elevator is then used to elevate the periosteum from the lateral orbital wall while keeping the periorbita intact as much as possible. The periosteum must be elevated from both the interior and exterior surfaces of the lateral wall of the orbit. The bone should be identified as far superiorly as the fossa of the lacrimal gland and inferiorly to just

above the level of the zygomatic arch. Careful elevation along the exterior surface proceeds in a posterior direction and then turns medially in the temporal fossa.

- Once the periosteum has been elevated from the bone, a wide ribbon retractor is inserted between the periorbita and bone by an assistant. A Desmarres retractor is placed over the cut surface of the skin. A reciprocating bone saw is used to cut through the lateral wall, parallel to the zygomatic arch; the tip of the saw blade is placed in the inferior orbital fissure, and the ostectomy is made from medial to lateral. Frequent pauses to assess the position and adequacy of protection of the orbital contents are essential. The second osteotomy is made just superior to the zygomaticofrontal suture with the tip of the saw blade inside the orbit. It is important to have good exposure of the lateral wall externally to gauge the depth of the saw blade and avoid cutting into the anterior or middle cranial fossa.
- A rongeur is now used to grasp the vertical strut, which is gently outfractured. It will be necessary to elevate the remainder of the temporalis muscle from the posterolateral surface of the bone with electrocautery. Bone wax is applied as needed, and any remaining small fragments of bone are removed with the same instrument. The sharp surfaces of the remaining zygomatic and frontal bones are smoothed with a burr or rongeur. Further bone may be removed superiorly and inferiorly and posteriorly until the sphenoid bone begins to widen.
- A short-bladed knife, such as a sickle knife, is now applied to the periorbita in a very superficial manner, directed posteriorly to anteriorly, to slit the fibrous septa and allow the orbital contents to prolapse into the temporal fossa. Care is taken to place no traction on the orbital adipose tissue and to remain superficial so that the lacrimal gland and lateral rectus muscle are not damaged. Bipolar cautery is used to obtain hemostasis.
- Careful closure of the wound is accomplished by precise realignment of the upper and lower gray lines of the eyelid with a single horizontal stitch of 6-0 absorbable material, such as polyglactin, buried laterally. The deep tissues are reapproximated with inverted 6-0 suture and the skin closed carefully with running 7-0 nylon or interrupted chromic gut suture. Before complete closure, a longitudinal strip of 0.25-inch

Penrose drain is placed into the wound to emerge between sutures. A patch is placed loosely over the eye to absorb drainage. The patient is admitted for observation overnight, both for pain control and to monitor for any hemorrhage (Figs. 151.5 and 151.6).

Common Errors in Technique

- Preservation of the middle turbinate limits expansion of the orbital contents and predisposes to synechiae.
- Injury to the ethmoidal arteries can result in a retro-orbital hematoma. Posteriorly, the optic nerve and carotid artery are at risk for injury.
- A small antrostomy or sphenoidotomy is prone to scarring and obstruction.
- Removal of additional bone lateral to the infraorbital canal does not contribute to decompression and risks injury to the infraorbital nerve.
- Excessive decompression of the orbital tissues near the nasofrontal recess can result in obstruction of the frontal sinus.

FIG. 151.5 Postoperative axial view of the patient from Fig. 151.3 with right optic neuropathy secondary to Graves orbitopathy. One week after balanced decompression, visual acuity in the right eye was 20/25

and Ishihara color vision was normal (17/18 plates). Note the herniation of the enlarged medial rectus into the bony defect *(circle)*.

FIG. 151.6 Postoperative coronal view of the patient from Fig. 151.3. Note the bony defects with herniation of the orbital contents *(circles)*.

- Excessive or aggressive removal of the medial wall superiorly can fracture the skull base and cause a CSF leak. Placing the saw blade too deep can injure the dura and brain with the superior lateral wall osteotomy.
- Injury to the infraorbital nerve can lead to loss of sensation of the midface.
- The medial rectus muscle, and to a lesser extent, the lateral rectus, are often infiltrated and enlarged and are susceptible to injury if the incisions in the periorbita are too deep.
- If the medial periorbita is incised first, herniation of orbital adipose tissue will hinder visualization for the superior incisions.
- The lateral rectus muscle is susceptible to injury during decompression of the lateral orbital wall.
- Ecchymosis of the periorbital tissues is common but may be associated with a hematoma.

- Unbalanced decompression of the orbit can result in significant diplopia. The diplopia is often transient but may require corrective surgery if it persists beyond 6 months.
- Careful realignment of the lateral commissure of the eyelids is necessary for an optimal cosmetic result.
- Bony decompression without adequate division of the periorbital septa is ineffective in decompressing the orbit.
- Any removal of intraconal adipose tissue must be done with a minimum of traction and from the inferotemporal quadrant (between the lateral and inferior rectus muscles) to decrease the risk of retrobulbar hematoma and injury to orbital structures.
- Monopolar cautery should be avoided near the apex of the orbit.

Postoperative Period

Postoperative Management

- Patients are administered a steroid pulse intravenously while undergoing observation overnight (4 to 8 mg every 8 hours thereafter while in the hospital). A rapid taper of oral steroid medication is adequate for most patients; those decompressed in an acute setting require a much more aggressive regimen and longer taper.
- Patients are instructed to not blow their nose for 2 weeks after the procedure, and a steroid/antibiotic ointment is applied to the sutures twice a day for a week.
- Nonabsorbable sutures are removed in 5 to 7 days.
- Intranasal splints are removed at 1 week, and a saline spray is used as necessary to minimize crusting. Mucosalization of the orbital tissues is usually complete by 2 months.
- Patients are counseled to expect some initial diplopia and that the final appearance is often not reached for at least 3 months.
    - Patients are observed for at least 6 months after surgery before consideration of extraocular muscle or eyelid surgery.

Complications

- The risks associated with endoscopic medial and inferior orbital decompression are similar to those after any endoscopic sinus surgery.
- New-onset or worsened postoperative diplopia will occur in about one-third of patients undergoing decompression of three walls,[10] but it has been observed in retrospective series; a "balanced decompression" consisting of only the medial and lateral walls is associated with only about a 10% incidence of new-onset diplopia.[8]
- If a CSF leak occurs intraoperatively, it should be assessed by a skull base surgeon and repaired intraoperatively. This may require removal of additional bone. If CSF rhinorrhea is confirmed postoperatively, it should be urgently repaired surgically.
- Manipulation of the infraorbital nerve can cause hypesthesia of the midface; it is usually transient if the nerve is not transected. Excessive removal of bone at the posterior margin of the maxillary antrostomy can injure the descending palatine nerve, resulting in numbness of the palate.
- Transection of the anterior ethmoidal artery can allow the end to retract into the orbital tissues resulting in a retrobulbar hematoma. This needs to be recognized and managed expeditiously based on intraorbital pressures. It may be necessary to further detach the lateral canthal ligament and delay closure of the lid incision.
- Epistaxis should be managed without nasal packing because this may result in an orbital hematoma.
- Orbital emphysema is the result of nose blowing and will resolve spontaneously. Monitor vision and observe for signs of orbital cellulitis.

Alternative Management Plan

- Irradiation of orbital tissues
- Some patients with shallow orbits and/or mostly proliferation of orbital adipose tissue (more so than muscle) may benefit from adipose tissue–

only decompression of the orbits.

- In some patients with mild proptosis but lid retraction, eyelid surgery may camouflage some proptosis and allow for better protection of the cornea, and orbital decompression may not be necessary.

Discussion

Evidence-Based Medicine Question

Which procedure provides optimal decompression of the orbit in patients with Graves exophthalmopathy?

Endoscopic decompression of the orbital apex gives excellent relief of CON. A small randomized trial of patients with CON showed that 45% of the patients treated with steroid required decompression surgery (three-wall coronal decompression) but that 82% of those treated initially with surgery still required pulse IV steroid, suggesting that IV steroid should be tried first. A small series of patients with CON were reported after treatment with a selective endoscopic orbital decompression (only the posterior medial orbital wall); all had stabilization or improvement of vision, and none developed new diplopia. These patients had reduction of proptosis averaging 3 mm. A long-term (median follow-up 5.2 years) review of transantral and transnasal decompressions (medial wall and floor only) showed a persistent decrease in proptosis of about 4.5 mm. A large meta-analysis of studies since 1990 showed a decrease in proptosis of up to 6 mm, with a form of balanced decompression (lateral and medial walls), with a 9% complication rate. Decompression of only the lateral wall decreased the effectiveness of the decompression by 50% (about 3 mm).

Editorial Comment

When considering an orbital decompression, the ENT surgeon must have the appropriate team with oculoplastics and endoscopic endonasal skull base experience. Additionally, the goals of the surgery and the underlying pathophysiology must be fully understood. Most orbital decompressions are carried out for Graves orbitopathy, although they

can be for tumors, trauma, or infections. When considering an orbital decompression, the underlying pathology must also be fully medically treated. This is especially important in Graves orbitopathy, and one should operate on patients with nonactive inflammatory disease who are optimally managed by endocrinology. Preoperative planning with a CT and MRI is warranted; orbital position and volumes can be compared from side to side. Surgically, the number of decompressed walls correlates directly with the reduction in proptosis, and with a balanced medial and lateral wall decompression, the average reduction in proptosis is between 4 and 5 mm. When there is optic nerve compression present, concomitant optic nerve decompression, usually from the endonasal approach, should be considered.

Errors in technique are usually related to incomplete and nonmaximal removal of the orbital bone, injury to the ethmoid arteries, or incomplete openings of the sphenoid or frontal sinuses that can become obstructed from the prolapsing orbital contents.

Review Questions

1. Orbital decompression for Graves ophthalmopathy is best performed during the acute inflammatory phase.

   a. True

   b. **False**

2. The superior limit of a medial wall decompression is

   a. The frontal-ethmoidal suture line

   b. **2 mm below the junction of the ethmoid roof and orbital roof**

   c. The superior margin of the medial rectus muscle

   d. The trochlea

3. The incisions in the periorbita should be parallel to the extraocular muscles to avoid injury to the muscle.

   a. **True**

b. False

4. Which of the following are possible complications of orbital decompression surgery?

a. CSF leak

b. Orbital hematoma

c. Orbital emphysema

d. **Hypesthesia of the mandibular nerve**

Orbital Abscess

Nikisha Q. Richards

Introduction

Subperiosteal orbital abscess (SPOA) is a well-defined complication of bacterial ethmoid sinusitis with potential vision and life-threatening sequelae. In fact, the most common cause of orbital cellulitis is sinusitis, especially of the ethmoid sinuses.[1] The severity of these potential outcomes emphasizes the importance of rapid clinical identification, risk stratification, and treatment. During the second half of the 20th century, these sequelae prompted surgical drainage of the orbit and sinuses in nearly all patients with this diagnosis. There have since been retrospective analyses showing bacteriology and response to antibiotic treatment correlating with the patient's age.[2] It has been speculated that age-related anatomic and physiologic differences in the sinuses may account for this correlation. The sinus cavities markedly enlarge from the neonate to the adult, but the ostia remain constant.[3] The rapid growth of the sinuses leads to a relative overwhelming volume to be drained by the unchanged size of the ostia. Bacteria can easily access the subperiosteal space through foramina and direct extension through thin bones such as the lamina papyracea.

Key Operative Learning Points

- After the patient is under general anesthesia, forced ductions are always performed in all directions of all SPOA patients before and after drainage of the abscess. This helps differentiate a paretic from a restrictive ophthalmoplegia, thereby allowing for clinical correlation when there is suspected cavernous sinus involvement. The contralateral eye can be used for comparison if uncertain.

- Ensure that the cornea is protected at all times.
- When using a sub-eyebrow approach, bevel the scalpel blade in the direction of cilia growth to help prevent the destruction of the hair follicles.
- When using an inferior approach:
  - Take care to follow the curvature of the apex of the orbital rim to help prevent premature entry into the orbit and thusly unwanted presentation of orbital adipose tissue.
  - Use a circumspect approach to the periosteum to help prevent dissection into the eyelid or even transection of the origin of the inferior oblique muscle (IOM).
- When using a medial approach:
  - Be cognizant of the origin of the IOM.
  - The caruncle is an easily identifiable and reliable external landmark for prediction of the IOM origin.[4] The origin of the IOM is just anterior to a small depression just below and lateral to the lacrimal sac fossa.[5]
  - "The rule of twelves"—The anterior-to-posterior length from the anterior lacrimal crest to the anterior ethmoidal foramen is approximately 24 millimeters. From the anterior ethmoidal foramen to the posterior ethmoidal foramen is approximately 12 millimeters, and from the posterior ethmoidal foramen to the optic canal is about six millimeters (Fig. 152.1).
  - Being cavalier in the approach to the medial periosteum can result in fracture of the ethmoid bone or even transection of the origin of the IOM.
- Take care not to use the globe as a fulcrum.
- Always obtain cultures/Gram stain of the abscess contents.

Preoperative Period

History

1. History of present illness
    a. Potential source of the abscess can be elicited by asking about recent sinus infections, preceding trauma compromising the integrity of the skin, or recent insect bites
    b. Onset of eye pain, headache, decreased vision, pain with movement of the eye
    c. Antibiotic or other treatment prior to presentation
2. Past medical history
    a. Previous episodes of orbital cellulitis or orbital abscess. How were they treated?
    b. Existing renal disease, integumentary or hematologic methicillin-resistant *Staphylococcus aureus* (MRSA) infection, chronic sinus infection
    c. Surgery including organ transplantation and previous sinus surgery
    d. Otherwise immunocompromised state
3. Medications
    a. Anticoagulants
    b. Allergies to antibiotics

Physical Examination

Every patient with orbital cellulitis, irrespective of the presence of a SPOA (Fig. 152.2), should have an ophthalmologic examination at least twice daily to include the following:

1. Assessment of periorbital/eyelid edema and erythema
2. Visual acuity
3. Color vision
4. Measurement of intraocular pressure
5. Evaluation of pupils for the presence of an afferent pupillary defect
6. Assessment of chemosis

7. An undilated evaluation of the posterior pole

8. Exophthalmometry

9. Extraocular motility

10. Associated pain with extraocular motility

Imaging

Computer tomography (CT) scan of the orbits with and without contrast or CT maxillofacial with and without contrast (Figs. 152.3 to 152.5)

Indications

- The following patients should undergo immediate surgical intervention:
  - Those less than 9 years of age with any of the following age-superseding criteria:
    - Decreased vision
    - Signs of optic neuropathy
    - Large SPOAs
    - An SPOA that is located anywhere except medially
    - Frontal sinusitis

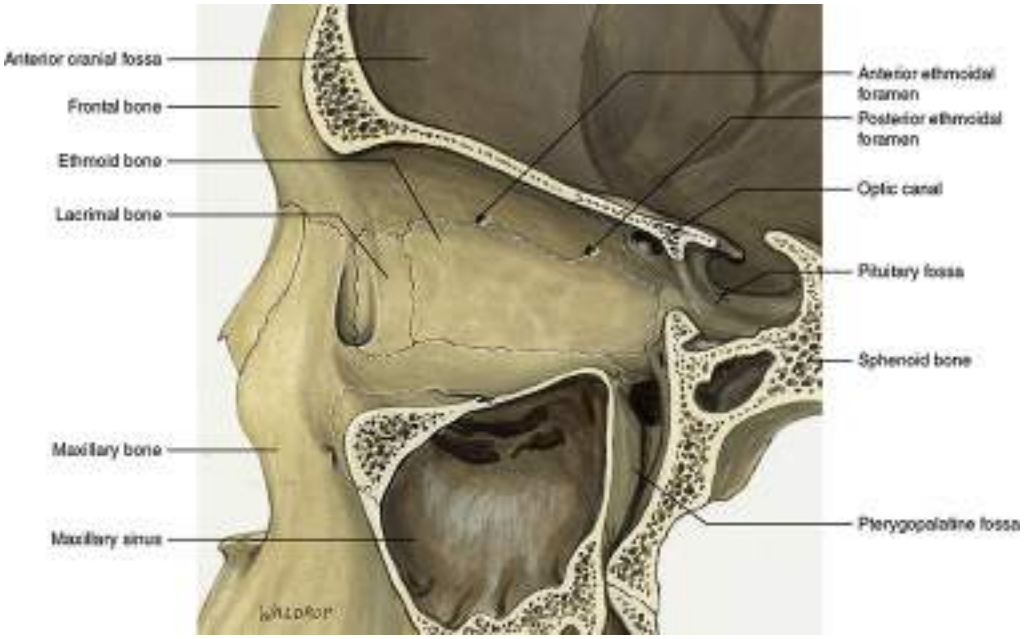

FIG. 152.1 Anterior lacrimal crest, posterior lacrimal crest, lacrimal sac fossa, anterior ethmoidal foramen, posterior ethmoidal foramen, frontoethmoidal suture, optic foramen. Dutton JJ. Atlas of Clinical and Surgical Orbital Anatomy. 2nd ed. Philadelphia: Saunders Elsevier; 2011, p 24, Fig. 2–5.

FIG. 152.2 Clinical appearance of subperiosteal orbital abscess.

    - Intracranial involvement
    - Risk factors for anaerobic involvement[1,6]
- The following patients should undergo surgical intervention within 8 to 24 hours:
    - All patients ≥9 years of age

FIG. 152.3 Contrast-enhanced computer tomography displaying coronal view of right subperiosteal orbital abscess.

    - Always consider:
        - Decrease in visual function (acuity and color vision)
        - SPOA size
        - SPOA location
        - Frontal sinus involvement

FIG. 152.4 Contrast-enhanced computer tomography displaying more posterior coronal view of right subperiosteal orbital abscess.

FIG. 152.5 Contrast-enhanced computer tomography displaying axial view of right subperiosteal orbital abscess.

- Intracranial extension
- Factors predicting anaerobic infection such as:
  - Age ≥9 years
  - Chronic sinusitis
  - Odontogenic origin

- Patients failing prompt response to intravenous antibiotics proceed to surgical drainage[2,6]
  - No clinical improvement after 72 hours
  - Clinical deterioration despite 48 hours of treatment
  - Lack of fever abatement after 36 hours of appropriate antibiotic treatment

Contraindications

1. Surgical factors
   a. Inadequate expertise of the surgeon

Preoperative Preparation

1. Evaluations by:
   a. Ophthalmologist
   b. Otolaryngologist well versed in endoscopic sinus surgery
   c. Internist/pediatrician
   d. Anesthesiologist

2. Keep patients on nothing by mouth (NPO).

3. Broad-spectrum intravenous antibiotics (e.g., third-generation cephalosporin or ampicillin/sulbactam + vancomycin or clindamycin) to include anaerobic coverage especially in those with signs of or suspected chronic sinusitis or an SPOA of odontogenic origin

4. A lateral canthotomy and cantholysis may be indicated to help relieve an orbital compartment syndrome.

Operative Period

Anesthesia

- General

Positioning

- Supine, positioning the patient on an eye stretcher may be helpful

Perioperative Antibiotic Prophylaxis

- Continue scheduled preoperative broad-spectrum intravenous antibiotics, but try to wait for perioperative administration until after culture samples are obtained.
- Choices:
  - Third-generation cephalosporin or ampicillin/sulbactam + vancomycin or clindamycin
  - Clindamycin or vancomycin only if the patient is allergic to penicillin

Monitoring

- Routine anesthesia monitoring

Instruments and Equipment to Have Available

1. 0.5 or Adson toothed forcep
2. Corneal protector
3. Ophthalmic ointment
4. Malleable and Desmarres retractors
5. Monopolar electrocautery with Colorado needle tip

6. Bipolar electrocautery

7. #15 Bard-Parker scalpel blade

8. Cottle elevator

9. Quarter inch Penrose drain

10. Curved Steven's tenotomy scissors

11. Westcott scissors

12. Cotton-tipped applicators

13. Jameson muscle hook

Key Anatomic Landmarks

See Figs. 152.1 and 152.6.

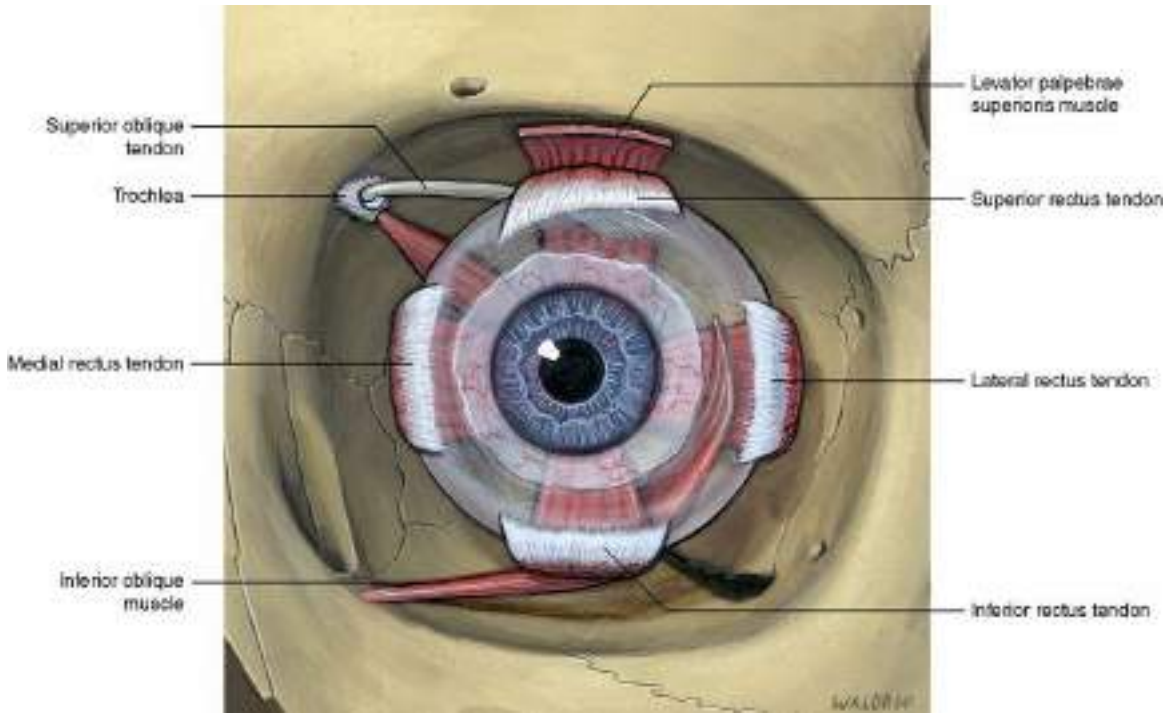

FIG. 152.6 Supraorbital notch/foramen and origin of the IOM (periosteum of the maxillary bone just posterior to the anterior lacrimal crest and inferior to the orifice of the lacrimal sac fossa). Dutton JJ. Atlas of Clinical and Surgical Orbital Anatomy. 2nd ed. Philadelphia: Saunders Elsevier; 2011, p 40, Fig. 3–4.

Prerequisite Skills

- Lateral canthotomy and cantholysis

Operative Risks

1. Penetration of the globe
2. Retrobulbar hemorrhage
3. Fracture of the ethmoid bone
4. Transection of the IOM
5. Scarring leading to lid malposition or strabismus
6. Loss of vision
7. Cerebrospinal fluid (CSF) leak

Surgical Technique

- Intraoperative evaluation after patient has been intubated
  - Forced ductions with 0.5 forcep in all directions
  - If patient was unable to comply with examination prior to intubation, this is an opportune time to perform the pupillary examination.

Subperiosteal Abscesses

Superior Orbit

- The superior orbit can be approached thru a sub-eyebrow or upper eyelid crease incision.
  - Sub-eyebrow approach (Fig. 152.7):
    - Consider a temporary tarsorrhaphy by passing a 5-0 or 6-0 monofilament suture partial thickness through the tarsal plate through or just adjacent to the eyelash line of the upper and lower eyelids in a horizontal mattress fashion.

FIG. 152.7 Sub-eyebrow incision for approach to superior orbit.

- Prior to the incision, note and mark the location of the supraorbital notch in order not to violate the neurovascular bundle.
- Inject local anesthetic with epinephrine subcutaneously.
- #15 Bard-Parker scalpel blade is used to incise the skin from the mid to lateral brow
- Maintain hemostasis at all times with bipolar electrocautery, but avoid cautery of the skin edge.
- Bluntly dissect through the orbital orbicularis muscle until the orbital rim is reached (Fig. 152.8).
- Incise the periosteum along the rim with monopolar electrocautery, and gently separate it from the bone with a Cottle elevator and then a malleable retractor while retracting the superior lip of the incision with a Desmarres retractor to expose and drain the abscess. A specimen of the abscess contents should be sent for culture and sensitivities.

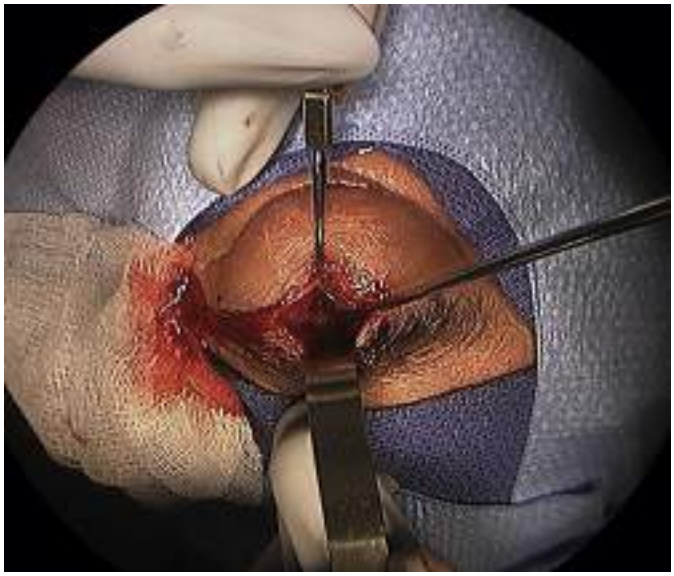

FIG. 152.8 Sub-eyebrow approach to superior orbit isolating frontal bone.

- Close the deep tissues with an absorbable suture such as 4-0 Vicryl in a buried knot fashion sometimes in two layers.
- Close the skin with a monofilament suture such as 6-0 nylon in a simple interrupted or running fashion to be removed 5 to 7 days later.

- Eyelid crease approach:
  - Consider a tarsorrhaphy as described in the sub-eyebrow approach.
  - Mark the upper eyelid crease with a sterile marking pen.
  - Inject local anesthetic with epinephrine subcutaneously.
  - Incise the skin with a #15 Bard-Parker blade.
  - Spring iris or Westcott scissors are used to dissect superiorly in the plane between the orbicularis and orbital septum until the orbital rim is reached.
  - Maintain hemostasis at all times with bipolar electrocautery.
  - Incise the periosteum along the rim with monopolar electrocautery and gently separate it from the bone with a Cottle elevator while retracting the lips of the wound with Desmarres retractors to expose and drain the abscess. A specimen of the abscess contents

should be sent for culture and sensitivities.

- Consider placement of an orbital drain.
- Close the skin in a simple running fashion with 7-0 or 8-0 absorbable or nonabsorbable suture. Nonabsorbable suture to be removed 7 to 10 days later.

Medial Orbit

- A combined endoscopic and external approach is most likely indicated.
  - Endoscopic ethmoidectomy by an Otolaryngologist should be undertaken, though decompression of the orbit may need to be performed first in cases where visual function is compromised (see Chapter 108).
  - Inject local anesthetic with epinephrine transconjunctivally in the area of the plica semilunaris taking care not to penetrate the globe.
  - Place a corneal protector lubricated with ophthalmic ointment over the globe.
  - The assistant should retract the medial eyelids with Desmarres retractors.
  - While tenting the caruncle anteriorly in a coronal orientation with a fine-toothed forcep, incise the conjunctiva between the plica and caruncle either with needle-tip cautery on low power or sharp Westcott scissors.
  - Bluntly dissect by spreading curved Steven's tenotomy scissors posteromedially in a 45-degree angle until the posterior lacrimal crest is reached.
  - Open the periosteum under direct observation, always protecting the globe with a malleable retractor.
  - Gently elevate the periosteum posteriorly until the abscess is identified and drained; a specimen of the abscess contents should be sent for culture and sensitivities.
  - Consider placement of a drain (rubber band, Penrose).
  - No suture closure is required.

Inferior Orbit

- Place a corneal shield lubricated with ophthalmic ointment over the eye.
- Expose and stretch the inferior forniceal conjunctiva over the inferior orbital rim with a malleable holding back orbital tissue and Desmarres retractor retracting the lower lid.
- Incise the forniceal conjunctiva with a Colorado microdissection needle on low power.
- Incise the periosteum at the inferior orbital rim in likewise fashion, and gently lift it from the orbital floor with a Cottle elevator to expose and drain the abscess; a specimen of the abscess contents should be sent for culture and sensitivities.
- No suture closure is required.

- Consider placement of a drain.
- Consider a superior traction stitch through the tarsus of the lower eyelid if placing a drain.

Lateral Orbit

- Although this is the least common site of an SPOA, a lateral approach can be used to access the lateral aspect of the superior and inferior orbit as well.[7]
- A cosmetically pleasing approach to the lateral orbit involves performing a canthotomy in the natural skin crease followed by an inferior cantholysis (see Chapter 153).
  - The periosteum of interest is incised and lifted to access the abscess.
- When attempting to access the lateral aspect of the superior and inferior orbit, a lateral bony orbitotomy may be performed as described in Chapter 151.

Intraconal Abscesses

Addressed similarly as the previously described subperiosteal

approaches as they often stem from the same origin as SPOAs. In certain situations, it is necessary to enter the intraconal space directly. This can be accomplished with either a medial or lateral approach. This requires surgeons familiar with ophthalmic and orbital techniques and will not be described here.

Common Errors in Technique

- Inadequate lubrication/protection of both the operative and fellow cornea intraoperatively
- Using the globe as a fulcrum
- Inducing corneal abrasions
- Premature removal of drain
- Not draining the abscess
- Medial orbit
  - Careless approach to the medial periosteum resulting in fracture of the ethmoid bone or even transection of the origin of the IOM
- Inferior orbit
  - Imprecise approach to the inferior periosteum resulting in dissection into the eyelid or even transection of the origin of the IOM
  - Not following the curvature of the apex of the rim to help prevent premature entry into the orbit and thusly unwanted presentation of orbital adipose tissue
- Superior orbit
  - Not beveling the scalpel blade in the direction of cilia growth to help prevent hair follicle destruction

Postoperative Period

Duration and method of delivery of antibiotics are determined by clinical presentation, culture results, immune system status, and the ability of the patient and family to follow up and administer antibiotics. At times, it is necessary to arrange for in-home nursing visits especially if the patient

has a peripherally inserted central catheter. All patients should continue to have twice daily ophthalmic examinations until clinical improvement is evident. Frequency of examinations is tailored according to clinical response.

Postoperative Management

1. Monitor vital signs.

2. Monitor leukocytes.

3. Remove drain when no longer expressing exudate (usually 24 to 48 hours after surgery).

4. Avoid nonsteroidal anti-inflammatory drugs for pain due to risk of bleeding into already tight orbit.

5. Oxymetazoline nasal spray/drops

6. Tailor antibiotic regimen based on Gram stain and culture results.

7. Convert to oral antibiotics after 24 to 36 hours of persistent clinical improvement.

8. Do not discharge patient until there is persistent clinical improvement for 24 to 36 hours while on oral antibiotics.

Complications

1. Penetration of globe—Place a foxshield over the eye and consult ophthalmology emergently for repair.

2. Retrobulbar hemorrhage—Perform canthotomy and cantholysis of eyelids, obtain hemostasis, and consult ophthalmology emergently.

3. Transection of the extraocular muscles (EOM)—Consult ophthalmology urgently for examination and possible repair.

4. Scarring—Refer to oculoplastics if inducing an eyelid malposition.

5. Loss of vision—Consult ophthalmology emergently.

Alternative Management Plan

Nonsurgical cases are managed with an average of 4 days of intravenous antibiotics and typically followed by three weeks of oral antibiotics along with oxymetazoline nasal drops or spray.[8] The antibiotic regimen and duration of surgical cases are dictated by clinical response and culture results. A knowledgeable infectious disease specialist colleague is an invaluable resource as well.

Discussion

Evidence-Based Medicine Question

When should an orbital abscess be drained?

A widely accepted management protocol was developed in 1994 from a series of patients from 1977 to 1992 that determined triage to medical or medical-surgical treatment and medical patients failing prompt response proceeding to surgical drainage.[2,6] Failure to promptly respond is defined as: no clinical improvement after 72 hours, clinical deterioration despite 48 hours of treatment, or lack of fever abatement after 36 hours of appropriate antibiotic treatment.[6,8] The following factors should always be taken into account: visual function (acuity and color vision), SPOA size, SPOA location, frontal sinus involvement, intracranial extension and factors predicting anaerobic infection such as age ≥9 years, chronic sinusitis, or odontogenic origin. Of course, the use of clinical judgment is always imperative, but essentially, all patients ≥9 years of age along with those less than 9 years of age with any of the accompanying age-superseding criteria including decreased vision, signs of an optic neuropathy, large SPOAs, an SPOA that is located anywhere except medially, frontal sinusitis, intracranial involvement, or risk factors for anaerobic involvement should undergo immediate medical-surgical treatment.[1,6] The nonsurgical approach in those patients less than 9 years of age has been validated longitudinally through 2012.[6,8]

Editorial Comment

This is a well-presented review of considerations for surgical drainage of orbital abscess. Almost never is this undertaken without concurrent drainage of adjacent sinus disease, the most common cause of

subperiosteal and orbital abscess. In the presence of abscess pockets located in other than the subperiosteal space, the involvement of an orbital surgeon is strongly suggested.

Given the clinical circumstances an ethmoidectomy may also be required (see Chapter 108).

Review Questions

1. Which of the following is not an indication to drain an orbital abscess?

   a. Signs of an optic neuropathy

   b. **Severe erythema of the eyelids**

   c. An SPOA involving the inferior orbit

   d. Clinical suspicion of anaerobic bacteria involvement

2. Which of the following statements is true?

   a. All orbital abscesses should be drained.

   b. Presence of a fever is an indication for immediate surgical intervention.

   c. **SPOAs can cause loss of vision and even death.**

   d. A lateral canthotomy and cantholysis are never indicated preoperatively.

3. Which of the following muscles is at risk for transection during approach to the medial or inferior orbit?

   a. **Inferior oblique**

   b. Superior oblique

   c. Inferior rectus

   d. Lateral rectus

Lateral Canthotomy

Roxana Fu

Introduction

The lateral canthotomy coupled with an inferior cantholysis is often the first step in many eyelid and orbital procedures. The detachment of the inferior crus of the lateral canthal tendon allows for greater horizontal laxity of the lower eyelid.[1] It is commonly used in lower eyelid reconstruction techniques[2] (i.e., semicircular advancement flap), inferior or lateral orbitotomies for greater exposure,[3] or in eyelid tightening procedures such as a lateral tarsal strip.[4] It is used as the sole procedure to emergently decompress the orbit in the setting of an "orbital compartment syndrome," a condition characterized by multiple cranial neuropathies within the orbit due to an acute increase in intraorbital pressure.

Aside from airway compromise, an orbital compartment syndrome is one of the few true emergencies for the head and neck surgeon. Immediate intervention should be performed at the time of diagnosis to prevent permanent loss of vision.[5-7]

Key Operative Learning Points

- Recognition of the potential for an orbital compartment syndrome in the setting of trauma, the postoperative period, or secondary to acute orbital or sinus pathology is required for a prompt diagnosis.
- Diagnosis of an orbital compartment syndrome is based on the clinical findings alone. Imaging is not sufficient to determine if a space-occupying lesion requires emergent treatment.
- Clinical presentation of etiologies varies; it is the *acute severity* and *loss*

of function that are the hallmarks of an orbital compartment syndrome.

- Lateral canthotomy combined with an inferior cantholysis is essential to gain horizontal eyelid laxity and therefore greater orbital capacity.
- Repeat intraocular pressure measurements are required to demonstrate adequate orbital decompression.
- Adjunctive medical management should not delay necessary surgical intervention.

Preoperative Period

Orbital compartment syndrome is a rare condition which, if unrecognized or untreated, can lead to blindness.[8] The most common causes are traumatic or iatrogenic etiologies[9] and can range from a rapidly progressing space-occupying lesion to severe acute orbital vascular congestion. Several potential causes of an orbital compartment syndrome, such as mild retrobulbar hemorrhage, may be managed conservatively with serial ophthalmic examinations.[10] It is the *loss of function* that is the hallmark of the development of an orbital compartment syndrome that requires immediate intervention.[7]

Regardless of the etiology, the presenting symptoms of pain or pressure in the eye, decreasing vision, and diplopia should prompt further examination for objective signs of an orbital compartment syndrome. These include proptosis, afferent pupillary defect, increased intraocular pressure, and decreased eye movement. While there are no large published case series guiding when treatment should be initiated, the loss of vision when accompanied by the aforementioned signs and symptoms should prompt emergent intervention.[7]

The orbit is enclosed by bone on all sides except anteriorly, and any forward displacement is limited by the eyelid apparatus and the tethering of the optic nerve to the globe. As intraorbital pressure rises, ocular perfusion decreases, leading to ischemia. Multiple cranial nerves within the orbit may be compromised, including the optic nerve and the nerves controlling eye movement.

Once the diagnosis is made, emergent orbital decompression is warranted by performing a lateral canthotomy and inferior cantholysis.[7]

The objective of the procedure is to allow for additional forward movement of the orbital contents, not actual drainage of the hematoma. Decreasing the intraorbital pressure restores normal circulation and prevents further loss of vision. Visual recovery is possible if this procedure is performed in a timely manner.[7]

Orbital compartment syndrome after endoscopic sinus surgery is rare.[9] If signs are present intraoperatively (sudden proptosis, afferent pupillary defect, globe firm to palpation compared to the contralateral side), a lateral canthotomy and inferior cantholysis is indicated, followed by conversion to an external approach. If diagnosed postoperatively, nasal packing is removed and the head is elevated to allow for drainage, followed immediately by lateral canthotomy and inferior cantholysis prior to re-exploration of the operative site in the operating room.

History

1. History of present illness
    a. Progressively decreased vision and pain in the eye on the affected side
    b. Binocular diplopia (double vision present with both eyes open, resolves with closure of either eye)
    c. Trauma
        1) Retrobulbar hemorrhage
        2) Orbital emphysema
    d. Recent surgery in the face
        1) Retrobulbar anesthesia for ocular surgery
        2) Periorbital surgery that violates the orbital septum (i.e., lower eyelid blepharoplasty)
        3) Endoscopic sinus surgery
    e. Severe orbital congestion
        1) Orbital cellulitis with or without abscess formation
        2) Idiopathic orbital inflammation (rare)
    f. Contributing maneuvers that increase intraorbital pressure (Valsalva,

vomiting, coughing, sneezing)

2. Past medical history

   a. Predisposing factors

      1) Orbital lesions that may spontaneously hemorrhage, such as vascular abnormalities (orbital varix, lymphangioma, arteriovenous malformations)

      2) Inherited or acquired coagulopathies

      3) Uncontrolled hypertension

      4) Rarely: connective tissue disorders (vitamin C deficiency, Elher-Danlos type IV)

3. Medications

   a. Anticoagulants

Physical Examination

1. Proptosis

   a. Forward displacement of the globe may be difficult to assess in the setting of periorbital edema. It may be helpful to compare one eye to the other.

2. Decreased extraocular motility

   a. Usually diffuse

   b. Assessment may be made difficult secondary to periorbital edema. Make use of the corneal light reflex to check for any disconjugate eye movement.

3. Elevated intraocular pressure

   a. In the acute setting, a handheld tonometer is preferred for its portability and ease of use.

   b. In the awake patient

      1) Use topical anesthesia with ophthalmic drops such as proparacaine or tetracaine.

      2) Have the patient focus on a distant target to facilitate

cooperation (for sustained fixation and eyelid opening).

3) If the patient is unable to keep his or her eyelids open, manually retract the upper eyelid to the superior orbital rim, with care not to place pressure upon the globe.

c. Difficulty opening the eyelids secondary to eyelid edema

1) Roll the eyelid margin tangentially away from the globe with a cotton-tip applicator, again with care not to place pressure upon the globe.

2) To gain further access to the globe, a Desmarres retractor can be used to retract the lower eyelid inferiorly. This may further elevate the intraocular pressure transiently but can be helpful in attempting to examine extraocular motility and to check for an afferent pupillary defect.

d. Check the contralateral intraocular pressure as an in vivo control.

e. Note: Accurate assessment of intraocular pressure is ideal but may not be readily available in the emergent setting. In the setting of additional signs and symptoms of orbital compartment syndrome, in lieu of delays related to finding a tonometer, manual palpation of the globe may be sufficient. The affected eye will be firmer compared to the contralateral eye if the elevated intraocular pressure is severe enough. Increased resistance to retropulsion of the globe compared to the contralateral eye may also be elicited.

4. Afferent pupillary defect

a. Check in a darkened room.

b. Have the patient fixate on a distant target.

c. A bright, but concentrated, light source is repeatedly swung from the unaffected eye to the affected eye.

1) An afferent pupillary defect is present if initial dilation, instead of constriction, is seen in the affected eye in response to a direct light stimulus.

2) An absolute afferent pupillary defect is seen when direct light stimulus over the affected eye elicits no pupillary constriction in the affected eye, and there is no consensual constriction of the unaffected eye.

d. Note: While an afferent pupillary defect is the most objective finding of optic nerve compromise, the finding alone does not diagnose an orbital compartment syndrome. It is this finding in conjunction with the additional findings that helps secure this diagnosis.

Imaging

1. Computed tomography (CT) scan

   a. Is not required for diagnosis of orbital compartment syndrome,[7] but it is helpful in discovering the definitive etiology.

   b. Concerning signs include the following:

      1) Proptosis—forward displacement of the equator of the globe beyond the orbital rim

      2) Straightening of the optic nerve

      3) Tenting of the posterior globe

      4) Lack of these features does not rule out an orbital compartment syndrome, as it is an evolving process that may not be captured on initial imaging.

   c. Large floor and medial wall defects do not preclude the development of an orbital compartment syndrome.

Indications

- Emergent—orbital compartment syndrome
- Initial steps for the following:
  - Lateral or inferior orbitotomy
  - Advancing tissue for reconstruction of the lower eyelid
  - Horizontal eyelid tightening

Contraindications

- None—This procedure is considered a low-risk intervention, especially in the setting of permanent loss of vision without surgical treatment.

The onus on the surgeon is early suspicion, evaluation, and an urgent canthotomy and cantholysis.

Preoperative Preparation

1. Evaluation with by an Ophthalmologist—if available

2. Intravenous sedation if the patient is uncooperative and it can be provided in a timely manner

Operative Period

Anesthesia

- Inject local anesthetic with epinephrine into the lateral canthus, down to the periosteum of the lateral orbital rim and lateral 1⁄3 of the lower eyelid.
- Topical ophthalmic drops such as proparacaine or tetracaine are necessary to provide anesthesia for the awake patient prior to Betadine application.

Positioning

- The procedure is done with the patient in a supine position with the iris plane parallel to the floor.

Instruments and Equipment to Have Available

- Toothed forceps (such as Adson)
- Straight blunt-tipped scissors

Key Anatomic Landmarks

- Lateral canthal tendon

- The eyelids are fixated to the lateral orbital rim by the lateral canthal tendon.

- Inferior canthal crus (Fig. 153.1)
  - The lateral canthal tendon divides into a superior crus attached to the upper eyelid and the inferior crus to the lower eyelid.
  - The inferior portion of the lateral canthal tendon is palpable as a distinct corded entity along the inferolateral orbital rim between the eyelid skin anteriorly and the palpebral conjunctiva posteriorly.

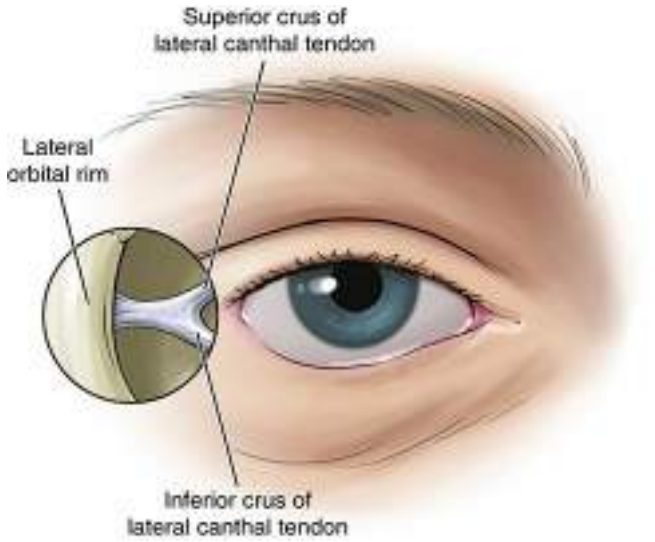

FIG. 153.1 The lateral orbital rim, the superior crus of the lateral canthal tendon, the inferior crus of the lateral canthal tendon.

FIG. 153.2 Scissors placed to perform a lateral canthotomy.

Prerequisite Skills

- Familiarity with the anatomy of the eye and eyelids

Surgical Technique

- Surgical approach
  - Sharp instruments should always be pointed away from the globe.
  - Resting one's hands upon the patient while operating may prevent inadvertent injury should the patient move during the procedure.
- Lateral canthotomy
  - The lateral canthus is incised for approximately one centimeter down to the lateral orbital rim. One blade of the scissors is inserted just inside the lateral canthal angle; one is placed on the skin. The tip of the internal blade should rest on bone (Figs. 153.2 and 153.3).
- Inferior cantholysis
  - Hold the lower eyelid anteriorly with toothed forceps (Fig. 153.4).
  - Retraction of the upper eyelid away from the lateral canthus is helpful but not always necessary.

FIG. 153.3 Lateral canthotomy incision.

FIG. 153.4 Toothed forceps holding the lower eyelid anteriorly, strumming the scissors along the inferior orbital rim between the skin and conjunctiva to find the tendon.

- Between the lower eyelid skin and inferior palpebral conjunctiva, palpate the inferior crus by strumming the scissors along the inferolateral orbital rim to find the tendon (see Fig. 153.4).
- After palpation of the tendon with the scissors, the distinct corded entity is incised. Several incisions may be necessary to completely release the lower eyelid.
- A superior cantholysis may be performed in a similar fashion with care to avoid the lacrimal gland given its propensity to bleed.
- These incisions proceed parallel to the orbital rim.
- Control any hemorrhage with pressure or bipolar cautery.

Common Errors in Technique

- Insufficient inferior cantholysis: The lower eyelid should be easily distracted from its attachment to the lateral canthus at the conclusion of the procedure (Fig. 153.5).
- Failure to use countertraction of the lower eyelid: Adequate and constant countertraction of the lower eyelid anteriorly with toothed forceps will place the inferior crus on traction, and the lower eyelid release will be felt in a graded fashion as each incision severs portions of the inferior crus of the lateral canthal tendon.
- Anticipating visual identification of the inferior crus: The inferior cantholysis is performed by palpation and of knowledge of eyelid anatomy.

FIG. 153.5 Laxity of the lower eyelid following lateral canthotomy and inferior cantholysis.

Postoperative Period

Postoperative Management

- Topical antibiotic ointment to the lateral canthotomy site for 1 week
- Serial examinations including measuring best corrected visual acuity, pupils, and intraocular pressure

- Eye pressure should be rechecked 30 minutes after the procedure.
- Failure to decrease the intraocular pressure below 30 mm Hg should prompt a superior cantholysis and possible intraoperative exploration for definitive treatment.

- Discontinuation of anticoagulants, reversal of coagulopathies, and treatment of uncontrolled hypertension if possible
- Patients with spontaneous, non-traumatic/non-iatrogenic, orbital hemorrhage without an orbital lesion/cause should undergo a systemic evaluation to rule out inherited or acquired etiologies of coagulopathies.

Complications

- Failure to completely sever the inferior canthal tendon
- Eyelid malposition, such as ectropion, can be corrected on an outpatient basis in the future.
- Injuries to the globe are rare and should be immediately recognized to prompt an ophthalmic evaluation and management.

Alternative Management Plan

While a multitude of adjunctive medical therapies have been described, such as systemic and topical intraocular pressure lowering agents and high-dose corticosteroids,[10] these measures are not immediate and should not delay surgical intervention. Patients at risk, but have yet to develop orbital compartment syndrome, may be conservatively managed with serial examinations, but these should be limited to cases with close collaboration with ophthalmology. Further decompression of the orbit in the operating room may be needed if these surgical and medical therapies fail to decrease the patient's intraocular pressure.

Discussion

Evidence-Based Medicine Question

What is evidence for performing a superior cantholysis after an inferior cantholysis?

While there are no large case series reporting the efficacy and need for a superior cantholysis after a lateral canthotomy and adequate inferior cantholysis is performed, Haubner et al. (2015) reported the intraocular pressure lowering effects of the procedures in a fresh-frozen cadaveric study. Eight orbits were injected with viscous material to simulate an orbital compartment syndrome. The range of intraocular pressures was from 30s to 80s after intraorbital injection. Seven orbits achieved a final pressure of less than 20 mm Hg with a lateral canthotomy and inferior cantholysis alone. The two orbits required an additional superior cantholysis to achieve a complete decompression, as described by the authors as a final intraocular pressure of less than 10 mm Hg.

Haubner F, Jägle H, Nunes DP, et al: Orbital compartment: effects of emergent canthotomy and cantholysis. Eur Arch Otorhinolaryngol 2015;272(2):479–483.

Editorial Comment

The "orbital compartment syndrome" is defined as an uncommon ophthalmologic surgical emergency characterized by an acute rise in intraorbital pressure, which may result in blindness. It is typically the result of facial trauma or a surgical procedure.

Lateral canthotomy is a brief but critical procedure for every otolaryngologist to be familiar with. Its use in emergency situations (increasing proptosis of any kind) and its place as the first step of other surgical procedures require careful rote memorization of the steps in this procedure and practice on a cadaver if possible.

Review Questions

1. Which of the following statements is false? Orbital compartment syndrome

   a. Can lead to permanent vision loss if untreated

b. Necessitates a prompt diagnosis to prevent delays in treatment

c. Is an indication for an emergent lateral canthotomy and inferior cantholysis

d. **Can be medically managed without the need for a lateral canthotomy/cantholysis**

2. Which of the following is not a potential cause for orbital compartment syndrome?

a. Fulminant sinusitis without signs of orbital inflammation on CT scan

b. **Cataract surgery with topical anesthesia only**

c. Thrombosis of an orbital varix

d. Sneezing after sustaining an orbital floor fracture

3. Which of the following signs should raise the suspicion of orbital compartment syndrome developing?

a. Symptoms of seeing flashing lights

b. **Sudden proptosis**

c. Monocular diplopia (double vision only present with the unaffected eye is closed)

d. Discharge from the eye

Orbital Exenteration

Tonya Stefko

Introduction

- The radical surgery of orbital exenteration is occasionally necessary in the management of cancer of the head and neck. For the Otolaryngologist, it will most frequently be due to the spread of a malignant tumor from the adjacent paranasal sinuses or the skull base. Some cancers arising in the skin will also require total or subtotal removal of the orbital contents. Invasive fungal infections are indications for aggressive débridement, sometimes including orbital exenteration. Rarely, a benign but locally aggressive tumor or intractable pain will be an indication.
- The most clear-cut indications for orbital exenteration are those involving malignant tumors with no hope of salvaging vision in the affected eye (Fig. 154.1). These situations most often include squamous cell carcinoma and other epithelial malignancies. In the largest reported series of orbital exenteration, squamous cell carcinoma (originating in the sinus, skin, or conjunctiva) accounted for one-third of exenterations.[1] A more recent series found basal cell carcinoma to be the most frequent diagnosis, followed by melanoma and sebaceous cell carcinoma.[2] Conversely, a review of 70 consecutive cases of maxillectomy found that 40% of these patients required concurrent orbital exenteration.[3] Imaging is likely to underestimate the extent of tumor invasion into the orbit, and the decision to proceed may need to be made in the operating room. The recent trend, particularly with squamous cell carcinoma, has been preservation of the orbit except in instances of proven invasion of the periorbita (by frozen section at the time of surgery). In several retrospective series there has been no difference in disease-free survival between patients treated with orbit-

sparing procedures and those whose surgery included orbital exenteration.[4]

FIG. 154.1 Patient with malignant melanoma destroying the globe, adnexa, and orbital contents.

- Malignant tumors of the orbit or eyelids, although not strictly invading the eye or periorbita itself, may require removal of the orbital contents because of insufficiency of the remaining tissue for protection of the globe (Figs. 154.2 and 154.3).
- Surgical decision making in the setting of aggressive infection is difficult. Most fungal infections of the orbit spread from adjacent sinuses, and two main types occur. Aspergillus affects both immunocompromised and immunocompetent hosts. In the former patients, the prognosis is extremely poor if the immune status cannot be improved and if intracranial involvement is present.[5] In the latter setting, exenteration is likely to be necessary in cases of apical involvement but not when the infection is confined to the anterior, inferomedial orbit,[6] where limited débridement may suffice.

FIG. 154.2 Advanced cutaneous melanoma of the eyelid with orbital extension.

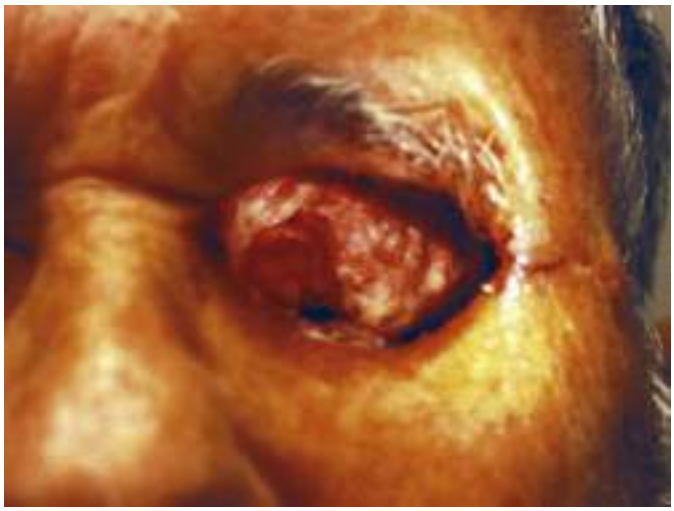

FIG. 154.3 Patient from Fig. 154.2, 12 days after exenteration with a split-thickness skin graft in the orbit.

- Rhino-orbital-cerebral mucormycosis is a rare but serious infection caused by *Rhizopus* species (occasionally *Mucor* or *Absidia*). It affects immunocompromised patients, most often those with a concurrent metabolic acidosis. These patients require aggressive surgical débridement to the level of bleeding tissue, with correction of the underlying medical abnormality. This has frequently included orbital exenteration in the presence of orbital signs, but one series revealed no difference in survival between patients with orbital involvement who

underwent exenteration and those who did not.[7] However, the overall mortality in patients with orbital involvement was higher (33% vs. 14%). The operation may be followed by hyperbaric oxygen therapy, which improves survival.[8] A recent review showed 12/14 patients with orbital involvement died of the disease, and the only two who survived had undergone orbital exenteration.[5]

- Three to 17% of patients requiring exenteration have benign orbital disease.[9] The various associated diagnoses include inflammatory disease, Stevens-Johnson syndrome, lymphangioma, meningioma, and others. These diseases are either painful, inadequately controlled medically, and "grossly disfiguring" or, although histologically benign, tend to invade adjacent tissue.[10] The pain associated with the disease most often resolves immediately after surgery.

Key Operative Learning Points

- In the practice of most Otolaryngologists, exenteration will be undertaken in conjunction with maxillectomy or during aggressive sinus débridement (e.g., for invasive fungal infection). During the informed consent process, if the decision whether to exenterate the orbit will be made at surgery, it must be made very clear to the patient and family that although every effort will be made to preserve the orbit and eye, this goal will not preclude complete eradication of disease.
- Total or subtotal exenteration should be planned. Subtotal exenteration most often means a partially lid-sparing technique (Fig. 154.4A), which is appropriate in most cases of benign disease and with tumors that primarily affect the posterior or deep portions of the orbit. It is inappropriate in any tumors affecting the skin, conjunctiva, or lacrimal gland. Lid-sparing exenteration gives an excellent color match to surrounding skin and heals relatively quickly. Globe-sparing exenteration has been described, with purported advantages of easier prosthetic fitting later.

FIG. 154.4 **A,** Patient with a sarcoma of the maxilla treated by maxillectomy. Recurrence in the orbit was treated with radiation therapy. The tumor recurred once again and destroyed the orbital contents. **B,** Computed tomography scan demonstrating invasion of the orbit and destruction of the bony orbital wall. **C,** Defect after orbital exenteration. **D,** Reconstruction with a rectus abdominis free tissue transfer.

Preoperative Period

History

- Complete medical history, with attention to:
  - Previous malignancy
  - Tobacco use
  - Infectious disease (human immunodeficiency virus [HIV], human papilloma virus [HPV])
  - Bleeding disorders

Physical Examination

- Complete examination of the head and neck focusing on:
  - Examination of the cervical lymph nodes
  - Nasal/sinus endoscopy, if indicated
- Before scheduling surgery, a complete ophthalmologic examination of the remaining eye is indicated both to guide surgical decision making and to maximize the remaining vision.

Imaging

- Patients who may be candidates for orbital exenteration should, at the very least, be evaluated by computed tomography (CT) or magnetic resonance imaging (MRI) (or both) of the orbits, sinuses (see Fig. 154.4), and brain. In the majority of cases that involve malignancy, positron emission tomography (PET-CT) is also indicated.
  - Patients with invasive fungal sinusitis may have minimal findings on imaging.
- When a neck dissection is anticipated, preoperative imaging of the neck and scintigraphy should be considered. The choice of imaging will be guided by the patient's diagnosis. In patients with malignancies contiguous with the orbit, it is likely that imaging will underestimate the extent of disease, and intraoperative histopathologic monitoring will be necessary.

Indications

- Malignant tumor of the lacrimal gland
- Patients with tumor invasion of the periorbita proven by frozen section examination
- Resection of most of the orbital floor frequently leads to loss of integrity of the eye because of dystopia, diplopia, or ocular surface problems. This may be compounded by postoperative radiation effects on the eye.

- Invasive fungal sinusitis with orbital invasion

Contraindications

- Patients with invasion of orbital bones only will probably have comparable survival if the orbital contents are spared.

Preoperative Preparation

- Before the operation, coagulation studies, a complete blood count with platelets, and typing and crossmatching of two units of packed red blood cells should be performed.
- In many instances, given the radical nature of the surgery, the pathology of the lesion should be independently confirmed by pathologists experienced in the field of head and neck or orbital disease.
- Reconstructive options should be considered before surgery.

FIG. 154.5 Patient 1 year after left orbital exenteration for adenoid cystic carcinoma arising in left maxilla,

reconstructed with an anterolateral thigh free flap.

- The simplest option is healing by secondary intention, or granulation. The advantages of such healing are shorter operating time, good color match to surrounding tissue, excellent visibility for monitoring of possible recurrence of disease, and a tendency to produce a shallow socket (easier for eventual patient care). Disadvantages include a long healing time and the necessity for several painful dressing changes.
- Split-thickness skin grafts, usually taken from the thigh, are frequently used to line the orbital cavity when total exenteration with removal of periosteum is performed (see Fig. 154.3). Although this leads to shorter recovery time and excellent visual monitoring for recurrence, a deeper cavity is formed, for which care and prosthetic fitting are somewhat more difficult. The pain encountered after this reconstructive option is generally from the donor site.
- Local or free tissue flaps are most commonly performed at our institution, particularly for defects resulting from concurrent partial or complete maxillectomy. Temporalis muscle, with or without cervicofacial, radial forearm, and rectus abdominis flaps (see Fig. 154.4), are most frequently mentioned. These flaps have the advantage of ample tissue and good vascularity, which is desirable in a field likely to require radiation therapy (Fig. 154.5). Disadvantages of longer operating time, donor site morbidity/disfigurement, and a requirement for highly specialized microsurgical techniques (in the case of free flaps) discourage their use in very sick patients. These options also render monitoring for local recurrence of disease more difficult.

Operative Period

Anesthesia

- General endotracheal anesthesia

Positioning

- Supine with vertex even with head of bed

Perioperative Antibiotic Prophylaxis

- cerebrospinal fluid (CSF) prophylactic dose (e.g., 2 g of cephalexin IV)

Monitoring

- Per anesthesia team

Instruments and Equipment to Have Available

- Suction
- Scalpels
- Monopolar cautery
- Bipolar cautery
- Curved enucleation scissors
- Snare
- Hemostatic agent
- Cottle elevator
- Dermatome if a split-thickness skin graft is planned

Key Anatomic Landmarks

- The frontoethmoidal suture is the level of the anterior and posterior ethmoid arteries and marks the level of the cribiform plate in most patients.
- The medial canthal tendon will be an area of dense adherence of tissue to bone and surrounds the lacrimal drainage system.

Prerequisite Skills

- Familiarity with orbital surgery

Operative Risks

- Bleeding requiring transfusion
- Postoperative infection
- Failure to control malignancy or infection
- Sino-orbital fistula
- CSF leak

Surgical Technique

- In the case of concurrent maxillectomy, that procedure is performed first.
- Surgical margins are marked (Fig. 154.6).
  - A suture tarsorrhaphy is usually helpful.
  - If the exenteration is to be a lid-sparing technique, an incision line several millimeters proximal to the eyelid margins and parallel to them is marked.
    - A scalpel is used to cut through skin and orbicularis muscle, and blunt dissection in the pretarsal/preseptal plane is then carried out to the level of the orbital rim.
    - The periosteum is incised, and the surgery proceeds as described in the following text.
- If the skin is to be included in the resection, the excision margins are drawn at the orbital rim and at least 1 to 2 cm from the cutaneous lesion (see Fig. 154.6).
- The marked areas may be infiltrated with local anesthetic with epinephrine to help with hemostasis.
- A no. 15 blade is used to make an incision through skin down to the periosteum. Bleeding from the supraorbital vessels should be expected.
- The periosteum is elevated with a Cottle or Freer elevator, beginning at

the superotemporal portion of the orbit where the bone is thickest.

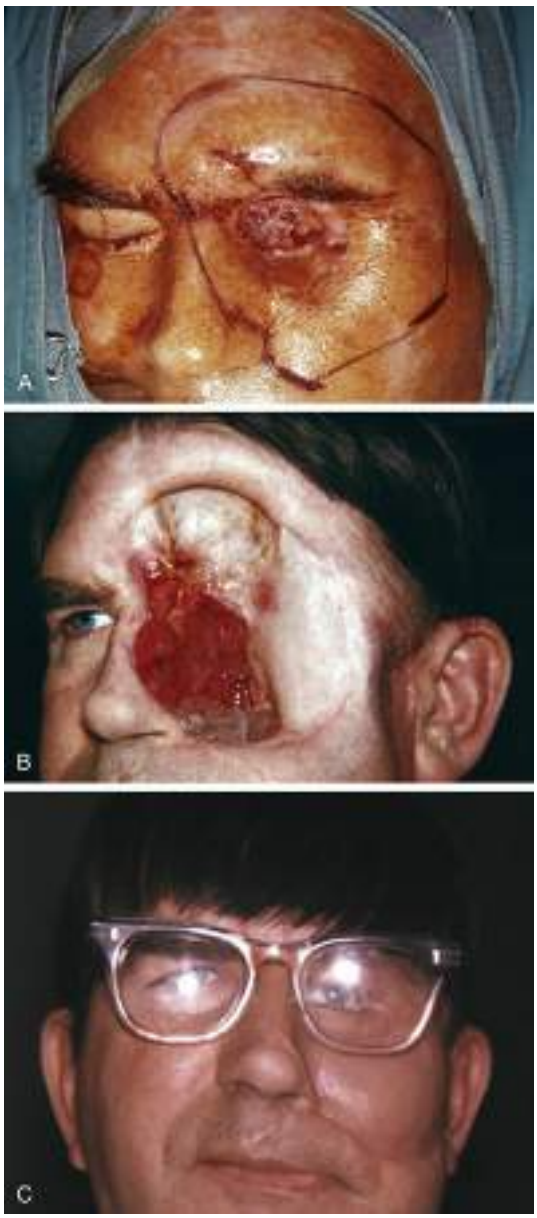

FIG. 154.6 **A,** Patient with recurrent basal cell carcinoma in a previously exenterated orbit. **B,** Postoperative defect lined with a split-thickness skin graft. **C,** Postoperative appearance with a prosthesis and glasses.

- Dissection in this plane continues circumferentially and posteriorly, with cautery of the zygomaticofacial and zygomaticotemporal vessels encountered in the lateral wall.
- Resistance will occur in the area of the trochlea (superomedially) and

at the canthal ligaments and may require sharp dissection in these areas.

  - The posterior limb of the medial canthal tendon should be elevated off the bone, and the lacrimal sac should be divided at its junction with the nasolacrimal canal.
  - The inferior oblique muscle originates just lateral to the sac and should be elevated with the periosteum.

- Dissection proceeds posteriorly toward the apex of the orbit.
- Special care should be directed to the following areas:
  - Elevation of the periosteum over the lamina papyracea must be carried out very gently so that no dehiscences are created in the bone.
  - The ethmoidal vessels must be divided and the bleeding controlled with bipolar cautery and bone wax.
  - Areas of the roof, particularly posteromedially, are often quite thin or contain frank dehiscences.
- The contents of the superior and inferior orbital fissures and the apical stump must now be divided, which may be accomplished with a curved knife, curved enucleation scissors, or a snare. The latter is tightened to a soft stop and tightened sequentially over a period of several minutes to assist with hemostasis. The snare may then be tightened completely to transect the apical stump, or curved scissors may be used to cut just anterior to it.
- The orbit should immediately be packed with gauze and pressure applied for 5 to 10 minutes.
- The apex should then be explored cautiously with suction and bipolar cautery to localize and control any bleeding.
- If the orbit is to heal by granulation, it should be lined with a nonadherent dressing such as Telfa followed by Xeroform gauze, packed with fluffed gauze, and bandaged tightly. A small pledget of cellulose (Surgicel) or other hemostatic agent may be placed over the apical stump.
- It may be possible in some patients to preserve the eyelids. After a skin

graft has been placed in the orbit, the margins of the eyelid are sewn together to provide a good appearance or at least a better appearance than if the orbit were open to view.

- If the skin of the lid has been spared, it is draped over the rim and spread posteriorly as far as possible. The remainder of the orbit may be left to granulate or may be covered with a split-thickness skin graft. If a split-thickness graft is used, it is harvested from a non–hair-bearing area of the inner surface of the thigh or the abdomen, and the donor site is covered with an adherent dressing. Dimensions of the graft are approximately 5 × 10 cm before meshing. The graft is carefully draped into the orbital cavity, with care taken to ensure that the epithelial side remains exterior. The graft is sutured in place at the rim with interrupted 7-0 chromic gut or silk suture. The wound is then dressed as discussed earlier.

- If a local or free flap is to be used for reconstruction, it is prepared and placed as dictated by the specific procedure. Fig. 154.5 shows a young patient one year after maxillectomy, radiation, and orbital reconstruction with lateral thigh free flap (he has declined further contouring of the tissue). The patient in Fig. 154.4A underwent a maxillectomy for sarcoma of the maxilla. A recurrence was treated with radiation therapy. The tumor recurred once again and destroyed the orbital contents and the orbital wall. The orbital defect was reconstructed with a rectus abdominis free tissue transfer.

- When flap reconstruction is not used, the pressure dressing remains undisturbed for 3 to 5 days. During this time the patient should have antibiotic coverage. After this time, the pressure dressing is gently removed, and the area is soaked with saline. After 5 to 10 minutes, the lining layer (nonadherent dressing such as Telfa or Xeroform) may be gently loosened from the underlying tissue. Minimal débridement should occur at this stage because areas of skin that appear devitalized may heal surprisingly well. The area is coated lightly with antibiotic ointment, and the patient and family are instructed to repeat the application of ointment twice daily. Ointment should also be applied to the light dressing placed over the orbit to prevent adherence. Vigorous cleaning of the area should be avoided.

- Rotation of a temporalis muscle flap (or its anterior half) through a defect created in the lateral orbital wall (either by removing the rim or

drilling through the wall) can be used to create a shallower cavity. If the anterior half is used, the posterior half may be moved forward to prevent temporal hollowing.

- The muscle is draped into the defect, sutured loosely in place with interrupted absorbable sutures, and either left to granulate, or the remaining lids are draped over it anteriorly.

Common Errors in Technique

- It is posteromedially that an iatrogenic cerebrospinal fluid leak may be created, either by direct trauma or by the use of monopolar cautery, which may travel through emissary foramina or dehiscences. Monopolar cautery should be avoided except in the anterior-most portion of the orbit.
- Sino-orbital fistulae most commonly occur in the area of the lamina papyracea.

Postoperative Period

Postoperative Management

- The patient is examined in the office 1 week postoperatively and then at regular intervals afterward as dictated by the healing process and the disease. Weekly or biweekly visits are appropriate in the first 4 to 6 weeks for cleaning of the socket and monitoring for infection. In most cases in which radiation therapy is not necessary, the patient is ready for prosthesis fitting in 3 months (see Fig. 154.6).
- Aggressive débridement of skin grafts early in the postoperative period is to be avoided.
- It has been reported that most patients are likely to wear an occlusive eye patch regardless of attempts at reconstruction. Prostheses may be fashioned by a prosthodontist and may be affixed by topical adhesive. Alternatively, prostheses may be fixed with magnets to osseointegrated implants.

Complications

- Intraoperative bleeding
  - Packing and pressure
  - Prothrombotic agents applied to the orbital apex
  - Transfusion of packed red blood cells if necessary
- Postoperative hematoma
  - Postoperative hematoma requires therapy if it occurs under a skin graft or in a free flap. The former may be drained by making a small incision in the graft, gently evacuating the hematoma, and then replacing the pressure dressing for 2 to 5 days. If this compromises perfusion of a free flap, the patient should be taken to the OR urgently for exploration.
- Postoperative infection
  - Must be vigorously treated with intravenous and then oral antibiotics, with judicious surgical débridement of devitalized tissue or drainage of purulent collections as needed
- Dehiscence of the surgical wound
  - Dehiscence of the surgical wound should raise suspicion of infection, which must be treated aggressively before considering secondary repair.
- Free flaps must be monitored carefully by Doppler ultrasound to ensure patency of the artery and vein, and a pressure dressing is contraindicated.
- Fistulas resulting from orbital exenteration may communicate with either the sinuses or dura.
  - If a bone or dural defect is noted intraoperatively, it should be repaired.
  - If the orbit is to heal by granulation or a skin graft is used, a small flap of extraocular muscle and adipose tissue may be spared and used to cover either the bone window or the dural repair.

Alternative Management Plan

- When tumor involves both orbital apices, other palliative options should be sought.

Discussion

Evidence-Based Medicine Question

Does orbital exenteration increase survival in patients with orbital malignancy?

A recent meta-analysis of the available literature assessing survival in patients with sinonasal malignancies involving the orbit suggests that patients in whom the orbit was not exenterated have a very slight increase in 5-year survival. However, their 95% confidence intervals evenly straddled an effect of 1 (i.e., no difference between the groups). The experience of one group with orbital exenteration for ethmoid malignancies finds it is mandatory to exenterate the orbit in cases where the invasion goes beyond periorbita, both for local control and for survival. The authors distinguish three grades of orbital invasion: invasion of the lamina papyracea, invasion of periorbita beyond the lamina, and invasion of the medial rectus, optic nerve, globe, or skin. In cases of maxillary SCC, a retrospective report of 139 patients showed that those with orbital invasion who were treated with orbit-preserving surgery had no difference in survival from those treated with radical surgery. All of their patients had undergone preoperative radiotherapy. Another more recent analysis seems to agree that sparing the orbit is indicated in those cases where invasion only involves the bony walls of the orbit or is confined to the periorbita (periorbita may be sampled by frozen section at surgery but adipose tissue cannot). They caution, however, that with massive invasion of the orbit (beyond orbital adipose tissue), it is not appropriate to spare the orbital contents and that in cases involving orbital adipose tissue, the limited resection should be undertaken only by experienced surgeons.

Editorial Comment

This chapter provides a comprehensive review of the use of orbital exenteration for infectious and neoplastic pathologies. An orbital exenteration has profound implications for the patient's quality of life especially in the psychologic and psychosocial domains. Therefore, it deserves careful consideration and surgical confirmation of imaging findings. Despite multiple attempts to clarify and better define its oncologic indications, controversy abounds. Nonetheless, as pointed out in this chapter, the current literature supports some important conclusions. Patients with tumors invading the bony orbit but sparing its soft tissues do not require an exenteration, as their oncologic outcome seems unaffected by the orbital preservation. However, it is important to recognize that anatomic preservation does not equate a functioning eye. Orbital function in these patients ultimately depends upon the adequacy of the reconstruction, need for postoperative adjunctive radiation or chemoradiation therapy (type of radiation, fractionation, and total dosage and extent of the field of treatment are important considerations), and the presence of concurrent cranial nerve VI or VII deficits. Performing an orbital exenteration to avoid a potential future complication is a complex and arguable decision that requires a very extensive and candid discussion between the patient and surgeon.

Conversely, patients with tumors that invade the orbital soft tissues may benefit from an orbital exenteration as long as the tumor can be cleared completely at all other locations. Its association with poorer outcomes is likely the result of tumors that are more aggressive. Periorbita is a formidable barrier; thus, a tumor rarely transgresses it. Nonetheless, to which degree the soft tissue must be invaded to constitute an absolute indication for an orbital exenteration is a highly contentious issue and varies according to the histopathology as well as the aforementioned functional issues. Correspondingly, an orbital exenteration for benign tumors must have a clear palliative value such as control of intractable pain.

Review Questions

1. Orbital exenteration is not indicated in which of the following

situations?

a. Rhinocerebral mucormycosis

b. Invasion of the orbital floor by squamous cell cancer of the maxillary sinus

c. **Capillary hemangioma involving both lids and the extraconal space**

d. Imaging evidence of frank invasion of the medial rectus muscle in the setting of an ethmoid tumor

2. The safest way to establish hemostasis of the apical stump in an orbital exenteration is by using monopolar cautery to divide the optic nerve at the annulus of Zinn.

a. True

b. **False**

3. Areas of greatest adherence of periorbita to bone include

a. The lacrimal gland fossa

b. **The trochlea**

c. The orbital floor

d. The zygomaticofacial neurovascular bundle

Rhinoplasty and Surgery of the Nasal Valve

Summit Kundaria, Paul Leong, and Benjamin W. Light

Introduction

Rhinoplasty includes functional, cosmetic, and reconstructive surgery to address the function and appearance of the nose. Functionally, the airway begins at the nostril, and issues such as static or dynamic collapse (collapse on inspiration) may present at the level of the external or internal nasal valve.[1,2] The nose is the central facial aesthetic unit that is divided into nine subunits, and its structure has a great impact on an individual's overall appearance. The anterior projection of the nose on the face makes nasal reconstruction an art that combines the functional and aesthetic aspects of rhinoplasty. True mastery of rhinoplasty, with all its aesthetic and functional nuances, requires a long learning curve and the dedicated focus of a developing surgeon.

Key Operative Learning Points

- For cosmetic rhinoplasty, the patient's motivations and expectations from surgery must be carefully explored. A realistic patient with sensible expectations is the foundation for a positive outcome.
- Patients with functional complaints may be best managed with concurrent septoplasty and inferior turbinate reduction.
- Altering the relative lengths of the medial crura and lateral crura will have predictable effects on nasal rotation and projection.
- All rhinoplasty should be performed with careful consideration of the aesthetic and functional consequences of the surgical manipulations being carried out.

Preoperative Period

Careful evaluation of patient motivations for surgery is critical to surgical success, as unrealistic goals or aesthetic alterations that are not surgically feasible should be discussed beforehand. Managing patient expectations is critical to the preoperative and postoperative course. A detailed anatomic evaluation of the patient's nasal anatomy including a full facial evaluation must be carried out.

History

History of Present Illness and Past Medical History

- Motivations for surgery
- History of prior nasal surgery or trauma
- Presence of nasal obstruction and, if it is present, at rest or with inhalation (static vs. dynamic collapse)
- Presence of anosmia
- History of easy bleeding or bruising
- Patients should be screened for psychiatric disorders at the surgeon's discretion.

Medications

- Antiplatelet and anticoagulants should be discontinued for 2 weeks preoperatively, as medically indicated.
- Patients should all be screened for over-the-counter and herbal medications that may increase bleeding risk, such as high-dose fish oil.

Physical Examination

- A complete examination of the head and neck should be carried out, with particular attention to the external nasal anatomy.

- The height of the nasion and rhinion should be noted, as well as the relative lengths of the nasal bones to the cartilaginous midvault.
- The nasal bones should be palpated for irregularity and signs of prior trauma.
- The thickness of the skin should be noted.
- The shape of the medial crura and lateral crura should be noted, as well as their relative support.
- The nasal-columellar relationship should be noted, as should the nasal projection.
- The tip should be evaluated for bulbousness, and the cause of this should be investigated (thick skin vs. shape of cartilaginous skeleton).
- The base of the nose should be evaluated for the shape and symmetry of the nostrils.

- Patients with nasal obstruction should have an endoscopic nasal examination to visualize the anatomic cause of obstruction, as the entire septum and inferior turbinates should be evaluated for deviation and hypertrophy, respectively.
- Examination of the patient during nasal inhalation (at a normal inhalation excursion and at a slightly elevated excursion) to evaluate for static and dynamic collapse of the internal and external nasal valves

Imaging

Any imaging that the patient had prior to consultation should be reviewed for bony anatomy and evidence of trauma, but imaging is not typically ordered when considering rhinoplasty alone. A full panel of rhinoplasty photographs should be taken, including frontal, oblique, basal, lateral, and lateral smiling.

Indications

- Improving the appearance of the nose

- Improving nasal obstruction from static or dynamic collapse of the internal or external nasal valve[3]
- Reconstruction after trauma or resection of cancer

Contraindications

- Medical comorbidities that would increase the risk of anesthesia or postoperative bleeding
- Unrealistic patient expectations or psychologic disorders that would place the patient at higher risk of postoperative dissatisfaction
- Active chronic nasal vasoconstrictor (rhinitis medicamentosa) use can increase the risk of intraoperative bleeding and interfere with the ability to use vasoconstrictors intraoperatively for hemostasis.

Preoperative Preparation

- Patients should be counseled about the postoperative care, including activity limitations, nasal rinses, and care of the nasal splints, if used.
- Expectations of improved appearance and function should be discussed, as well as the likely presence of palpable asymmetries and irregularities that may not be visually perceptible.
- General health clearance if necessary

Medication restriction list, including anticoagulants, should be reviewed with the patient 2 weeks prior to the procedure.

Operative Period

Anesthesia

- Although rhinoplasty may be done with local anesthesia, sedation, or general anesthesia, the latter is the preferred method because of patient comfort and control of the airway in the case of severe epistaxis.

Positioning

- The patient is positioned supine with both arms tucked to allow the surgeon and assistant easy access to the facial area.

Perioperative Antibiotic Prophylaxis

- A single dose of IV antibiotic that covers skin flora (usually weight-dosed cephazolin if the patient is not allergic to penicillin) is given prior to the first incision.

Monitoring

- No special intraoperative monitoring is necessary for rhinoplasty alone.

Instruments and Equipment to Have Available

- Septorhinoplasty set
- Osteotomes (straight and curved, guarded)
- Rasps
- Freer elevator
- Converse scissors

Key Anatomic Landmarks

- Glabella
- Nasion/radix
- Rhinion
- Supratip
- Tip

- Infratip lobule
- Anterior septal angle
- Posterior septal angle
- Head of inferior turbinate
- Septum (cartilaginous and bony)
- Nasal bones
- Upper lateral cartilages
- Lower lateral cartilages
- Maxillary spine
- Nasal-columellar angle

Prerequisite Skills

- Septoplasty

Operative Risks

- Patient dissatisfaction with aesthetic result
- Nasal valvular collapse due to interrupted support mechanisms
- Scarring leading to airway blockage or unacceptable appearance
- Postoperative epistaxis
- Septal perforation
- Anosmia
- CSF leak

Surgical Technique

- Anesthesia
  - After the induction of general endotracheal anesthesia, the patient is positioned with the head of the bed turned 90 degrees and with both

arms tucked so that the surgeon and assistant can both be at the patient's side without being limited by the patient's arms.

- It is important to secure the patient's endotracheal tube in a way that does not distort the anatomy of the upper face and lip, as these landmarks are used throughout surgery to assess the patient's nose.
- The patient's entire face is cleaned with ophthalmic betadine, and the patient is draped so that the entire face is visible.

- Local anesthesia
  - Open rhinoplasty begins with injection of local anesthesia into the planned incision sites and areas to be undermined.
  - A 1:1 mixture of 1% lidocaine and 0.5% Marcaine 1:100,000 with epinephrine is typically used. In the case of open rhinoplasty, this includes the transcolumellar incision, marginal incisions, and in the subcutaneous plane throughout the skin-soft tissue envelope and osteotomy sites.
  - If septoplasty is to be done concomitantly, then injection of the local anesthetic into the mucosa of the septum is also carried out.
- "Opening" the nose
  - The skin overlying the caudal margins of the lateral crura are first incised, followed by sharp dissection with converse scissors over the superficial aspects of these lateral crura to create pockets medial to the incisions, toward the nasal tip, as illustrated in Fig. 155.1.
  - The transcolumellar incision, usually designed as a "gull-wing" configuration as seen in Fig. 155.2A, is carried out with a scalpel through skin only, ensuring that the medial crura are not injured. This incision is extended horizontally past the flare of the medial crura and then vertically toward the dome as seen in Fig. 155.2B, paralleling the course of the caudal margin of the lower lateral cartilages.
  - The skin is elevated over the medial crura with converse scissors inserted at the vertical aspect of one incision and aimed in a subcutaneous plane toward the contralateral vertical incision as seen in Fig. 155.3.
  - Once this tunnel is finished, the deep aspect of the transcolumellar

incision can be completed. The columellar artery often needs to be cauterized at this point, and then sharp dissection with scissors resumes to follow the caudal margins of the medial crura, as seen in Fig. 155.4A, to the nasal tip and to connect this flap to the previously dissected tunnels overlying the lateral crura.

- Sharp dissection is used to continue to elevate the soft tissue flap toward the nasion as seen in Fig. 155.4B, identifying the upper lateral cartilages and ensuring that dissection is carried out superficial to these as well as the nasal bones.
- Once the nasal bones are identified, sharp dissection is continued in the subperiosteal plane to the nasion. Hemostasis can be achieved by bipolar cautery or pressure but is usually not necessary unless dissection was carried out laterally into branches of the angular artery anastomosis.

FIG. 155.1 The marginal incision is made just caudal to the lateral crus and dissection followed on the superficial surface.

- The medial crura are retracted laterally, and the plane between them is sharply dissected to identify the caudal septum. Subperichondrial planes are identified on each side of this, and these flaps are raised bilaterally past the bony-cartilaginous junction. This approach can be used for the septoplasty and is especially useful in cases of severe deviations of the caudal septum causing nasal vestibular stenosis.
- In cases of lesser deviation of the septum, lack of caudal septal

deviation, and when extra-corporal septoplasty is not indicated, a simple hemitransfixion incision may be more appropriate for a septoplasty.

- The attachments of the upper lateral cartilages to the septum are identified in a submucosal plane and are transected sharply, taking care to not injure the nasal mucosal lining.
- The nasal skeleton is now opened, and the septal cartilage is available for harvesting grafts, and the previously identified goal of surgery is addressed. We will now divide the nasal skeleton into thirds from superior to inferior and outline manipulations that can affect the appearance and function of the nose.

- Upper third
  - The bony upper third of the nose consists primarily of the nasal bony pyramid. In cases of a deficient projection of bony pyramid, grafting can be carried out with autologous cartilage with or without muscle fascia or perichondrium to augment the nasion.
  - Such maneuvers move the nasion superiorly, which can add balance to a nose that appears too short because of a low nasion.
  - More commonly, the nasal bones need to decrease in projection, in the case of dorsal hump removal. The hump typically has cartilaginous and bony components, with the cartilaginous hump resected sharply as shown in Fig. 155.5 and the bony aspect commonly addressed with osteotomies.
  - The osteotomies commonly used are shown in Fig. 155.6.
  - A dorsal osteotomy is carried out with care taken to have the plane of the osteotome in a path that leaves the remaining nasal bones of equal height as shown in Fig. 155.7.
  - Once the bony hump is removed, the patient is left with an "open roof," that is, lateral nasal bones with a flat, open dorsum without bony covering. Unless the nasal bones are medialized with lateral osteotomies, the patient can be left with an open roof deformity.

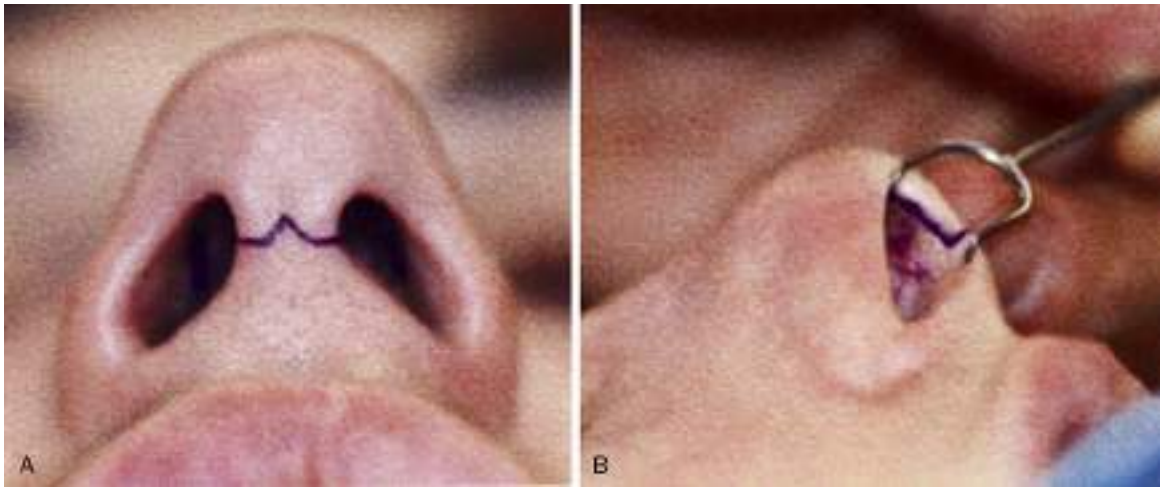

FIG. 155.2 **A,** Design of a transcolumellar incision. A five pointed "gull-wing" design is used. **B,** View of the lateral aspect of the transcolumellar incision.

- The lateral osteotomies are carried out by engaging an osteotome to the pyriform aperture, usually on the ascending process of the maxilla at the level of the lateral attachment of the inferior turbinate. It helps to mark the patient's path of the osteotomy on the skin for an inexperienced surgeon so that both sides can be done symmetrically.
- Fig. 155.8 demonstrates the technique often followed for an appropriate lateral osteotomy. The High-Low-High technique is followed in the execution of this maneuver. The terminology "High-Low-High" can be confusing and merits more detailed discussion.
  - Starting "High" on the pyramidal aperture above the root of the inferior turbinate allows for the preservation of a triangular segment of maxillary bone that respects the ligamentous lateral suspensory attachment extending from the distal lateral crura.
  - Preserving this relationship avoids potential medialization of the lateral confine of the nasal valve. Preceding "Low" or posterior on the ascending process of the maxillary bone allows for the majority of the length of the bone incision to approximate the nasofacial junction under relatively thick lateral nasal skin.

FIG. 155.3 The transcolumellar incision is completed sharply with the tissue scissors, making sure to stay superficial to the medial crura.

- More anterior osteotomies proceed through thinner bone (less structurally viable) and may be more easily palpable through thinner medial nasal skin.
- The "High" end point of the osteotomy follows an anterior apex curvature. This allows the more predictable set point of the "back fracture" (illustrated with a perforated line in Fig. 155.8) required to allow medial mobilization of the nasal sidewall segment.
- The apex of the osteotomy is terminated at the level of the medial canthus so as to prevent a "rocker" deformity protrusion of anterior margin of the bone at the superior fracture sight.

- Most often this osteotomy is performed through the endonasal approach to avoid potential external visible puncture trauma/scar potentially associated with percutaneous osteotomy techniques. The percutaneous osteotomy technique has advantages when dealing with severe upper third nasal deformities where extensive dorsal osteotomy work is necessary to mobilize old fractures.
- Once the bones are medialized adequately, gentle contouring can be carried out with a fine rasp in order to smooth any bony irregularities, as the skin in this region is thin and patients tend to notice bony asymmetries for this reason. A patient who underwent a dorsal hump removal is shown in Fig. 155.9.

- Middle third
  - The middle third of the nose consists primarily of the upper lateral cartilages and their attachment to the septum.
  - During open rhinoplasty, the cartilaginous septum is readily accessible to contour to the patient's desired look. This maneuver should be done with care, as over-resection of the dorsal septum can lead to functional and cosmetic issues. If there is any twisting or deviation of the dorsal septum in this area, it should be addressed.
  - A common intervention in the middle third of the nose is grafting, namely, spreader grafts. These long, flat grafts typically made out of septal or auricular cartilage provide dorsal support to the middle vault and prevent or treat middle vault collapse. They serve a functional goal of preventing or treating collapse of the internal nasal valve, as well as a cosmetic goal of preventing an inverted "V" deformity, which is a mismatch of width between the bony and cartilaginous dorsum.

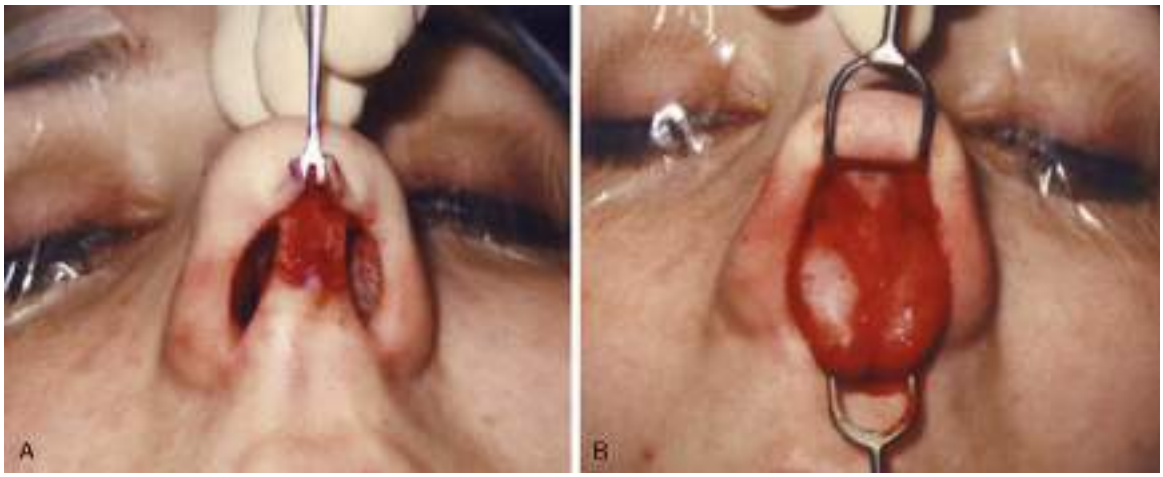

FIG. 155.4 **A,** The skin envelope is retracted while sharp dissection is used to elevate the skin envelope from the tip cartilages. **B,** Inferior retraction of the nasal tip cartilages aids in dissection toward the nasion.

  - Spreader grafts are versatile, as they can be carried out symmetrically for the reasons above or asymmetrically to treat a deviated dorsal septum. They are typically secured in place using three separate interrupted horizontal mattress sutures to prevent

any shifting or twisting of the grafts, as any movement would be visible or palpable to the patient.

FIG. 155.5 Once the skin envelope has been elevated, a dorsal resection can be carried out with the scalpel or scissors, based on surgeon preference. Shown is the technique with the angled Foman scissors.

FIG. 155.6 Shown are the curved left and right osteotomes *(above)* and the straight Rubin osteotome.

FIG. 155.7 A Rubin osteotome is used to carry out the dorsal osteotomy.

- After spreader grafts are placed, the upper lateral cartilages are typically secured to them in their native position, using interrupted horizontal mattress sutures.
- A variation of spreader grafts using cartilage harvested from elsewhere is to perform turn-in flaps using native upper lateral cartilage. In this case the portion of the upper lateral cartilage that otherwise would be resected to reduce the height of the cartilaginous dorsum is scored and "turned-in" before reattachment to the dorsal aspect of the septum.
- This approach can provide a stable reinforcement of the midvault of the nose, without requiring cartilage from elsewhere in the nose or ears.

- Lower third
  - The lower third of the nose is a complex structure that includes the nasal tip and caudal portion of the septum. It is typically seen as a tripod with the paired medial crura as the inferior leg and two superolateral legs consisting of each lateral crura.
  - Any manipulation of the length of any leg of the tripod will have a predictable effect, such as increasing rotation (shortening the lateral crura) or decreasing tip rotation (shortening the medial crura). One must keep in mind that the lower lateral cartilages can have a high degree of asymmetry, irregular curvatures in the areas of the domes, and variable orientation, despite a somewhat symmetric appearing

external nose.

- This is mentioned because manipulations of the lower lateral cartilages can give a wide variety of effects that must be taken with care as to not give an undesirable aesthetic or functional effect, with the most common functional issue being static or dynamic collapse of the external nasal valve due to removal of its support.
- Manipulation of the nasal tip can disrupt the major and minor tip support mechanisms.
- Major tip support mechanisms

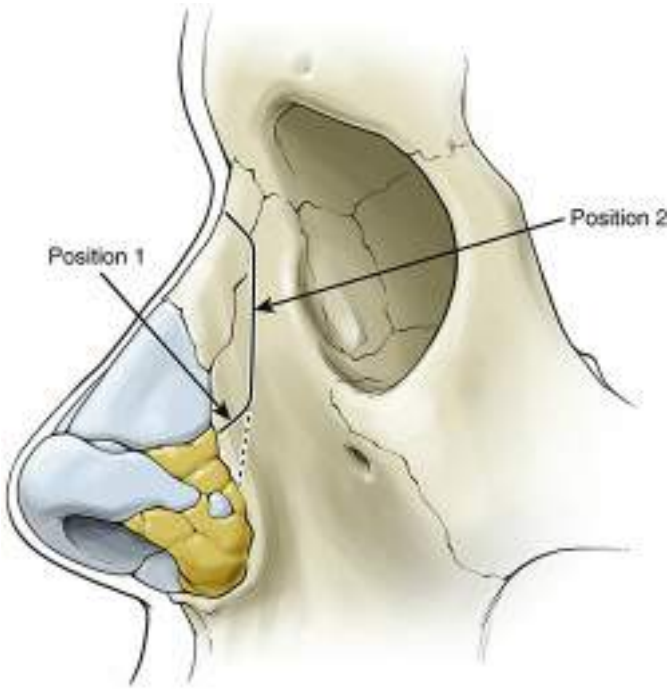

FIG. 155.8 Demonstration of the High-Low-High lateral osteotomy technique. The angle of approach for the first segment of the osteotomy is demonstrated at position 1. The incision is then angled superiorly along the nasofacial junction as noted in position 2. Adapted from Larrabee WF Jr. Open rhinoplasty and the upper third of the nose. Facial Plast Surg Clin North Am 1993;1:23–38.

FIG. 155.9 Shown are preoperative *(left)* and postoperative *(right)* pictures of the lateral view, **A,** and base view, **B,** of a patient after rhinoplasty consisting of a dorsal reduction and deprojection.

  - Strength of the lower lateral cartilage
  - Attachment of the medial crura to the septum
  - Attachment of the upper lateral cartilage to the lower lateral cartilage
- Minor tip support mechanism
  - Dorsal septum
  - Intermodal ligaments
  - Membranous septum
  - Nasal spine
  - Surrounding skin and soft tissues
  - Alar sidewalls
- A cartilage-sparing set of manipulations to first consider is altering

the relative lengths of the lateral crura and medial crura.

- Lateral crural steal is when the lateral crura are recruited into the tip with horizontal mattress sutures, making the medial crura relatively longer and lateral crura relatively shorter, which increases tip projection. Similarly, the medial crura can be recruited to the lateral crura for the opposite effect.
- The manipulations of the nasal tip are numerous due to its anatomic complexity, with some of the more common maneuvers described below.
  - The lateral crura can be trimmed at the cephalic margins to decrease the bulbousness of the nasal tip as shown in Fig. 155.10. In addition to shaping the tip, the cephalic trim maneuver can increase rotation. Calipers are used to measure the amount of native cartilage left to prevent over-resection.

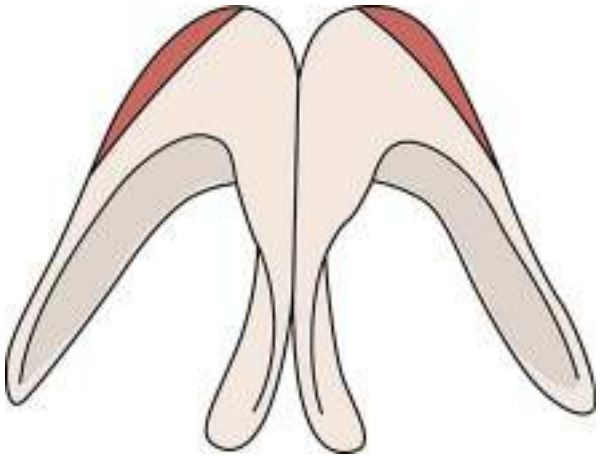

FIG. 155.10 The red areas show the resected portion of the lateral crura in a conservative cephalic trim. This can help refine the appearance of the nasal tip.

  - The tip can also be refined by domal suturing, using horizontal mattress sutures in each dome to change its contour as shown in Fig. 155.11.
  - The domes can also be divided and reapproximated in a configuration that gives the surgeon an intended look, with an example of this illustrated in Fig. 155.12.

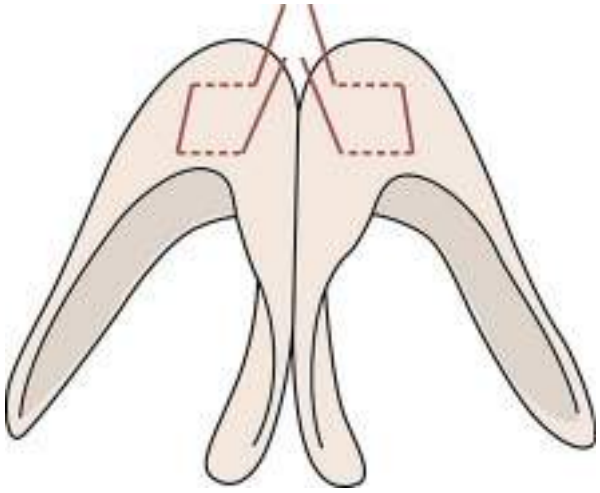

FIG. 155.11 Depicted are horizontal mattress transdomal sutures to narrow the nasal tip.

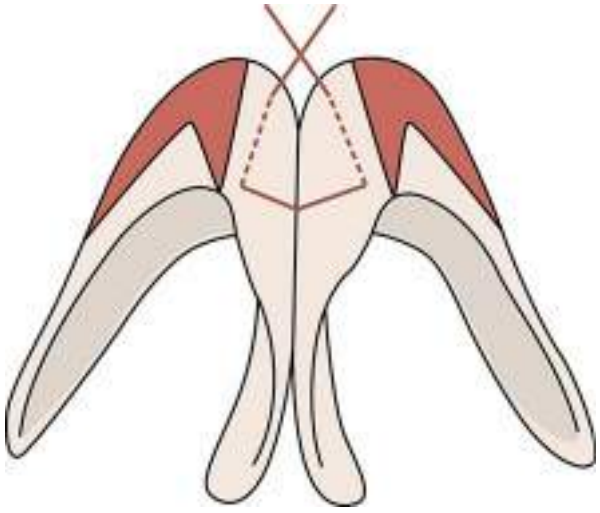

FIG. 155.12 A vertical dome division is carried out with a cephalic trim and reconstructed with interdomal sutures and reapproximating the lateral crura to the tip cartilages. This serves to narrow a “boxy” tip.

- The lateral crura can also be divided overlapped, and sutured in place as a cartilage-sparing maneuver that decreases the length of the lateral crura as depicted in Fig. 155.13.
- A similar overlapping technique can be used with the medial crura. By combining the overlapping technique of the medial and lateral crura, the surgeon can exercise control over both the degree of rotation and projection simultaneously. Care must be taken to

not excessively destabilize the tip with more extensive maneuvers.[4]

- The lateral crural strut graft is a technique for reshaping and repositioning the lateral crura. This graft is composed of a strip of autogenous cartilage sutured to the under surface of the lateral crura. Lateral crural struts can be used to improve a boxy nasal tip, malpositioned or excessive cephalic lateral crura, rim retraction, and concave lateral crura.
- If external nasal valve collapse is compromising the patency of the nasal airway, lateral crural strut grafts can be a useful approach to rehabilitate this area.
- Lastly, cartilage grafting can be used between the tip and the soft tissue envelope to sculpt the tip and infra-tip while helping mask irregularities in the cartilaginous skeleton.

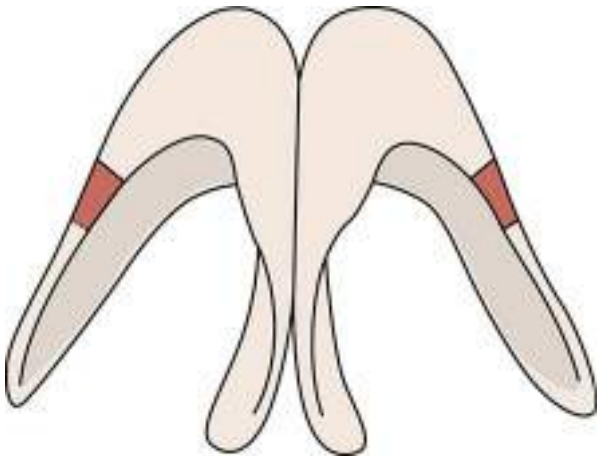

FIG. 155.13 The lateral crural overlay is depicted here with the red areas showing the area of overlap.

- Another powerful tool at the surgeon's hands is septal extension grafting, which is a cartilage graft that overlies the caudal septum and extends between the medial crura.[5]
- By affixing the lower lateral cartilage to the septal extension graft, the surgeon can alter the projection and rotation in virtually any fashion desired.
- This can be done to move a deviated septum toward the midline

(placing a left-sided graft on a right-deviated caudal deviation) and serves the purpose of supporting the tip with cartilage.

- Several tip support mechanisms are interrupted during the approach to open rhinoplasty, and the process of scarring is progressive over time, usually leading to de-projection of the nasal tip over time. Septal extension grafting provides a way to secure the medial crura to the septum to support the tip using a septo-columellar suture.
- If the graft does not overlay the septum but is an end-to-end extension of the caudal septum, then it is called a caudal strut graft. These provide less thickness to the septal cartilage in the area of overlap of the septal extension graft with the septum but also lack the stability that this overlap provides.
- Caudal strut grafts are useful in straightening irregularly shaped medial crura.

- Closure
  - Once all of the cosmetic and functional aspects of surgery are completed, the skin envelope needs to be reapproximated to its native position.
  - This is done by first suturing the midline of the transcolumellar incision, followed by the apices of the "gull-wing" incision with 6-0 permanent monofilament suture.
  - After the apices, additional interrupted sutures are used between them, and then 6-0 fast-absorbing plain gut can be used to reapproximate the marginal incisions. Silastic splints can be placed, particularly if there is concern of synchecia formation. The nasopharynx is suctioned, and an orogastric tube is passed to decompress the stomach and esophagus prior to reversal of anesthesia.

Common Errors in Technique

- Inadequate exposure
- Inadequate hemostasis
- Elevating tissues in the wrong plane

- Over-resection of cartilaginous support of dorsum or tip
- Uneven or incomplete osteotomies
- Failure to restore tip support after interrupting it

FIG. 155.14 Inverted V deformity.

Postoperative Period

Postoperative Management

- Patients typically have external nasal splints which remain for 1 week postoperatively.
- Silicone nasal splints to support the septum and prevent adhesions between the septum and lateral nasal wall stay in place for 1 week and require the frequent use of saline spray (every 2 to 4 hours) to prevent crusting. This is started the day of surgery and continued while the splints remain in place.
- Pain control with acetaminophen and opioids is usually only necessary for the first few days postoperatively.
- Patients are asked to avoid nose blowing for 2 weeks postoperatively and to use intranasal saline spray instead.
- Splints and tape are removed at the 1-week visit, and a nasal examination is carried out; crusts are removed to improve the nasal

airway.

- Postoperative epistaxis can be managed with topical vasoconstrictors (such as oxymetazoline spray) and infrequently requires intervention such as packing or placement of absorbable hemostatic agents.

Complications

- Polybeak deformity—appears as dorsal fullness and can result from over-resection of the nasal bones, under-resection of the cartilaginous septum, or scarring of the supratip region and is treated with steroid injection in the case of scarring or secondary rhinoplasty to address the anatomic cause
- Open roof deformity—manifests as a widened and frequently asymmetric bony nasal dorsum. This complication can be caused by:
  - Greenstick lateral osteotomies, which will frequently return to their preoperative position
  - Failure to appropriately mobilize the nasal bones medially
  - Overly aggressive nasal packing
  - Failure to appropriately correct a deviated perpendicular plate of the ethmoid
- Inverted V deformity—is collapse of the nasal midvault and internal nasal valve, resulting in a cosmetic and functional problem. It is the result of a dorsal resection without providing support to the midvault and is treated with providing this support, often by using spreader grafts to the cartilaginous dorsum (Fig. 155.14).
- Bossae—are the result of irregularities in the tip cartilages, which can be symmetric or asymmetric and visible. These are treated with secondary rhinoplasty to address the specific cause of the bossae.

Alternative Management Plan

- Hyaluronic acid-based injectable fillers are used as a "nonsurgical rhinoplasty" by some practitioners to treat asymmetries and augment the nasal dorsum. This is controversial due to reports of vascular

complications (embolization of filler material) but is an increasingly common procedure.

Evidence-Based Medicine Question

Do objective measurements of nasal proportions correlate with facial attractiveness?

There have been many ideals of nasal proportions described. One example is the numerous methods described to assess nasal tip projection. A study of 300 lateral facial views showed no correlation among these measurements (as described by Goode, Simons Baum, Powell, and Crumley) with each other or with facial attractiveness as assessed by 78 viewers. This is just one of many illustrations that should make readers skeptical about relying on any single objective measurement too much without assessing the patient as a whole.

Editorial Comment

There are a variety of methods to measure nasal tip projection. Probably, the most common method is the one developed by Dr. Richard Goode, which measures the patient's tip projection and compares it to the length of the nasal bridge (normal ratio: 0.55 to 0.60). In practice, most experienced rhinoplasty surgeons do not actually measure tip projection but rather use a visual gestalt to determine if a nasal tip is over or under projected.

Review Questions

1. Which of the following structures does NOT contribute to the internal nasal valve?

   a. Septum

   b. **Lower lateral cartilage**

   c. Upper lateral cartilage

d. Inferior turbinate

2. Lateral crural steal (recruitment of lateral crural cartilage to the midline) would have which effect on tip rotation and nasal projection?

   a. **Increase rotation, increase projection**

   b. Increase rotation, decrease projection

   c. Decrease rotation, increase projection

   d. Decrease rotation, decrease projection

3. Indications for an open approach to the septum, rather than an approach via a hemitransfixion incision, do not include

   a. Caudal septal deviation

   b. A preoperative plan that might require an extra-corporal septoplasty

   c. Very severe septal deviation

   d. **Deviation of the bony nasal septum**

Blepharoplasty

Grant S. Gillman

Introduction

As our population continues to grow older, society's emphasis on a more youthful appearance continues to increase and has led to rising interest in reversing the visible signs of aging. The periorbital region is one of the first areas of the face to show signs of aging. Correction of this imperfection can significantly "turn back the clock" of aging and has thus led to the popularity of aesthetic surgery on the eyelids. Owing to the critical role that the upper and lower eyelids serve in protecting the globe, the surgeon must be very attentive to the delicate balance between form and function when performing blepharoplasty. To that end, the surgeon must be intimately familiar with the anatomy of the upper and lower eyelids and periorbital area[1,2] to make the best preoperative decisions in order to facilitate well-executed surgery.

Key Operative Learning Points

1. Be conservative with eyelid surgery. One can always do more, but complications resulting from overaggressive eyelid surgery can be very difficult to correct.

2. For upper eyelid surgery, preoperative skin markings should be checked and rechecked to avoid excessive excision of skin.

3. Opening the orbital septum low toward the tarsal plate in the upper eyelid increases the risk of injury to the levator aponeurosis and iatrogenic ptosis.

4. Patients with a very prominent, protrusive globe ("pseudoproptosis") in which the corneal plane lies anterior to the inferior orbital rim on

lateral view—the so-called negative vector—are at high risk for postoperative eyelid malposition with lower lid transcutaneous approaches.

5. Absolute hemostasis is necessary to minimize the possibility of postoperative retrobulbar hematoma.

6. Overaggressive removal of skin or adipose tissue from the upper or lower eyelids can create a hollowed, gaunt appearance, in addition to functional complications such as lagophthalmos and eyelid malposition.

Preoperative Period

History

1. History of present illness

   a. Prior periorbital surgery, previous blepharoplasty, visual difficulties, glaucoma, or dry eye symptoms. Concerns regarding other ophthalmic conditions (e.g., dry eyes, glaucoma, ptosis) merit preoperative evaluation by an ophthalmologist.

2. Past medical history

   a. Prior periorbital surgery: Cosmetic (blepharoplasty and/or brow lift) or reconstructive (skin cancer)

   b. Medical illness: Hypertension, diabetes, thyroid disease, facial muscle weakness, cardiovascular disorders

   c. Medications:

      1) Antiplatelet drugs

      2) Herbal products

      3) Alcohol

Physical Examination

1. General

   a. Visual acuity (eye chart)

b. Size, shape, configuration, and symmetry of the bony orbit and palpebral aperture. Patients should be made aware of asymmetries preoperatively.

2. Upper eyelid

a. Brow position: Determine the extent to which brow ptosis might be contributing to the apparent upper eyelid skin excess. In men, a youthful brow position rests at the level of the superior orbital rim; in women, ideal brow position is about 1 cm above the orbital rim. Significant brow ptosis should prompt a conversation with the patient about the merits of a brow-lift or combination brow-lift and blepharoplasty.

b. Eye closure: Pre-existing lagophthalmos is an absolute contraindication to upper eyelid blepharoplasty. Lagophthalmos will be exacerbated if upper lid surgery is performed.

c. Eyelid ptosis: Blepharoplasty alone will not correct eyelid ptosis and can make it more apparent. Depending on the experience of the surgeon, ptosis repair might require the expertise of an oculoplastic surgeon.

d. Position and symmetry of the upper lid folds and supratarsal creases

e. Record the degree of excess skin in each eyelid and adipose tissue in each adipose tissue compartment (medial and central compartments).

3. Lower eyelid

a. The presence of scleral show, and the position of the globe in the orbit. Asymmetries should be pointed out to the patient preoperatively.

b. Lower eyelid tone: If lid tone is poor, there is increased risk of lower lid malposition postoperatively. Consider alternative techniques to standard skin-muscle lower lid blepharoplasty or a concomitant canthoplasty or canthopexy.

1) “Snap test” (the lid distraction test): The lower lid is drawn anteriorly outward from the globe with the thumb and forefinger. More than 10 mm movement of the lid margin is

considered abnormally lax. In addition, note how long it takes for the lower lid to return to its pretest position. A normal, youthful lid will snap back immediately.

2) "Lid retraction test": The lower lid is drawn inferiorly toward the orbital rim, and once again one observes for abnormally slow return of the lid to its normal position.

c. Record the degree of excess skin in each eyelid and adipose tissue in each adipose tissue compartment (medial, central, and lateral compartments). Excess adipose tissue in the lower lid compartments is accentuated by upward gaze. Applying pressure to the patient's globe with the eyelids closed helps delineate the location of excess adipose tissue in both upper and lower eyelid compartments. Orbicularis oculi muscle hypertrophy is also recorded.

4. Preoperative photographs

a. Full facial view and close-up frontal (eyes open, closed, and gazing upward), oblique, and lateral views of the eyes

Imaging

None

Indications

1. Upper eyelid blepharoplasty

a. Dermatochalasis (upper eyelids): Cosmetic or functional (visual field restriction), depending on the degree of skin excess and hooding of the upper eyelids. A functional upper eyelid blepharoplasty will require documentation with automated visual field testing.

2. Lower eyelid blepharoplasty

a. Pseudoherniation of adipose tissue ("bags"), with or without a vertical excess of skin

Contraindications

1. Medical comorbidities with increased risk for general anesthesia

2. Pre-existing ophthalmologic concerns: Severe dry eyes; preexisting lagophthalmos or minimal tissue excess (risk of hollow-looking orbit postoperatively) in particular should be considered as contraindications to eyelid surgery.

3. Unrealistic expectations or difficult patient

Preoperative Preparation

1. Discontinue all potential anticoagulant/blood-thinning medications.

2. Ophthalmologic evaluation/clearance when indicated by any concerns in ophthalmologic history

Operative Period

Anesthesia

Local anesthesia supplemented by intravenous sedation is generally adequate for aesthetic surgical procedures on the eyelids. Patients needing resection of skin only of the upper eyelids may tolerate local anesthesia alone. Occasionally the patient or anesthesiologist may feel more comfortable with general anesthesia, particularly if eyelid surgery is combined with other procedures. Patient comfort is a requisite for maximal surgical safety.

Positioning

Supine

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin intravenously given before the skin incision

Clindamycin or gentamicin if allergic to penicillin

Monitoring

None

Instruments and Equipment to Have Available

1. Basic plastics/oculoplastics set

Key Anatomic Landmarks

1. Upper border of the tarsal plate in the upper eyelid lies level with the tarsal crease. Incisions or dissection should not be below this level.

2. The levator aponeurosis fuses with the orbital septum and attaches to the upper tarsal plate. For removal of adipose tissue in the upper eyelid, opening the orbital septum 5 mm or more above the tarsal plate minimizes the risk of iatrogenic ptosis.

3. The medial adipose tissue pad in both the upper and lower eyelids is distinguished from central or lateral adipose tissue pads by a paler, whiter color.

4. The inferior oblique muscle sits between the medial and central adipose tissue pads of the lower eyelid.

Prerequisite Skills

1. Familiarity with the surgical anatomy

2. Experience with oculoplastic surgery

Operative Risks

1. Upper eyelid blepharoplasty
    a. Excess skin excision: Avoidable with assiduous preoperative skin markings and measured excision (see operative technique)

b. Retrobulbar hemorrhage: Patiently cauterizing (bipolar) or clamping and cauterizing the pedicle of the adipose tissue pad being removed will minimize the risk or traction or avulsion of orbital vessels.

2. Lower eyelid blepharoplasty

a. Retrobulbar hemorrhage (discussed previously)

b. Inferior oblique injury with secondary diplopia: A heightened awareness of the muscle position between the medial and central adipose tissue pads of the lower eyelid is necessary to identify and avoid inadvertent muscle trauma.

c. Lower eyelid malposition (scleral show, ectropion)

Surgical Technique: Upper Eyelid Blepharoplasty[3,4]

1. Skin markings: Incisions are marked preoperatively with the patient sitting upright and the brow held in proper position. The curvilinear inferior incision is marked along the patient's natural upper eyelid crease, which lies at the upper edge of the tarsal plate. This is typically 8 to 12 mm above the lash line in the midpupillary line and 5 to 6 mm above the medial and lateral canthi. If the crease is less than 8 mm from the lash line centrally, measure the marking centrally to lie 8 to 10 mm above the lashes. At the lateral canthus, the marking sweeps laterally and upward toward the tail of the brow, as much as needed to excise the skin that accounts for any lateral hooding. The incision rarely needs to extend beyond the lateral orbital rim. Medially, the incision marking should not extend more than 1 to 2 mm beyond the punctum of the eyelid. Extending the incision into the concavity at the medial orbit risks creating a webbed scar across this area. To mark the upper incision, hold the patient's brow in its correct anatomic position when determining the amount of skin to be resected. A "skin pinch" technique is used to determine the amount of excess skin. Centrally the excess skin is gently grasped with fine forceps and lifted until slight eversion of the lashes occurs. The upper incision is marked at the point where the lower incision meets the upper limit of the excess skin. This is done in at least four positions across the upper eyelid. The marks are then connected to outline the upper incision line (Fig. 156.1). Test the planned excision at

multiple levels by pinching the upper and lower incision markings together (before injecting the local anesthetic) and checking to avoid excess eversion of the lid margin and risk of lagopthalmos postoperatively. Conservatism is always recommended.

2. Infiltrate the local anesthetic: Inject with a 30-gauge, 1.5-inch needle between skin and the underlying orbicularis oculi (1 to 1.5 mL per eyelid).

3. Skin excision: The skin is incised (15 blade) along the markings and excised with a 15-blade scalpel, a needle-tip cautery, or sharp scissors. Hemostasis is obtained with a needle-tip electrocautery (Fig. 156.2).

4. To accentuate the supratarsal crease, excise a 3-mm strip of orbicularis muscle using fine forceps and curved scissors in the midportion of the wound.

5. Removal of orbital adipose tissue (if indicated): With finger pressure on the globe, the bulging excess adipose tissue in the orbital compartments is seen through the orbital septum. A small opening is made in the orbital septum over the adipose tissue compartment to be addressed. Excess adipose tissue is teased through the opening in the septum with fine forceps and a cotton swab (Fig. 156.3). Only adipose tissue that is easily delivered through the orbital septum is resected. A small amount of local anesthetic is injected into the base of the adipose tissue pedicle for hemostasis and comfort. A small hemostat is then placed across the base of the adipose tissue pedicle. Small scissors are used to excise the adipose tissue, leaving a small cuff above the hemostat to be cauterized before releasing the hemostat. Alternatively, one can slowly cauterize across the base of the adipose tissue (bipolar cautery) without clamping the pedicle, thereby minimizing the risk of excess traction on the posterior orbital vessels from manipulating a hemostat.

FIG. 156.1 Outline of an upper eyelid blepharoplasty incision.

FIG. 156.2 Hemostasis achieved after skin excision. Orbicularis oculi visible within the wound.

6. Skin closure: Simple interrupted sutures can be placed in the incision lateral to the lateral canthus to reduce tension along the closure line. The remainder of the incision is closed with running a 6-0 monofilament subcuticular suture (Fig. 156.4), a running locking suture, or simple interrupted sutures (surgeon preference). Mastisol and small Steri-Strips are used to anchor the medial and lateral ends of the suture.

FIG. 156.3 Orbital adipose tissue is teased through the opening made in the orbital septum (upper eyelid lateral compartment).

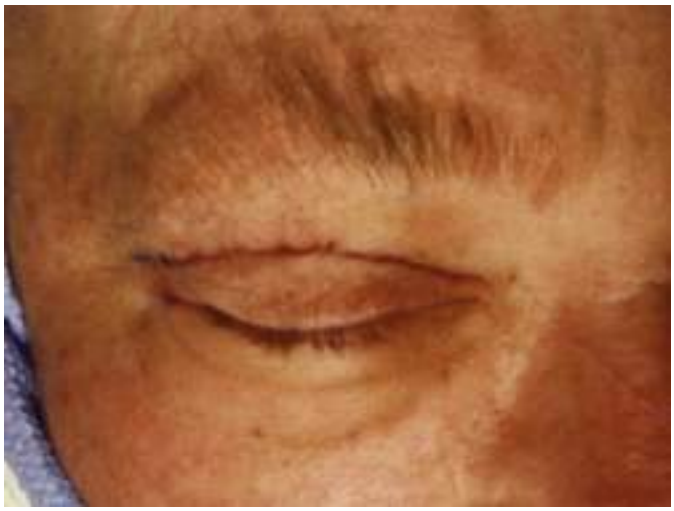

FIG. 156.4 Interrupted stitches approximate the wound edge lateral to the lateral canthus. Closure of the remaining incision with a subcuticular stitch.

FIG. 156.5 Lower eyelid everted with a blunt double hook to expose the conjunctiva (right eye). Conjunctival incision (with needle-tip electrocautery) just below the inferior edge of the tarsal plate (left eye). Note the corneal protector in place.

Surgical Technique: Lower Eyelid Transconjunctival (Preseptal) Blepharoplasty

In patients with a minimal excess of skin, a transconjunctival approach[5] to the lower lids is preferred. As compared to a transcutaneous approach, the transconjunctival approach minimizes the risk of developing lower eyelid retraction (scleral show or frank ectropion) in patients with poor lid tone. In patients with significant excess skin of the lower lid or those who already have lower lid laxity for which correction (canthoplasty, canthopexy) is planned, a transcutaneous (subciliary) approach[6] is used with elevation of a skin-muscle flap.

1. Infiltration of local anesthesia: Once the patient is sedated, the conjunctivae are topically anesthetized with 0.5% ophthalmic tetracaine or proparacaine hydrochloride solution, and corneal shields lubricated with ophthalmic ointment are used for corneal protection. Lidocaine (1%) with 1:100,000 epinephrine is injected with a 27- or 30-gauge needle in the conjunctiva along the planned incision and percutaneously deep to the orbicularis of the lower lid to anesthetize and hydrodissect the plane of dissection.

2. Conjunctival incision: Retract the lower lid margin with a wide double prong hook. A conjunctival incision is made with a needle-tipped cautery 1 to 2 mm below the tarsal plate (Fig. 156.5) and deepened to divide the attachment of the lower lid retractors to the inferior tarsus. Medially, the incision stops short of the punctum of the lacrimal duct to avoid injury to the lacrimal canaliculi, and laterally the incision is carried as far as necessary to provide adequate exposure of the adipose tissue compartments.

3. Traction suture: A 5-0 silk or nylon bridle suture is placed through the inferior conjunctival incision margin, with a hemostat on the free ends of the suture. The hemostat is passed over the patient's forehead, retracting the conjunctiva and inferior retractors up over the cornea. This provides countertraction for the dissection and protects the underlying cornea.

4. Preseptal dissection: An assistant retracts the eyelid margin with a wide double hook or a Desmarres retractor. Preseptal dissection (Fig. 156.6)—between the overlying skin and muscle and the underlying orbital septum—is carried down to the orbital rim with a combination of sharp and blunt dissection. The orbicularis is separated from the septum by pushing the muscle anteriorly and inferiorly with a cotton swab. Orbital adipose tissue is seen behind the orbital septum (Fig. 156.7).

5. Incise orbital septum: Pressure on the globe will cause the orbital adipose tissue to bulge forward; a small opening is made in the septum overlying the adipose tissue compartments to be addressed. The adipose tissue from each compartment is addressed separately. Adipose tissue is teased from the surrounding fascia and attachments with fine forceps in one hand and a cotton-tipped swab in the other (Fig. 156.8). Only adipose tissue that can be easily delivered without excess traction should be removed. A small amount of local anesthetic should be injected into the base of the adipose tissue pedicle before excision.

6. Adipose tissue removal: A fine hemostat is placed across the base of the mobilized adipose tissue. Fine scissors are used for sharp resection, leaving a small cuff of adipose tissue above the hemostat, which is then cauterized. Alternatively, one can use bipolar cautery slowly and incrementally across the base of the adipose tissue (without a hemostat) and fine scissors to incise the cauterized stump and excise the adipose tissue. Only adipose tissue that extends above the plane of the inferior orbital rim without traction is excised. Staying at this level minimizes the

risk of injuring the inferior oblique muscle, which lies between the medial and central adipose tissue compartments. Each adipose tissue compartment is addressed individually. The medial adipose tissue pad is distinguished from central or lateral adipose tissue by its paler color. Once adequate resection has been performed, replace the lower lid in its anatomic position. Examine the lower lid with and without pressure on the globe. Re-explore any area that looks prominent, and be attentive to bilateral symmetry. With the patient in the supine position, a slight concavity of the overall contour of the lid will generally ensure a good result.

7. Closure: It is not necessary to close the conjunctival incision. It will heal uneventfully, even if left unsutured. Alternatively, a single fast-absorbing 6-0 catgut suture (with an inverted buried knot) can be placed to align the conjunctival wound, positioning it lateral or medial to the corneal limbus (corneal-scleral junction) to avoid corneal irritation from the suture. A small amount of excess skin can be removed by subciliary "pinch" excision at the same time if only a minor amount of skin resection is needed.

Preoperative and postoperative photos of a lower eyelid transconjunctival blepharoplasty patient are seen in Fig. 156.9.

Surgical Technique: Lower Eyelid Transcutaneous (Skin-Muscle Flap) Blepharoplasty

Transcutaneous lower lid blepharoplasty is reserved for patients with excess skin or hypertrophy of the orbicularis muscle as well as those with lower lid laxity that would benefit from a planned suspension procedure. In patients with a significant disparity in the amount of excess skin and muscle, separate skin and muscle flaps are raised to the level of the infraorbital rims, and the appropriate excesses are dealt with individually. This is much less commonly done and likely accounts for no more than 1% to 2% of all blepharoplasty procedures. All other transcutaneous blepharoplasty patients are treated with the standard skin-muscle flap technique described herein.

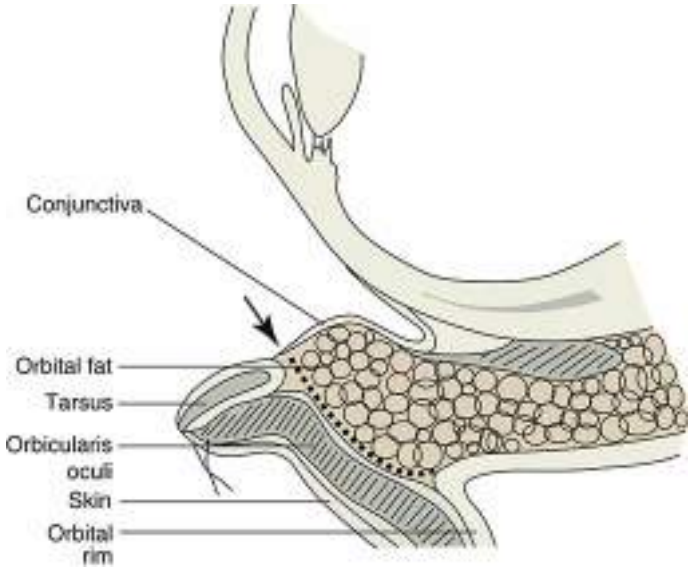

FIG. 156.6 Sagittal schematic view of the plane of dissection for preseptal transconjunctival blepharoplasty. The *arrow* indicates the level of the conjunctival incision, just below the inferior edge of the tarsal plate. The dissection then proceeds *(dashed line)* toward the inferior orbital rim in the plane between the orbicularis oculi and the orbital septum overlying the orbital adipose tissue compartments.

FIG. 156.7 After preseptal dissection in the plane between the orbicularis oculi and the orbital septum, a Desmarres retractor placed deep to the muscle exposes

the orbital septum, through which one can see the underlying orbital adipose tissue compartments (right eye). A bridle suture is in place to retract the conjunctiva superiorly for corneal protection.

1. Incision marking: The lower eyelid incision is marked parallel and 1.5 to 2 mm below the lash line (Fig. 156.10). Adequate access can often be achieved with an incision extending medially only as far as the medial limbus of the cornea, lengthening the incision further if need be. Beyond the lateral canthus, the incision angles slightly downward and lateral, extending 5 to 7 mm parallel to or in a lateral periorbital skin crease (crow's foot). This extension should be only as long as needed to remove the redundant skin. The vertical separation between the lateral extents of the upper and lower eyelid incisions should be at least 5 to 7 mm.

2. Local anesthesia: Lidocaine (1%) with 1:100,000 epinephrine is injected along the incision and deep to the preseptal orbicularis oculi, with a 27-gauge, 1.5-inch needle. The eyes are lubricated with ophthalmic ointment.

FIG. 156.8 Central compartment adipose tissue being teased though an opening in the orbital septum with the aid of a cotton-tipped applicator (right eye).

3. Skin incision, submuscular dissection: A 15 blade is used to incise the skin of the small extension beyond the lateral canthus or along the entire

subciliary incision, through skin only. The incision lateral to the canthus is then deepened to a submuscular (preseptal) plane. Through it, using fine scissors with a blunt spreading motion, one can blindly predissect deep to the muscle inferiorly and medially down to the orbital rim to separate the muscle from the septum deep to it (Fig. 156.11). Small, sharp curved scissors are then tunneled medially under skin in the pretarsal area, superficial to the orbicularis oculi, and the subciliary incision is completed through skin only. To this point, the dissection has involved skin only in the pretarsal area, superficial to the pretarsal orbicularis muscle. The dissection in the preseptal area has been deep to the orbicularis.

4. Connect the pretarsal and preseptal dissections: The planes of the skin-only elevation (pretarsal) and the skin-muscle flap dissection (preseptal) are connected by incising the muscle below the tarsus, approximately 3 to 5 mm from the lash line (Fig. 156.12). Leaving the pretarsal orbicularis muscle intact to act as a hammock helps support the lower lid, decreasing the likelihood of lid malposition.

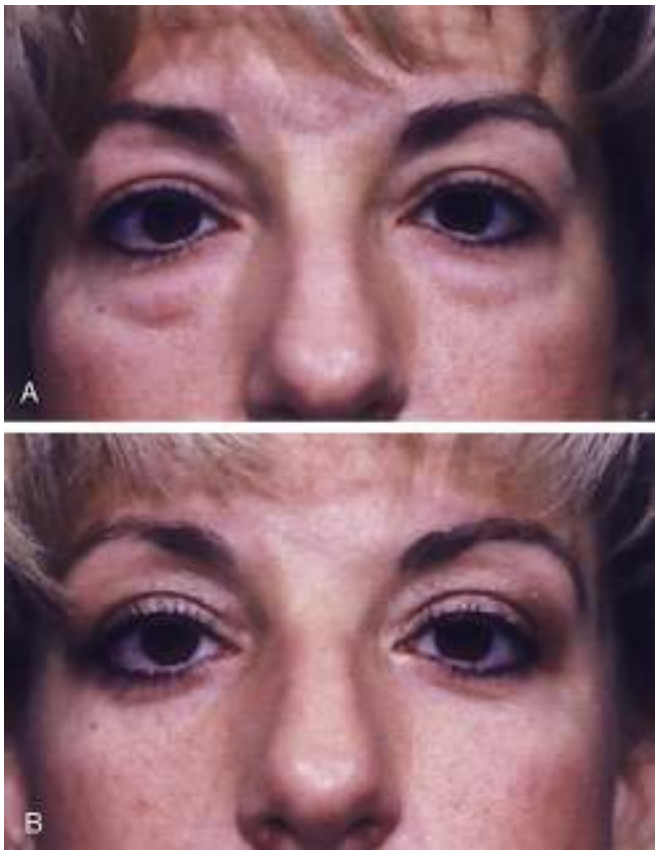

FIG. 156.9 Preoperative, **A,** and postoperative, **B,** views of a lower eyelid transconjunctival blepharoplasty patient.

FIG. 156.10 The subciliary incision is marked approximately 2 mm below the lash margin and extends 5 to 7 mm beyond the lateral canthus.

FIG. 156.11 The initial blind submuscular dissection should proceed easily without encountering any resistance through the relatively avascular plane

between the orbicularis oculi and the orbital septum deep to it. The dissection is carried toward the inferior orbital rim.

FIG. 156.12 The muscle is incised below the level of the subciliary incision with a “blade-in, blade-out” maneuver to connect the skin-only pretarsal dissection with the submuscular elevation below the tarsus.

5. Complete elevation of the skin-muscle flap: A bridle suture is placed through the superior incision margin or the gray line to retract the conjunctiva cephalically for corneal protection. The skin-muscle flap is retracted by an assistant with a wide blunt double-ball hook. The skin-muscle flap is elevated down to the level of the infraorbital rim, exposing the entire orbital septum (Fig. 156.13).

6. Adipose tissue removal: Small openings are made through the orbital septum to facilitate dissection of adipose tissue from each compartment (central, medial, and lateral) as needed. Adipose tissue removal proceeds as previously described for the preseptal transconjunctival approach.

7. Skin trim: The skin-muscle flap is redraped over the lower lid lashes in an upward and slightly lateral direction. An incision is made into the skin-muscle flap at the level of the lateral canthus to the point at which the overlapping skin meets the cut edge of the infraciliary margin. That point is sutured with 6-0 Prolene, and the excess skin is effectively divided into two triangles of excess skin—one medial and one lateral to

the suture (Fig. 156.14). The extra skin is then judiciously excised—first the lateral triangle and then the medial triangle (Fig. 156.15), to allow for a tension-free skin closure. A conservative skin excision minimizes the risk of lid malposition. A thin strip of orbicularis is then excised from beneath the upper margin of the skin-muscle flap. Failure to do so would result in overlapping of this muscle over the pretarsal orbicularis that was not elevated.

FIG. 156.13 A bridle suture retracts the tarsus and conjunctiva superiorly for corneal protection. The skin-muscle flap is elevated and retracted toward the inferior orbital rim to expose the orbital septum and the underlying orbital adipose tissue compartments.

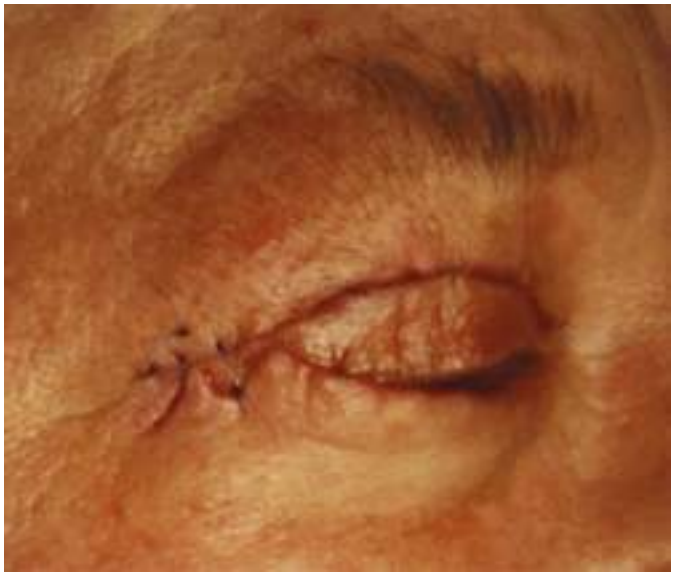

FIG. 156.14 The skin-muscle flap is redraped over the infraciliary incision. An incision is then made into the flap at the lateral canthus as far as the edge of the overlapped infraciliary incision. That point is secured with 6-0 Prolene suture, thereby effectively dividing the skin excess into two separate triangles—one medial and one lateral to the canthus.

FIG. 156.15 Excision of the excess triangular skin

medially. In a similar fashion, the excess skin is trimmed lateral to the suture (lateral to the lateral canthus).

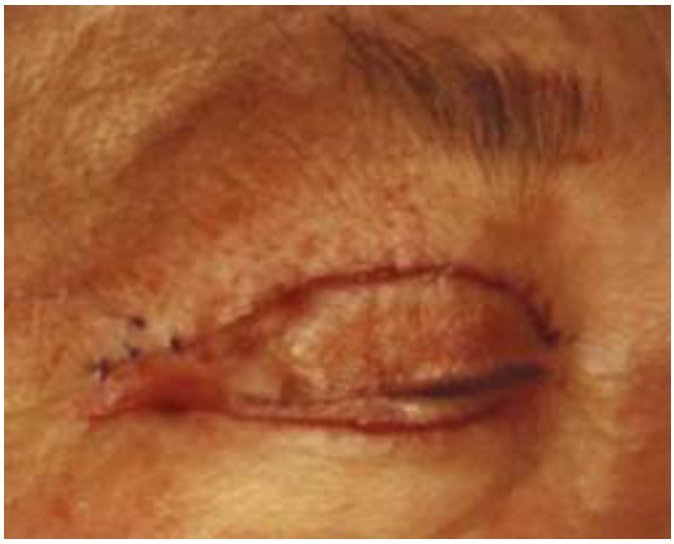

FIG. 156.16 Skin-muscle flap blepharoplasty, just before skin closure with easy tension-free approximation of skin edges.

8. Flap suspension, skin closure: Once hemostasis is verified, a flap suspension suture of 5-0 polyglactin is placed to support the lower lid through the healing period.[5] The orbicularis muscle under the skin-muscle flap is grasped medial to and below the lateral orbital tubercle (Whitnall's tubercle) and suspended with a buried inverted suture to the periosteum at the lateral orbital tubercle. It is important to get a good bite of periosteum and sufficient purchase on the muscle *without* dimpling the overlying skin. The skin edges should now lie gently approximated (Fig. 156.16) for easy tension-free closure. The incision is closed with interrupted 7-0 Prolene suture lateral to the canthal angle and interrupted or running 6-0 fast-absorbing gut suture along the subciliary portion.

Preoperative and 4-month postoperative photos of a patient who underwent both an upper eyelid as well as a lower eyelid skin-muscle flap blepharoplasty are seen in Fig. 156.17.

Common Errors in Technique

1. Asymmetric scar placement: This is easily avoidable with attention to preoperative markings.

2. Inadequate skin excision (upper eyelids): This is avoidable with attention to the preoperative markings. Conservative skin excision is always warranted to prevent lagophthalmos, but using a pinch technique as described will allow for an appropriate skin excision.

3. Failure to support lower eyelid with skin muscle flap lower blepharoplasty: Placement of the suspension suture as described is valuable for prevention of scleral show/lateral rounding of the lower lid.

Postoperative Period

Postoperative Management

1. Ice packs/cool compresses

2. Lubrication (if needed—artificial tears for daytime dryness; Lacri-Lube ointment for nighttime protection)

3. Wound care: The incision is gently cleaned with a cotton swab soaked in hydrogen peroxide 3 to 4 times daily, and ophthalmic antibiotic ointment is then applied.

4. If a transconjunctival approach is used for the lower lids, an ophthalmic antibiotic drop with steroid is used for the first 5 days postoperatively. Contact lenses should be avoided for at least 1 week after surgery.

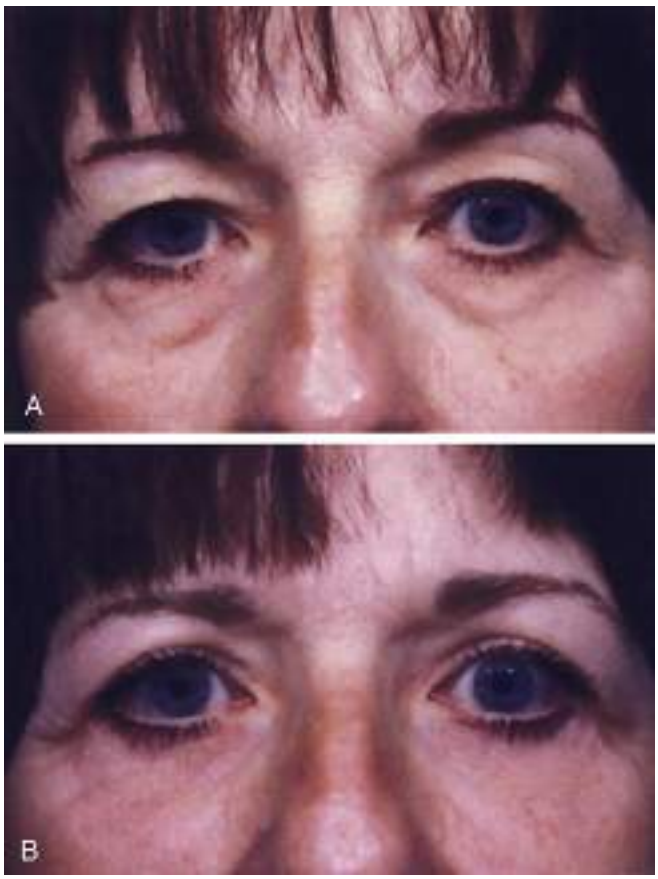

FIG. 156.17 Preoperative, **A,** and postoperative, **B,** views of a patient who had an upper eyelid blepharoplasty and a lower eyelid skin-muscle flap blepharoplasty.

5. Nondissolving sutures are removed at 5 to 7 days.

Complications[7]

1. Corneal injury: Prevention involves corneal lubrication to prevent desiccation during surgery. Protective corneal shields can be placed during blepharoplasty. The surgeon should be cautious when using gauze near the cornea. Eye pain, tearing, and scleral injection suggest a corneal injury. This should prompt an evaluation by an ophthalmologist. Fluorescein staining can be used for diagnosis, and treatment includes ophthalmic antibiotic ointment and an occlusive dressing until healing is complete.

2. Wound separation: Infrequently the lateral aspect of the wound might separate slightly when sutures are removed. This is treated with Steri-

Strips or the wound should be resutured if necessary.

3. Asymmetries: Postoperative asymmetries may reflect unrecognized preoperative asymmetries of excess lid skin or asymmetric preoperative brow position. Noting such asymmetries *preoperatively* and discussing them with the patient increases acceptance of minor postoperative asymmetries. If a brow procedure is not indicated or desired, asymmetric skin excision may be necessary to address differences between the two sides. Asymmetry in adipose tissue excision can also be apparent postoperatively. Attention to detail intraoperatively minimizes the risk of such problems. Asymmetry persisting several months postoperatively may require revision surgery.

4. Dry eyes: Postoperative edema is the most common cause and should settle over 1 to 3 weeks. The interim use of artificial tears and lubricating ointment helps prevent keratitis. Other causes of dry eyes include an unrecognized preoperative condition, injury to the lacrimal gland (uncommon), and excess skin resection. Excess skin resection will require repair with a full-thickness skin graft replacement.

5. Epiphora: Excess tearing is common during the first 48 hours postoperatively. It typically results from edema or temporary muscular atony, which impairs the function of the lacrimal drainage system and generally resolves as the swelling subsides. Other possible causes include eversion of the punctum (secondary to either edema or ectropion, discussed later) or, uncommonly, injury to the canaliculus.

6. Lagophthalmos: Most commonly, lagophthalmos is due to immediate postoperative edema. It is treated with lubricating ointments and time. Lagophthalmos due to over-resection of upper lid skin can lead to desiccation and corneal injury. In such cases, release of the upper lid along with skin grafting must be considered. Prevention requires carefully measuring the amount of skin to be resected (via the aforementioned pinch technique) several times before any skin resection.

7. Ptosis: Temporary “pseudo-ptosis” secondary to swelling is not uncommon in the first postoperative week. Persistent ptosis suggests injury to the levator expansion when opening the orbital septum. The levator apparatus is at risk in the inferior portion of the wound close to the upper border of the tarsal plate, where the levator fuses with the orbital septum. Excising muscle or opening of the septum is safest if one

stays away from the lower portion of the wound after excision of skin. Persistent ptosis should be corrected by reinsertion of the levator into the tarsus or dermis.

8. Extraocular muscle injury: The inferior oblique muscle lies between the medial and central adipose tissue compartments of the lower lid. It should be looked for in every case, although it is not always seen and injury is uncommon. Care must be taken to avoid clamp, cautery, or sharp injury to this vulnerable muscle during removal of adipose tissue. If immediately identified, the transected ends should be approximated. Diplopia on upward lateral gaze indicates injury to the muscle. Persistent postoperative diplopia lasting longer than 1 to 2 weeks should be evaluated by an oculoplastic surgeon.

9. Lower lid malposition: Excess "scleral show" in the immediate postoperative period may be due to edema and transient paresis of the orbicularis oculi muscle. It will often resolve as the edema diminishes and muscle functions returns. Massage of the lower lid in an upward and outward direction is beneficial. Tape support of the lower lid can lessen the degree of scleral show, decrease tearing, and improve comfort. Unappreciated preoperative lower lid laxity may also contribute to postoperative ectropion. To resupport the lid, a canthopexy or canthoplasty may be required. If the ectropion is due to overaggressive skin resection, correction will likely require complete scar release and full-thickness skin grafting after several months of observation and conservative management. The best means of treatment is prevention. A transconjunctival approach avoids the contraction associated with healing of the skin and muscle incisions used for the infraciliary approach. In addition, patients with any degree of laxity who require skin excision via an infraciliary approach should be considered for prophylactic lateral canthopexy.

10. Retrobulbar hematoma/visual loss: This is the most feared complication of blepharoplasty and develops as a result of vascular injury with retraction of the bleeding vessel into the retrobulbar space. The eye becomes firm, chemotic, and progressively more proptotic. The lids cannot close, as the globe continues to bulge outward. Increasing intraocular pressure can lead to ophthalmoplegia, ischemia of the optic nerve, and visual loss. A retrobulbar hematoma typically develops within the first 4 to 6 hours postoperatively. Prompt diagnosis and

management are critical to prevent permanent visual loss. Initial treatment involves simultaneous opening of incisions; iced saline compresses; 20% mannitol (2 g/kg) as an osmotic agent to decrease intraocular pressure; acetazolamide (Diamox) 500 mg intravenously; dexamethasone (Decadron) 10 mg intravenously; control of hypertension (if present); head elevation; and correction of any coagulopathies. Visual acuity should be evaluated frequently. Any deterioration in visual acuity coupled with elevated intraocular pressure signifies impending optic nerve ischemia. In this situation, removal of all external sutures and lateral canthotomy/inferior cantholysis are indicated on an emergency basis for orbital decompression. Emergency ophthalmic consultation is necessary but should not delay performance of canthotomy and cantholysis.

Discussion

Evidence-Based Medicine Question

What factors might contribute to postoperative dry eyes syndrome, and what steps might be taken preoperatively to better assess risk?

In a 10-year retrospective review of 892 patients undergoing blepharoplasty by a single surgeon, a self-reported dry eye questionnaire was administered to patients before and (minimum 3 weeks, mean follow-up 26 months) after surgery.[8]

Overall 26.5% of patients reported dry eyes syndrome (DES) at some time following surgery. DES was significantly more common in patients undergoing concurrent upper and lower lid blepharoplasty, with use of a skin-muscle flap blepharoplasty and in patients with temporary postoperative lagophthalmos. This highlights the need for all patients undergoing blepharoplasty to be assessed preoperatively for risks including scleral show, lagophthalmos, dryness, positive snap test result (lower lid laxity), prior surgery, and negative vector, all of which can further increase risk.

In summary, the incidence and reporting of DES may be underestimated, and appropriate preoperative assessment and counseling should be routine.

Editorial Comment

Abnormal tear film breakup and a Schirmer test are not good predictors of possible postblepheroplasty dry eye complications. A patient's anatomy (e.g., negative vector, lower lid laxity) and history are more important predictors of postoperative dry eye problems than ocular tests.

Review Questions

1. The inferior oblique muscle is at risk

   a. Between the medial and lateral adipose tissue pads of the lower eyelid

   b. Between the lid retractors and conjunctiva of the lower eyelid

   c. Between the central and lateral adipose tissue pads of the lower eyelid

   d. Between the punctum for the lacrimal duct and medial adipose tissue pad of the lower eyelid

   e. **Between the medial and central adipose tissue pads of the lower eyelid**

2. The benefit of a transconjunctival approach to the lower eyelid is

   a. Shorter incision

   b. Better exposure of orbital adipose tissue

   c. Better visualization of the inferior oblique muscle

   d. Better control of lower lid laxity

   e. **Lower risk of postoperative lower lid malposition**

3. The inferior incision for an upper lid blepharoplasty

   a. Should be placed at the upper border of the levator aponeurosis

   b. Is best made through skin and the underlying orbicularis to facilitate flap elevation in a submuscular plane

c. Should be place just above the lash line

d. **Should be made at the upper border of the tarsal plate**

e. Should be made at the lower border of the tarsal plate

4. Management of retrobulbar hemorrhage might include (circle all that might apply)

a. Lasix 60 mg as a stat intravenous (IV) dose

b. Emergency lateral canthopexy

c. **Lateral canthotomy**

d. Activation of the overhead emergency response team

e. Emergency inferior canthectomy

5. Possible causes of scleral show/lid malposition include all of the following except

a. **Overly aggressive upper eyelid blepharoplasty**

b. Scarring and retraction between the anterior and middle lamella of the lower eyelid

c. Aggressive skin excision in lower eyelid blepharoplasty

d. A subciliary approach to lower eyelid blepharoplasty

e. Unrecognized preoperative lower lid laxity

Brow Lift

Benjamin W. Light, and Paul Leong

Introduction

The brow lift procedure is a rewarding one to master. It allows for both functional and cosmetic concerns to be addressed, resulting in above average patient satisfaction. One of the earliest signs of aging is brow ptosis coupled with an accumulation of redundant tissues in the glabella region and forehead rhytids. A combination of sun exposure and time induced facial skin laxity allow brow tissue to migrate down past the superior orbital rim creating a "bunching" of glabella and eyelid anatomy. Patients frequently present with functional complaints of visual impairment; the often describe a weight or heaviness of their eyelids that limits their ability to remain attentive or focus due to impairment of vision and irritation of their eyelids weighing on their upper eyelid lashes. This downward migration of the upper face also leads friends and coworkers to perceive this brow heaviness as an outward appearance of tiredness, disgust, or angriness which can be very frustrating to the individual (Fig. 157.1A) As such, for either functional or cosmetic purposes, the brow lift can be a very beneficial procedure for the patient.[1]

In general, the closer the incision site of the brow lift approach to the actual brow region, the more control the surgeon may exert over the final position of the brow and its shape. Brow shape and position must be weighed against other variables such as patient acceptance, visibility of the scar, and risk of complications. Approaches to brow shaping, elevating, and stabilizing have changed a great deal over the past several decades with more recent advances allowing for a decrease in visible scars, healing time, and complications.

Often a brow lift is coupled with blepharoplasty (staged or synchronous) for optimal functional and cosmetic benefit. Performing the

brow lift prior to a blepharoplasty is recommended to allow fixation of the brow position before determining if the blepharoplasty is even necessary. If eyelid surgery is performed, initial proper brow stabilization allows precise measurements for eyelid skin markings.

Key Operative Learning Points

1. Proper selection of brow lift approach

2. Functional and cosmetic concerns in patient selection

3. Avoidance of pitfalls and complications associated with various brow lift approaches

Preoperative Period

History

1. History of present illness:

   a. Note concerns that the patient has regarding brow appearance and symmetry.

   b. Discuss any history of visual disturbances.

2. Past medical history

   a. Prior treatment: Any use of neurotoxin in the frontalis or upper face within the 6 months prior to evaluation is important to note prior to surgery, as this can significantly alter the baseline relationship of scalp, brow, and eyelid position.

   b. Medical illness: History of facial nerve injury or palsy should be sought. Personal or family history of bleeding disorders or easy bruising is important to note. Past history of methicillin resistant staphylococcus aureus (MRSA) infections should be taken into consideration with respect to perioperative prophylaxis and hygiene. Patients using continuous positive airway pressure (CPAP) masks for treatment of obstructive sleep apnea (OSA) may need to forego the use of the mask for several weeks after a brow lift depending on the surgical approach and the type of mask used. Proper OSA

treatment options may be discussed preoperatively for this eventuality. History of ophthalmologic surgery or treatment should be documented.

c. Surgery: Previous surgeries of the upper face including excision of skin cancer (and repair techniques used to close the defect), blepharoplasty, forehead surgery, or traumatic injuries to the scalp/forehead are important to explore. Any history of postoperative nausea and vomiting should be explored in anticipation of preemptive perioperative pharmacologic intervention.

d. Family history: Information on familial hairline recession and hair loss patterns in both male and female patients is important to consider when selecting the proper brow lift approach.

e. Medication: The use of antiplatelet medications, alcohol, or herbal products

f. Incidental: In anticipation of postoperative questions regarding swelling, routine inquiry as to the patients preferred sleeping position is needed. Preoperative discussion of the influence of sleep position on dependent edema can eliminate concerns when patients experience significant asymmetry of eyelid or brow swelling/bruising.

Physical Examination

1. Hairline position: The height of the forehead is an important variable in the selection of the proper brow lift approach. Each technique influences the hairline position and brow height in unique ways as described later.

2. Scalp: Hair thickness, color, and quality should be assessed to determine how visible a scar is likely to be when positioned around or behind the hairline.

3. Brow position: Note the position of the brow relative the orbital rim. Medial and lateral brow position is assessed. The quality of brow hair is noted. Thinning of lateral inferior brow due to plucking is noted and should be discussed with the patient (Fig. 157.2).

4. Eyelids: The presence of eyelid hooding due to dermatochalasis or eyelid ptosis should be noted.

5. Facial nerve: Baseline facial nerve function should be evaluated for strength and symmetry. Facial nerve dysfunction may often affect brow position and dynamics.

6. Trigeminal nerve: Preoperative function of the trigeminal nerve is important to note as the supraorbital and supratrochlear branches may be at risk during the procedure.

FIG. 157.1 Before **(A, C)** and after **(B, D)** photographs demonstrating typical results from a midforehead brow lift approach used in men. Other brow lift techniques are often not as much an option for men with high or no hairline to mask the incision sites.

7. Facial scars: The presence of facial scarring is important to note. Scarring of the forehead and scalp may result in disruption of natural

dissection planes during surgery or asymmetric preoperative scar contracture that may need to be factored into the brow lift planning.

Imaging

A panel of preoperative photographs is necessary in cosmetic and functional brow lift patients. Frontal, oblique, and lateral photographs are recommended and required by insurance companies for preauthorization purposes. As patients with brow ptosis often have an unconsciously high baseline function or tone in the frontalis muscle to correct for longstanding visual deficit, they must be reminded at the time of photography to relax the forehead musculature to get an accurate image of their resting brow position.

Indications

1. Brow and forehead ptosis leading to secondary dermatochalasis with visual field defect greater than 25 degrees as measured by visual field testing. Ophthalmologists and optometrists regularly perform such testing as a screen to determine who may benefit from brow lift or blepharoplasty for functional visual improvement.

2. Facial nerve paralysis: Unilateral brow lift may be necessary to restore brow height for both functional and cosmetic purposes on the side of nerve dysfunction. The goal is to set the static brow height of the denervated side to somewhere between the lowest and highest positions of the opposite dynamic brow.

3. Forehead rhytids: Cosmetic concerns of aging of the upper face are more common after age 40. The brow lift procedure is often performed in conjunction with other facial restoration procedures such as face-lift, mid-face lift, upper and/or lower blepharoplasty, or rhinoplasty. Facial resurfacing techniques should be avoided on the upper face if done concomitantly.

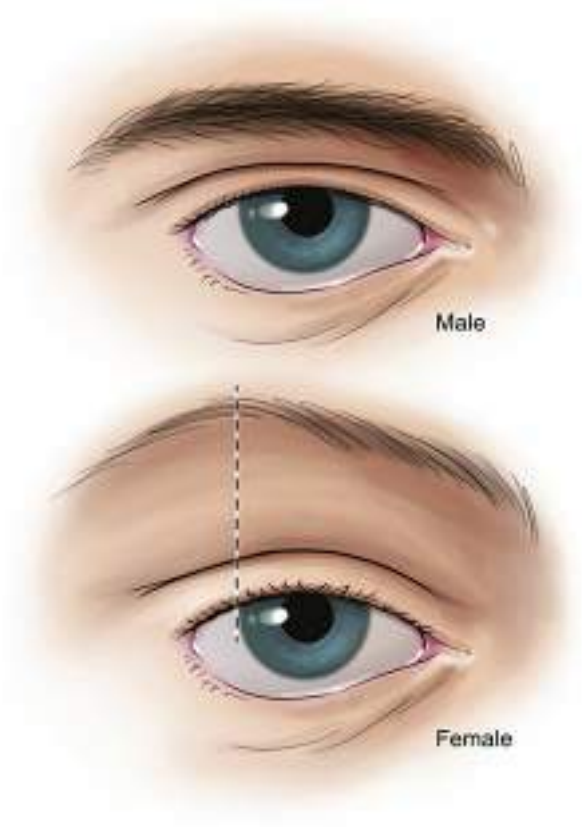

FIG. 157.2 Ideal brow position is relative.

The male brow is typically more inferior in position, has fuller or thicker hair content and may be flatter when contrasted to the female brow. The female brow usually arches laterally and reaches its zenith somewhere around the junction of the medial two thirds and lateral third near a vertical line drawn vertically through the lateral limbus.

4. Horizontal and vertical static glabella "scowl" lines.

Contraindications

1. Patients with wound healing concerns (i.e., smoking or diabetes) generally do reasonably well healing scalp and forehead wounds due to the excellent blood supply to these tissues. Approaches to brow lift that avoid subcutaneous skin dissection should be chosen in this population.

2. General health concerns that may preclude anesthesia should be

considered and investigated.

Preoperative Preparation

1. Hibicleanse scalp and hair wash the night prior to and morning of the operation.

2. Medication restriction list reviewed with the patient 2 weeks prior to the procedure. Anticoagulants are avoided.

3. Cardiac or general health clearance if deemed necessary.

Operative Period

Anesthesia

General: Brow lift surgery may be done under awake sedation but for comfort, patients may prefer a general anesthetic.

FIG. 157.3 Standard instruments used in an endoscopic brow lift procedure (clockwise from top left): bone bridge anchor system, endoscopic camera/light cord/30-degree endoscope with sheath, various straight and curved periosteal elevators, endoscopic insulated grasper and scissor.

Positioning

Supine: Positioning the patient so the cephalic scalp is as close to the upper edge of the operating table is important when performing the endoscopic approach to brow lift as much of the movement of the instruments may be hampered otherwise. Also, using a modified narrow headrest adapter for the operating table is advised for similar reasons.

Perioperative Antibiotic Prophylaxis

One to three grams Ancef is given IV preoperatively. Clindamycin 600 mg IV is given preoperatively when the patient is allergic to penicllin.

Monitoring

Facial nerve monitoring is not necessary.

Instruments and Equipment to have Available

1. For the endoscopic brow lift technique, specialized instrumentation includes (Fig. 157.3):

   a. Multiple straight and curved periosteal elevators with varying tip configurations

   b. Thirty-degree nasal endoscope with specialized sheath to facilitate endoscopic visualization using a standard OR camera/video system and monitor

   c. Specialized insulated curved endoscopic scissors and graspers to facilitate dissection and cautery

   d. Bone-tunnel or Endotine fixation system

2. Typical minor plastic instruments, retractors, and periosteal elevators are necessary for most other brow lift approaches.

Key Anatomic Landmarks

1. Frontal branch of the facial nerve

2. Trigeminal neurovascular bundle

3. Temporalis fascia divestment

4. Lateral orbital ligament

5. Sentinel vein

6. Corrugator supercilii and procerus muscles

7. Ideal brow position (see Fig. 157.2).

Prerequisite Skills

1. Facility with endoscopic technique is necessary to perform the endoscopic approach to brow lift.

Operative Risks

1. Improper plane of dissection: The surgeon needs to understand exactly which plane of dissection is necessary to achieve the desired results as each brow lift technique requires unique and often multiple levels of dissection.

2. Injury to the frontal branch of the facial nerve: Depending on the approach selected, careful anatomical dissection and conservative use of cautery or traction in the region of the nerve path is warranted to help avoid injury and resulting significant disfigurement.

Surgical Technique

With the patient seated in an upright position, manual elevation of the brow is useful to determine the extent of elevation necessary for best results. This can be done in front of a wall-mounted mirror with good lighting having the surgeon elevate the patient's brow from behind the patient.

Plucking of lateral caudal brow hair is a common cosmetic practice to create the appearance of lateral brow elevation. Proper brow elevation often requires lifting of the lateral brow region sufficient to elevate thick brow skin to or above the superior orbital rim. In those patients with

severely thinned lateral brow hair the resultant brow may look "overly raised" when brow hair is used as the primary determinant of proper postop brow position. Identification and preoperative counseling of these patients are important to set expectations. The patient may be encouraged to allow resumption of hair growth in the lateral brow postoperatively.

The goals of any brow lift approach are to raise the brow position and to abrogate the depressing effect of the glabella musculature when possible. Using the approaches outlined below, one can achieve good results tailored to the patient's specific requirements.

Direct Brow Lift

Camouflaging the incision in the upper hair edge of the brow, the direct brow lift technique allows for excellent management of brow position (Fig. 157.4). It is less adequate in the treatment of glabella ptosis and lateral orbital hooding than other brow lift options as the shorter horizontal length of the incision site may limit medial and lateral elevation potential. It is a good choice for use in unilateral facial paralysis cases given its capacity for significant change in brow position using a unilateral well-concealed incision.

1. After marking the incision site with the patient in the upright position, 1% lidocaine with 1:100,000 epinephrine is injected to the operative area.

2. Half-strength betadine solution (betadine solution mixed 50:50 with balanced salt solution) is used to sterilize the brow and eyelid area. Full-strength betadine is used to sterilize the remaining field.

3. A fusiform horizontal incision is created inside the upper row of hairs in the brow hairline taking care to bevel the incision in the direction of the hair shafts. Cutting across upper brow hair shafts may result in loss of hair near the incision. The most superior incision should be beveled to help create an everted skin closure. The horizontal length of the incision should be limited and not extend past the superior brow hair-bearing margin.

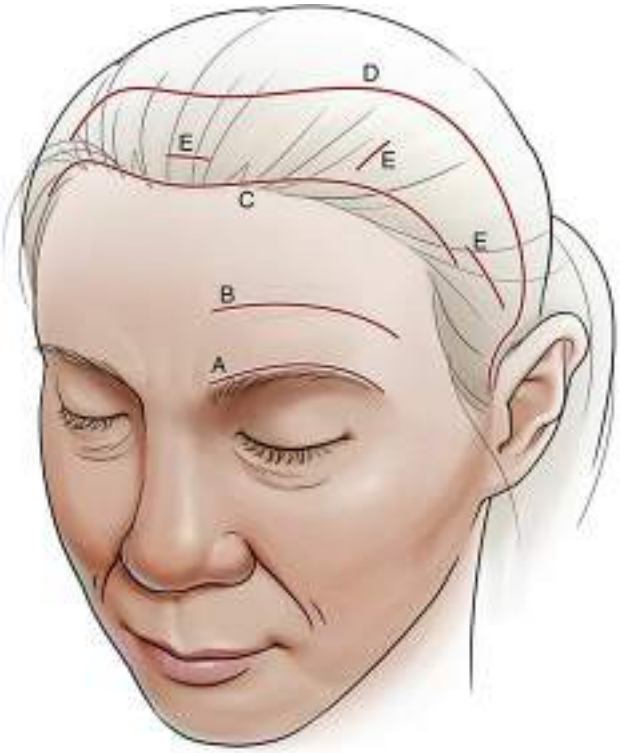

FIG. 157.4 This illustration demonstrates the incision sites used in various brow lift approaches: **(A)** Direct brow lift, **(B)** Midforehead brow lift, **(C)** Hairline incision brow lift, **(D)** Coronal incision brow lift, **(E)** Endoscopic brow lift.

4. Superior edge subcutaneous dissection can be performed to improve forehead rhytids in this region. Detachment of the affected skin from the forces exerted by deeper forehead muscle activity will allow improvement in static rhytids.

5. Medial sub-orbicularis muscle dissection may allow for sectioning of glabellar muscles if necessary.

6. After hemostasis is achieved with bipolar cautery, ptotic orbicularis and frontalis muscle may be sutured to the periosteum of the lower forehead using multiple well-positioned 4-0 prolene simple stitches to achieve adequate correction of lateral, central, and medial brow ptosis.

7. Wound closure using 5-0 pain dysfunction syndrome (PDS) simple subcutaneous sutures oriented to create eversion of the wound edges is necessary. 5-0 prolene subcuticular or 6-0 prolene superficial simple interrupted wound closure is then performed.

Midforehead Brow Lift

This approach to brow lift can be effective in men with unpredictable hairlines. The resulting scar is particularly well concealed when the technique is used in patients with deeper preexisting static forehead rhytids.[2] Given the incision placement proximity to the more mobile inferior forehead tissues, it affords excellent control of brow position along the entire width of the brow. Using a potentially broader horizontal incision than the direct brow lift, it is somewhat better at addressing medial brow/glabella ptosis than direct brow lift, but not as good as other approaches using superiorly based incisions (see Fig. 157.4). The obvious downside to using this technique is a potentially visible scar positioned in the midforehead (see Fig. 157.1).

1. After marking the incision site with the patient in the upright position, 1% lidocaine with 1:100,000 epinephrine is injected to the incision site and supraorbital rim area.

2. Half-strength betadine solution (betadine solution mixed 50:50 with balanced salt solution) is used to sterilize the brow and eyelid area. Full-strength betadine is used to sterilize the remaining field.

3. A fusiform horizontal incision is created in the midforehead taking care to bevel the incision to allow for eversion of the skin edges on closure. The contralateral brow lift incision site should be planned in an asymmetric fashion with each incision site centered on a horizontal rhytid of varying vertical position. This asymmetric scar placement will allow for greater concealment potential. The horizontal length of the incision can be extended to overlap at different heights medially for correction of medial forehead/glabella ptosis and may extend laterally past the lateral edge of the frontalis muscle.

4. Limited subcutaneous superior dissection is performed to allow some eversion of this skin margin upon closure. The inferior subcutaneous undermining may be carried inferiorly more extensively in the plane just above the frontalis muscle to the level of the brow if necessary. Great care must be taken in lateral dissection to avoid injury to the frontal branch of the facial nerve and in medial dissection to avoid the supraorbital neurovascular bundle.

5. The amount of skin removed is based on the lift required and takes

some experience to judge adequately. Over excision of skin must be avoided. Fixation is achieved using 4-0 prolene to secure the soft tissues of the brow and orbicularis to superior periosteum.

6. Sharp dissection near the midline allows transition to a deeper subperiosteal plane of dissection giving access to the glabella musculature. Surgical sectioning of the corrugator and procerus muscles, if deemed necessary, is possible using this approach.

7. After meticulous hemostasis is achieved with bipolar electrocautery, the wound is approximated using 4-0 PDS simple interrupted subcutaneous sutures. 6-0 prolene simple interrupted or vertical mattress sutures allow surface closure with an emphasis on eversion of the wound edges.

Hairline Incision and Coronal Brow Lift

The hairline and coronal brow lift techniques are carried out in similar fashion but vary in design and placement of the incision. The coronal incision technique raises the position of the hairline, whereas the hairline incision technique lowers the hairline position and may result in a potentially more visible scar. Both techniques allow for: (1) excellent elevation of the full brow including lateral orbital hooding; (2) reduction in frontalis, corrugator and procerus induced rhytids; and if needed, (3) correction of glabellar skin ptosis.[3]

1. Incision sites and the entire forehead are infused with 1% lidocaine 1:100,000 epinephrine.

2. The curvilinear coronal incision (see Fig. 157.4) is placed in a position such that with intended removal of 1 to 2 cm of skin from the anterior leading edge of skin, the resultant incision will be located roughly 3 cm posterior to the hairline. The incision should be created parallel to the hair follicles if possible. The lateral extension of the incision may curve anteriorly downward to extend to the level of the helical root if necessary.

3. The hairline incision is created a few millimeters behind the hairline with the incision created in a beveled fashion to cut across the anterior hair follicles. This allows for growth of hair through the skin closure to aid in camouflaging the scar.

4. Medial exposure and dissection from the above approaches are facilitated anteriorly and inferiorly in the subgaleal plane to a point approximately 3 cm above the brow.

5. Sharp dissection to the subperiosteal plane is performed from this level inferiorly to the nasal bones taking care to preserve the supraorbital and supratrochlear neurovascular bundles.

6. The lateral incisions of each approach extend to the temple hair where dissection is carried down to the superficial layer of the deep temporal fascia. Anterior dissection and exposure to the orbital rim is carried out in the layer between this fascia and the temporoparietal fascia that contains the frontal branch of the facial nerve.[4]

7. The arcus marginalis is released at the level of the orbital rim allowing mobilization of the lateral brow.

8. In either technique, an adequate amount of skin is excised anterior to the incision and multilayer wound closure facilitates sufficient tension for brow fixation. Some surgeons suggest using tissue adhesives or bone-anchoring techniques for adjunct brow support during the healing phase.

9. For closure of the coronal incision wound, subcutaneous 4-0 vicryl deep sutures and superficial staples are used. This method is used for the hair-bearing lateral closure in the temples of the hairline incision technique. The medial forehead hairline closure is performed with 4-0 vicryl deep interrupted sutures and 5-0 or 6-0 prolene simple interrupted and/or vertical mattress sutures.

Endoscopic Brow Lift

This procedure offers some advantages over the options described above. It allows for smaller, well-concealed incisions behind the frontal and temporal hairlines (Fig. 157.5). It offers potential for less forehead and scalp numbness and the ability to apply multivector brow correction with central superior vector and lateral oblique vector lift forces. The approach may also allow for earlier resolution of tissue swelling and less blood loss than other brow lift options.[5]

The approach may not be useful in patients with a convex forehead and high hairline position as the endoscope may not be able to visualize

inferior medial anatomy well. High hairlines may be elevated further using this technique and the relatively high point of fixation may limit control of brow shape in some patients. The use of the Endotine fixation system and preoperative neurotoxin adds expense to this approach.

1. One week prior to the procedure, neurotoxin is administered to the brow depressor muscles of the glabella and lateral orbicularis to assure less inferior pull on the forehead tissues after the procedure while the periosteum is healing back to the skull in the elevated position. While evidenced-based support for this practice may be lacking, we have noted that this measure can be helpful in our patient population.

2. Incision sites are marked and injected with 1% lidocaine, 1:100,000 epinephrine. Local anesthetic is infiltrated in the skin of the brow, across the forehead, and along the conjoint tendon bilaterally.

3. Medial dissection is facilitated using a central horizontal 1.5 cm incision and two vertical 2 cm incisions placed over the intended apex of the lateral brow bilaterally (Fig. 157.6).

4. Directed (nonendoscopic) subperiosteal dissection is widely carried out using a curved periosteal elevator downward to a level roughly 1.5 cm above the orbital rims and posteriorly to the vertex scalp and beyond as can be reached.

FIG. 157.5 Before **(A, C)** and after **(B, D)** photographs demonstrating typical results from endoscopic brow lift technique. (Patient A, C underwent lower blepharoplasty and rhinoplasty as well.)

5. Oblique temporal incisions are created for lateral dissection. Directly visualized dissection precisely on the surface of the superficial layer of the deep temporal fascia overlying the temporal muscle is performed using an elevator for wide field elevation of the flap to a point roughly 2 cm lateral to the orbital rim (see Fig. 157.6 shaded area).

6. Using a 30-degree endoscope in a protective sheath, dissection is visualized for dividing the conjoint tendon between the medial subperiosteal and lateral subgaleal planes at the superior temporal line (Fig. 157.7).

7. Endoscopic release of forehead tissue from bone and deep fascia are necessary to allow superior mobilization of the brow tissues. In the lateral dissection a confluence of fascia along the conjoint tendon makes dissection more difficult. In anterior dissection from this point toward the lateral canthus care should be taken to spare the sentinel vein so as

not to predispose the patient to more prominent visible superficial periorbital/temple veins postoperatively. Also, a branch of the temporozygomatic sensory nerve often accompanies this vein. Damage to this nerve may cause unnecessary numbness in the zygomatic area. Release of the precanthal ligament and superior orbital ligament are necessary to maintain long-term results using this technique.

8. Endoscopic facilitation of medial dissection is performed to release periosteum at the level of the orbital rim, glabella, and superior temporal crest (see Fig. 157.6 shaded area). Taking great care to spare the supraorbital neurovascular structures, the glabella muscles (corrugator and procerus) are divided. Superficial to the corrugator the depressor supercilii are encountered and divided as well. Some surgeons suggest making a horizontal myotomy of the orbicularis oculi as well. Over resection of the corrugator muscle can lead to an unpleasing widened inter-brow distance postoperatively.

9. Lateral fixation is achieved using a 3-0 PDS suture securing the anterior temporal flap in an oblique vector posterosuperiorly to the temporalis fascia. Staples are used to close the wound.

10. Central fixation is achieved in the two paramedian vertical incision sites using one of many options. The Endotine system is an easy-to-use bone anchor that absorbs over time and provides for temporary firm superior fixation of brow, forehead, and scalp tissues. Alternatively, a cortical tunnel system can be used to allow suture fixation of forehead skin to a tunnel drilled into the outer cortex of the skull. Some advocate for tissue glue use as the sole fixative while others recommend using removable external screw fixation. Wounds are closed superficially with staples.

FIG. 157.6 Endoscopic brow lift dissection limits and incision site locations. **A,** midline central and **B,** Para median central cavity incisions. **C,** Temporal incision site. **D,** Frontal branch of facial nerve course predicted by a line drawn from the lower tragus to the temporal crest 1.5 cm superior to the tail of the brow.

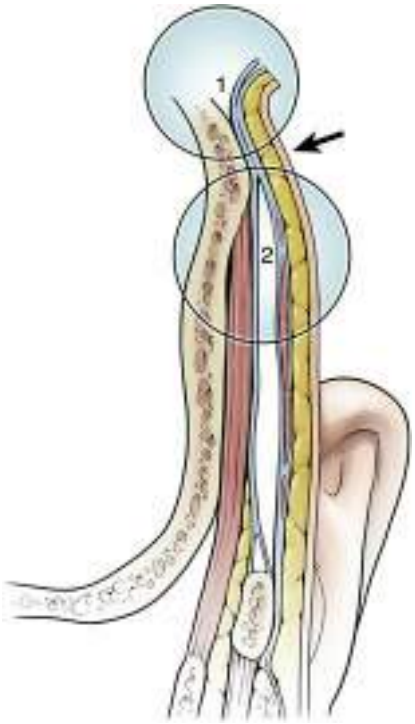

FIG. 157.7 Arrow marks the temporal crest and transition between (1) medial subperiosteal and (2) lateral subgaleal dissection planes.

Common Errors in Technique

1. Inadequate dissection and release of procerus and corrugator muscles.

2. Inadequate dissection and release of the arcus marginalis and lateral orbital tissues during endoscopic brow lift.

3. Improper wound closure techniques leading to visible and unsightly scars. Eversion of wound edges during closure and postoperative light dermabrasion will lead to less visible scars.

4. Inadequate correction of brow position can occur due to error in surgical judgment when performing either excisional brow lift or endoscopic techniques. Individual forehead skin laxity/tightness and forehead/scalp mobility vary greatly between individuals. This must be taken into consideration when assessing how much skin/muscle to remove/plicate, or how much superior vector tension to place during endoscopic procedures. Experience and deep consideration are necessary to determine the proper brow position for long-lasting functional and

cosmetic results.

5. Extensive dissection of the forehead skin in the subcutaneous pre-frontalis plane should be avoided as this may result in skin necrosis.

Postoperative Period

Postoperative Management

1. Pain management: Though not necessarily an extremely painful recovery, pain management is necessary for the patient's comfort, but also for the prevention of undo blood pressure elevation due to pain. This is extremely important for prevention of excess bruising, swelling, and potential hematoma formation. It is a significant point of discussion emphasized in preoperative counseling of all patients. Certain patients have a preconceived notion that "pain medicines are bad to take." These individuals need to be reassured that when used properly they can facilitate recovery safely and not be addictive.

2. Blood pressure control: Thoughtful discussion of preoperative blood pressure status with treatment (if necessary) carried through the postoperative period is necessary to avoid excess risk of edema, bruising, and hematoma.

3. Swelling and bruising control: Elevating the head of the bed for several nights after the procedure is recommended for control of edema around the eyes and temple. Salt avoidance is recommended postoperatively. Timely pharmacologic intervention for postoperative nausea is necessary to avoid excess swelling and bruising secondary to the forceful retching that accompanies vomiting.

4. Anticoagulants are avoided for a two-week postoperative period if possible.

5. Forehead skin sutures are removed 5 to 7 days postoperatively depending on their location. Scalp staples located in hair-bearing regions are left in place for 10 days.

6. Skin closure sites are treated with mupirocin ointment twice daily. Scalp wound closures are cleansed with peroxide periodically to keep them clean, but no ointment is used as it seems unnecessary to prevent

infection and may tangle and mat the hair significantly. Hair washing is allowed over the scalp wounds after 48 hours. Hair coloring is to be avoided for several weeks after surgery (in all seriousness, a discussion may be had with the patient to have hair colored just prior to the procedure to avoid consternation on their part after surgery).

7. Keflex 500 mg po ENM is prescribed for 7 days.

8. Preoperative discussion regarding restricted postoperative physical activity is strongly recommended. Patient expectations should be set to anticipate 10 days of limited activity to avoid straining or increased heart rate.

Complications

1. Hematoma: This is a rare complication if preoperative bleeding risks are properly evaluated and controlled. Meticulous hemostasis is the most important feature in preventing hematoma formation. The use of postoperative pressure dressings or wound drains is not usually necessary.

2. Infection: This is rare, in part due to the high degree of blood flow to the scalp and forehead skin. Perioperative antibiotic prophylaxis is recommended.

3. Asymmetry of brow position: If the initial preoperative evaluation reveals resting asymmetry, this should be corrected if possible. Many preoperative asymmetries are noted to be functional in that an unconscious application of uneven frontalis muscle activity is to blame due to the urge to "unhood" the vision from the dominant eye visual field. Often this resolves if the procedure succeeds in resolving the superior visual deficit but this should be addressed with the patient preoperatively.

4. Injury to the frontal branch of facial nerve: This can be temporary or permanent and results in significant and disfiguring upper facial dramatic functional asymmetry. Great care should be taken in the elevation of tissues near the facial nerve. Proper technique used to help protect the facial nerve during each surgical approach is emphasized in the Surgical Technique section.

5. Paraesthesia or numbness of the forehead and frontal scalp in the distribution of the first branch of the trigeminal nerve: direct, midforehead, and hairline incision brow lift approaches may have numbness above the level of the incision. During manipulation of the neurovascular bundle using the endoscopic, coronal, or trichophytic approach, great care is taken to preserve the structures, but traction on the nerve often leads to some supraorbital or supratrochlear neural dysfunction. The nerve deficit may be temporary or prolonged but is not necessarily permanent as sensation may return even up to a year out from the procedure.

6. Visible scars: Meticulous wound closure technique must be applied to the closure of wounds during brow lift procedures of all types. Counseling the patient regarding the potential placement of visible scars is of paramount importance during the proper preoperative selection of the surgical approach.

7. Hair loss: Incisions created behind the hairline usually heal well and are very well concealed. Hair loss around incision sites is possible but this is often temporary. Judicious use of electrocautery and gentle tissue handling technique is warranted to avoid this outcome.

8. Overcorrection leading to a "Surprised" look: Fortunately, both cosmetic and functional brow lift patients are notably improved from the preoperative state using judicious technique and modest resection of glabella musculature; thus, obviating the need for extreme corrective forces to be applied to the surgical technique.

Alternative Management Plan

1. Chemical brow lift: Selective use of neurotoxin to relax brow depressor muscles.

2. Ultherapy: Directed use of transcutaneous ultrasound energy to create brow elevation.

Discussion

Treatment of the upper face and forehead in the aging face patient remains an important component of overall facial rejuvenation. While in

some surgeons' practices brow lift surgery has become less frequent over the last 10 years, this procedure retains a key role in optimizing outcomes.

As in all surgery, brow lift results are optimized when the patient is properly selected and the appropriate technique is applied. If brow lift surgery is used in the wrong patient (e.g., when the brows have not significantly descended with age) the result will be an appearance that does not seem natural to the patient. Alternatively, if the correct patient is selected, but overzealous techniques are used, results like the "surprised look" are possible. Neither of these errors should compel the surgeon to ignore the potential of brow lifting. The key is to recognize what the appropriate indications are to perform a brow lift, to select the optimal brow lift approach given the patient's particular anatomy, and then to apply this technique judiciously. Brow lift surgery remains a powerful tool to improve the cosmetic appearance and functional status of the patient.

Evidence Medicine Question

Is there evidence that endoscopic brow lift results can be expected to persist over the longer term?

Yes. Jones BM et al. reported that using objective measurements and validated subjective scoring systems that a brow lift produces a subtle elevation, with a natural eyebrow morphology close, with minimal long-term relapse.

Jones BM, Lo SJ: The impact of endoscopic brow lift on eyebrow morphology, aesthetics, and longevity: objective and subjective measurements over a 5-year period. Plast Reconstr Surg 132(2):226e–238e, 2013. http://dx.doi.org/10.1097/PRS.0b013e3182958b9f.

Editorial Comment

In the typical patient presenting with primarily lateral brow ptosis, a limited incision of 4 to 5 cm in length in the temporal scalp can elevate the temporal brow. This technique places the deep supraorbital nerve branches that innervate the frontoparietal scalp at minimal risk, does not require endoscopic instruments, and can be combined with

transpalpebral resection of the corrugator supercilii muscles and procerus muscle.[6]

Review Questions

1. If a patient is felt to have a lower frontal hairline and the surgeon wishes to elevate the hairline as well as improve the brow position, what is the best brow lift approach?

   a. Endoscopic

   b. Direct

   c. Midforehead

   d. **Coronal**

2. If the surgeon is planning both an upper lid blepharoplasty and a brow lift procedure, which procedure should be done first?

   a. Upper lid blepharoplasty

   b. **Brow Lift**

   c. It does not matter

3. A forehead morphology that has a notably convex shape makes the endoscopic approach to brow lifting more challenging?

   a. True

   b. **False**

Face lift

Mark Mandell-Brown

Introduction

Much has been written about the aging face. The face lift procedure (rhytidectomy) is a critical component in addressing the issues of volume loss, sagging tissues, deep rhytids, jowling, and skin stretching. There are numerous trademarked names and even more nontrademarked names including "Vampire Lift," "Weekend Face lift," "Advanced Lift," "Quick Face lift," mid face lift, deep plane face lift, "Swift Lift," "Liquid Face lift," and composite lift.

While many of these are promoted for marketing in a highly competitive environment, the now defunct "LifeStyle Lift" with its multimillion dollar national marketing campaign brought face lift procedures to the attention of the general public and demonstrated the popularity and demand for rejuvenation procedures.

The public, in its thirst for noninvasive facial rejuvenation procedures, has embraced nonsurgical radiofrequency devices such as the Venus Legacy, Vanquish, and minimally invasive Thermi Lift as well as cryotherapy devices such as Cool Sculpting. Brief one time or repetitive nonsurgical treatments have caught the public's fancy.

The "Liquid" Face lifts in which hyaluronic acids such as Juvaderm, Voluma, Perlane or hydroxyapatite, (Radiesse) or poly-L-lactic acid (Sculptra) are used to fill out the volume loss with aging and heredity are increasingly popular. These products can "lift" the soft tissue and restore a more youthful appearance. Adipose tissue transfer has also gained in popularity to fill out the tear trough and add facial cheek volume. The "Vampire Lift" capitalizes on the public enchantment with vampires and uses platelet-rich plasma obtained from the patient's blood. This technique, when added with soft tissue fillers, supposedly improves

facial rejuvenation by adding volume with healing blood factors.

Minimally invasive face lifts using barbed sutures have also been used, but many of these techniques have been removed by the Food and Drug Administration (FDA). However, the Silhouette Lift has recently gained popularity with an absorbable suture that suspends the sagging facial tissues.

Fortunately, there will always be demand for a well-performed face lift procedure. The key to obtaining a good result and avoiding complications requires knowledge, critical assessment, and surgical expertise.

Key Operative Learning Points

- In-depth knowledge of facial and neck anatomy is essential for the successful rhytidectomy.
- Placement of incisions is critical to preserve the natural hairline in the temple and posterior neck.
- Careful planning is required to preserve the sideburn tuft of hair in a natural nonraised position.
- Preservation of the facial nerve is based on understanding the three key danger points. Injuring the temporal branch of the facial nerve can occur halfway between the lateral orbit and the temple hairline where the nerve is fairly superficial as it courses in the superficial temporalis fascia.
- The superficial muscle aponeurotic system (SMAS) was named by Mitz and Peyronie to describe the fascia system that is just deep to the facial skin and subcutaneous tissue. The SMAS is contiguous with the platysma in the neck.[1]
- Erb's point is located along the posterior border of the sternocleidomastoid muscle, midway between the mastoid and the clavicle. The greater auricular nerve emerges anteriorly to supply sensation to the ear and posterior cheek. The spinal accessory nerve courses along the posterior edge of the sternocleidomastoid muscle to supply motor function to the trapezius muscle.[1] (Fig. 158.1)

- With deep plane face lift techniques, Stensen's duct must be preserved, as it courses parallel to the buccal branch of the facial nerve. The duct travels in a line from the tragus to the corner of the mouth. What is deep plane? It is defined as the cleavage plane separating the SMAS from the deep cervical fascia.

Preoperative Period

History

Consultation: As with all cosmetic surgeries, the consultation is critical for examining the patient and the patient's motivation, medical history, and performing a physical examination. A questionnaire can be helpful for determining the patient's area of interests, prior procedures, and a brief psychologic profile to determine whether any of the patient types to avoid are evident.

1. Areas of interest: Circle all that apply: sagging neck, face jowling, brow position, wrinkles, skin discolorations, wrinkles, smoker's lines.

2. Prior cosmetic procedures

3. Past medical history—medical history especially diabetes mellitus, coagulation defects, use of anticoagulants, herbal products, reactions to anesthesia, scarring

4. Past surgical history—cosmetic and noncosmetic

5. Social history—married, divorced, separated/work history

6. Psychologic history—psychologic counseling, life changes, holding grudges, suicide ideation, reasons for seeking face lift, sleep and eating habits to evaluate for depression

7. Smoking history—Some surgeons insist on a 2- to 3-week period of cessation of smoking prior to the face lift and 3 weeks after the surgery. Others refuse to operate on smokers with concern for skin flap viability. Some surgeons perform a urine nicotine test the morning of surgery and cancel the face lift if the test is positive. Others may have their patients sign a waiver that they have been informed that smoking may jeopardize their healing.

8. Computer imaging—There are 2D and 3D systems available. The photos can be used in the consultation to demonstrate the surgeon's anticipated but not promised goals of surgery. Incisions can also be demonstrated to the patient. The computer imaging enhances communication between the patient's goals and what the surgeon believes is an obtainable result.

Physical Examination

Assessing the degree of platysma banding, jawline jowling, submental fullness, nasolabial jowling, brow ptosis, masseter hypertrophy, ptosis of submandibular glands, tear trough prominence, mid-cheek hallows, skin laxity, and Fitzpatrick skin type

Imaging

Photographs aid in evaluating the patient and recording for the medical record.

- Frontal view, lateral views, oblique views, animated views to evaluate the function of the facial nerve preoperatively. Consistent positioning of the patient for pre- and postoperative analysis is important. Using a solid blue or black background also aids by eliminating background distraction.

Indications

Determining the patient's motivation for a face lift procedure is as important as knowledge and skill in performing a face lift. Patients who have realistic goals and genuine interest in looking better but not perfect and understand the importance that guarantees cannot be provided are excellent candidates for the face lift.

Contraindications

Proper patient selection is critical to having a patient who is satisfied with his or her result and avoiding a malpractice suit. An excellent review of patient types shows to avoid the following[2]:

1. The overly narcissistic patient

2. The single immature male who is obsessive neurotic (SIMON) patient

3. The body dysmorphic patient

4. The unstable patient undergoing major lifestyle changes—for example, loss of job, divorce

5. The culturally estranged patient—desires major change to alter natural culture features

6. The exceptionalism patient—the patient who refuses to talk to staff, fill out paperwork, refuses to follow medical instructions, overly demanding

7. The unrealistic patient—brings photos of his or her youth—wedding photo, graduation photo—and expects to have the surgeon recreate

8. The multiply operated patient—lavishes praise on you and denigrates prior surgeons

Preoperative Preparation

Cessation of smoking at least 3 weeks prior to surgery is advocated by some physicians. Discontinuing aspirin, vitamin E, fish oil, and other platelet-inhibiting herbal products or medications is recommended 2 weeks prior to surgery. Arranging for transportation and an overnight caretaker following surgery is essential for procedures performed with Intravenous (IV) sedation or general anesthesia.

Operative Period

Anesthesia

- The selection of the anesthesia technique is determined by the surgeon's preference, patient's preference, and the face lift technique selected. Some surgeons prefer general anesthesia, especially, for the more extensive face lift procedures.
- Other surgeons prefer IV sedation and an oral airway with oxygen cannula and carbon dioxide monitor.

- Sequential compression is recommended to prevent deep vein thrombosis.
- Public attention has been piqued with the ability to perform face lifts under local anesthesia. Surgeons often use oral anxiolytics or hypnotic medications. It is still important to monitor the patient's vital signs.
- Most surgeons use 1% xylocaine with 1,100,000 epinephrine along the incision line and in a field block.

Positioning

- The patient is placed supine typically with arms tucked comfortably by the side.
- The surgical table must allow convenient access to the patient's head.
- Some surgical chairs recline and also serve as a recovery chair.

Perioperative Antibiotic Prophylaxis

- A cephalosporin or other antibiotic is given 1 hour prior to surgery either intravenously or orally.
- Many surgeons prescribe continued oral antibiotic for a period of 5 to 7 days following surgery.
- With increased antibiotic resistance, there is a trend to give a one-time preoperative dose.

Monitoring

- Blood pressure, pulse oximetry, and Electrocardiogram (EKG) should be monitored for IV sedation or general anesthesia.
- It is important to monitor the patient's temperature when agents that trigger malignant hyperthermia are used.

Instruments and Equipment to Have Available

- Double skin hooks
- Senn retractors
- Army-Navy retractors
- Knife handles and blades
- Metzenbaum scissors
- Face lift scissors
- Needle holders
- Tissue forceps (Griffith-Brown, Castroviejo)
- Headlight
- Lighted retractor
- Iris scissors
- Suture scissors
- Liposuction cannulas
- Adipose transfer cannulas
- Monopolar and/or bipolar cautery

Key Anatomic Landmarks

Skin: laxity and rhytids

Muscles: zygomaticus major and minor, masseter, platysma, orbicularis oculi, frontalis, procerus, corrugator supercili, orbicularis oris, masseter, depressor anguli oris, sternocleidomastoid, temporalis

Distribution of adipose tissue

Nerves: facial nerve-temporalis, zygomaticus, buccal, marginal, cervical, greater auricular, trigeminal-supraorbital, infraorbital, supratroclear, mentalis

Vessels: facial artery and vein, superficial temporal artery and vein, jugular vein—external and internal, carotid artery

Salivary glands: submandibular gland, parotid gland, and Stensen duct

Skeletal: cervicomental angle, mandible, zygoma, mastoid, frontal bone, zygomatic arch

Retaining ligaments: zygomatic, masseter, mandibular, parotid

Prerequisite Skills

- Training in Otolaryngology, Oral Maxillofacial Surgery, or Plastic Surgery is important for a thorough understanding of the anatomy, proper handling of soft tissue, and nuances of the surgical procedure.
- Attending face lift courses, watching videos, and using fresh cadavers can aid the surgeon in developing the skills to perform face lift surgery.

Operative Risks

Controlled blood pressure, proper anesthesia with adequate level of sedation and monitoring, adequate preoperative screening for coagulopathies, and collagen vascular disorders can all decrease operative risks. Attention to detail to achieve meticulous hemostasis, preservation of the facial nerve, and avoiding excess wound tension on the skin flaps will decrease surgical risk. See "Postoperative Period: Complications."

Surgical Technique

Planning the Incision

1. The three critical areas for planning the incision involve the temple sideburn tuft, the tragus, and the postauricular hairline incision.

- The incision can follow the temple sideburn beveled to protect the hair follicles. This protects the sideburn hair and preserves the sideburn in its natural position. However, the incision must be carefully closed to avoid a visible scar.
- Alternatively, the incision can extend superiorly into the temple hair. The incision is hidden in the temple hair. However, the sideburn hair is

elevated 1 to 2 cm with the flap elevation. Only if the patient has a very low sideburn is this option used. One of the telltales of a face lift or repeat face lift is that this option continuously elevates the sideburn hair in an unnatural more superior manner.

- The incision can be made pretragal or posttragal. The pretragal incision requires less contouring to recreate a natural tragus. For men, the pretragal incision preserves the nonhair-bearing area anterior to the tragus. The hair bearing flap is advanced just to the anterior vertical incision, and no hair is brought to the tragus, which is posterior to the incision.
- The posttragal incision is more hidden. However, careful reconstruction of the tragus must be undertaken to avoid amputating the tragal cartilage and producing a flattened appearance. In females, the posttragal incision is typically used. For men, the bearded skin will be brought into the tragus—necessitating shaving in this difficult area or having laser hair removal or other means to de-epilate the hair on the tragus.
- The posterior neck incision can be planned to follow the neck skin/hair junction or proceed posteriorly into the occipital hair. Following the hair/neck skin junction makes it less likely to stair step the hairline, applies less traumatic shock to the hair follicles, and eases closure.
- The advantage of planning the incision into the occipital hair is that the incision is hidden for those who wear their hair up or favor short hairstyles. However, shock to the hair follicles may cause iatrogenic alopecia and a stair-stepped pattern if the flaps are not properly aligned.
- Patients are given the options for each of these designs so that they are involved in the planning and are properly informed as well as take ownership of the ultimate decision. Finally, a "time out" sheet indicating the placement of the incisions is reviewed the morning of surgery and signed off by both the patient and the surgeon on a facial diagram sheet.

Flap Design

There are a multitude of cheek/neck flaps and techniques. The more

commonly used flaps include skin flap, treatment of SMAS with plication versus imbrication, high SMAS lift, "S" lift, and deep plane face lift.

1. For some patients with minimal jowling and only mild skin laxity or in patients who desire a tuck up lift after prior adequate treatment of the SMAS, a skin flap may suffice.

The incisions are drawn preoperatively and demonstrated and agreed by the patient. The incision is made with the 15 blade on a Bard Parker handle. Nonpenetrating towel clamps are then used to provide traction and elevate the flap with face lift scissor dissection. Multiple tunnels are created by spreading the scissors in the superficial subcutaneous plane. Spreading is performed parallel to the facial nerve, and the multiple tunnels are connected with the face lift scissors beneath the skin flap. Hemostasis is achieved with the bipolar cautery in the area of the branches of the facial nerve or greater auricular nerve. Monopolar cautery may be used along the incision edges.

2. Skin flap

- The skin flap may be undermined from 4 to 7 cm anteriorly in the cheek and/or neck area. The excess skin is then redraped posteriorly and superiorly applying traction with temporary regular width staples or penetrating towel clips at two key areas—superiorly near the anterior auricle and upper sideburn and posteriorly near the mastoid. The excess skin is then trimmed around the ear with the Metzenbaum scissors.

  Note: To avoid a pixie ear or pulling inferiorly in an unnatural position, absolutely no tension can be placed around the ear lobule. Undue tension will result in a "pixie" or scarred down ear lobe.

- The postauricular skin can be tacked after making darts with the 15 blade and approximating the dart with a staple bringing the neck skin to the incision. Several Burow triangles are thus created, and the excess skin can be excised with the 15 blade.

  Note: Excess posterior skin of the neck can be treated by advancing the skin of the posterior neck skin toward the ear or by extending the incision posteriorly and creating a final Burow triangle to trim the excess skin.

3. Treatment of adipose tissue

The second component to consider is the subcutaneous and deep subplatysmal adipose tissue. Various techniques to improve this layer include:

- Once the skin flap is elevated, open tubing suction of the cheek and neck flap may be used. The sterile suction tubing can be connected to high wall suction, and the excess fatty subcutaneous tissue can be liposculptured.

Note: Avoid suctioning directly on the subdermal adipose tissue just deep to the skin with either the open tubing method or the cannula method. This will create indentations on the skin surface or thin the skin to the point that a reticular capillary pattern occurs on the skin. Direct subdermal suction may also compromise the skin vascular network and cause necrosis of the skin.

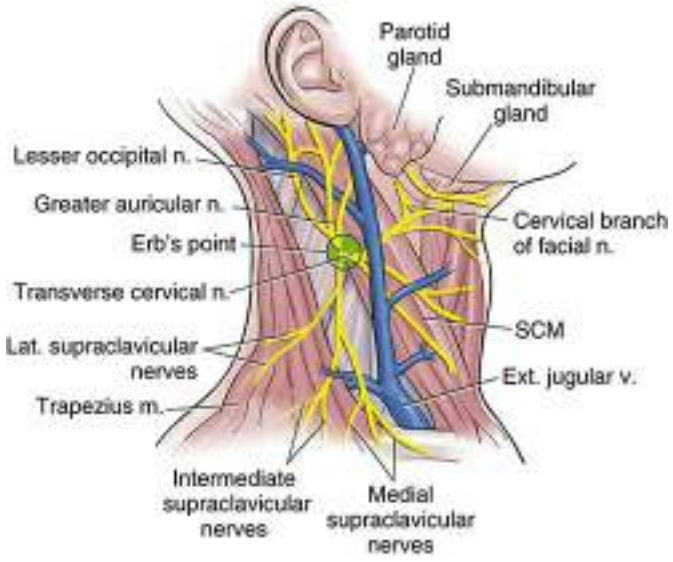

FIG. 158.1 Erb's point is an anatomic landmark where the greater auricular nerve and spinal accessory nerve are located along the posterior edge of the sternocleidomastoid muscle halfway between the mastoid process and the clavicle. When performing flap elevation, the greater auricular nerve courses very superficially over the sternocleidomastoid muscle. The spinal accessory is deeper and courses posteriorly, but it can be injured with posterior neck flap elevation.

- Cannula method can also be used. There are numerous facial cannulas of all sizes that can be connected to high wall suction or an aspirator unit. The two options for cannula liposuction include using tumescent anesthesia along the cheek and neck. Then prior to flap elevation, perform liposuction (through 2-mm small openings along the planned incision) in the cheek, neck, and submental area. Then the skin flaps can be elevated as the skin is already undermined with the liposuction tunnels.
- Alternatively, once the skin flaps are partially elevated, under direct vision, the cannulas can be used to sculpt excess adipose tissue in the cheek and jawline as well as directly through a submental incision.

  Note: Always keep the cannula parallel to the skin. Use caution in the neck around the external and internal jugular vessels.

4. Treatment of SMAS imbrication versus plication

- *Imbrication* is overlapping the aponeurotic layer as in fish scales or roof tiles. *Plication* is folding and suturing the aponeurotic layer. No undermining is performed, and the SMAS is tacked over the parotid fascia. With imbrication, the SMAS is undermined and advanced posteriorly or superiorly and sutured to the underlying parotid-masseteric fascia in the cheek or the deep fascia in the temporalis (Fig. 158.2).
- Plication may be the SMAS treatment of choice for the novice face lift surgeon or for some patients with minimal jowling. Permanent sutures such as a 2-0 Ethibond can be used to anchor the SMAS without undermining. Four or five sutures can be placed to overlap the SMAS in preauricular and neck deep fascia. This carries less risk of injury to the facial nerve or parotid duct since no undermining is performed.
- Imbrication is the procedure of choice for more extensive jowling. The SMAS is undermined starting at a line drawn from the outer canthus to the angle of the mandibular angle. Metzenbaum scissors can be used to spread in a direction parallel to the facial nerves. Some surgeons prefer to identify the nerves while undermining, and some prefer to maintain a fascial layer over these essential motor nerve branches. When close to the facial nerves while using bipolar cautery for hemostasis, the assistant should be watching for facial muscle twitching to warn of the proximity to the facial nerve branches.

FIG. 158.2 Incision planning can be individualized for the patient's hairline and goals. The sideburn is preserved without further elevation *(green)*. If the incision is made superiorly into the temporal hair *(black)* the sideburn tuft is raised as the face lift flap is advanced superiorly. However, this incision is more hidden compared to the sideburn *(green)* incision. The incision then extends along the pre- or posttragal area. The posttragal *(green)* incision is more hidden. However, bearded skin will be advanced to this line, so shaving over the tragus may necessary for bearded skin. The pretragal *(red)* incision may be visible in some patients, but the bearded skin will be advanced only to this line and not further posterior onto the tragus. Posteriorly, the incision follows the postauricular sulcus and then curves either along the hairline *(green)* or into the hair *(blue line)*. For patients who have short hair, the hair incision is more camouflaged.

- The SMAS is undermined for 3 to 5 cm in the cheek and neck area and then advanced posteriorly and superiorly to create a tighter sling that is anchored with 2-0 Ethibond or similar permanent sutures to the

underlying deeper fascia. In some thin patients, the SMAS may be fairly attenuated, and creating a SMAS sling to plicate may be challenging (Fig. 158.3).

- The high SMAS lift is useful for patients with deeper nasolabial furrows and midface jowling.[3] For these patients, the SMAS is undermined above the zygomatic arch. More extensive undermining is required to treat the perioral, infraorbital, and midface. However, less undermining is performed in the neck area, preserving playsmal/skin attachments. The parotidomasseteric and zygomatic ligaments are released. The SMAS is then secured in an oblique direction parallel to the zygomatic major muscle. The SMAS is anchored to the deep temporalis fascia (see Fig. 158.3). Thorough knowledge of the temporal branch of the facial nerve is required to avoid injury as it traverses over the zygomatic arch to innervate the fontalis muscle.

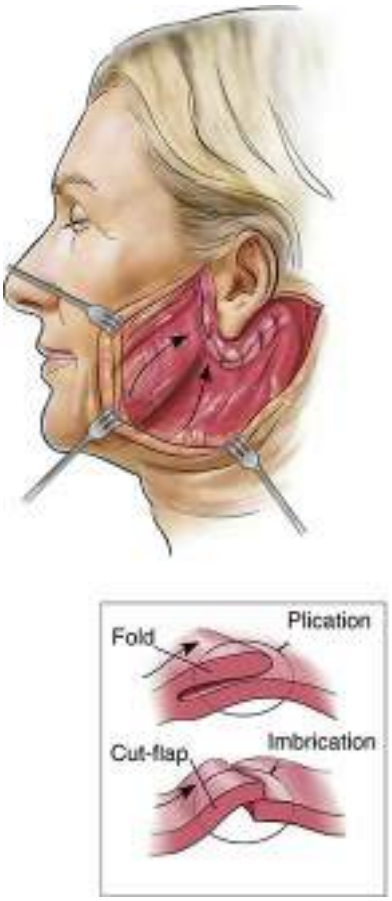

FIG. 158.3 Plication and imbrication are diagrammatically illustrated. Plication is folding tissue layers over and

securing with sutures. Imbrication involves undermining and advancing the redundant tissues prior to suturing.

S Lift

- The original S lift is a short-flap face lift that utilizes a purse string suture "O" plicating the SMAS to the fascia of the zygomatic arch.[4] This "O" suture can be combined with "U" and "M" purse string sutures creating a longer flap with imbrication of the SMAS after vertical and lateral partial SMAS resection. The purse string sutures close the SMASectomy. To protect the temporal branch of the facial nerve, the zygomatic fascia is secured 1 cm anterior and inferior to the temporal nerve over the zygomatic arch.
- The "U" suture closes the vertical SMASectomy with a 2-0 Vicryl extending 2 cm anterior to the skin incision and extending from the zygoma arch fascia to a point 1 to 2 cm below the mandible with small purse string bites.
- The "O" suture closes the lateral SMASectomy with a 2-0 Vicryl in the direction of the nasolabial fold and 30 degrees anterior to the "U" suture anchoring the resected SMAS edge to the zygomatic arch periosteum with purse string bites.
- The "M" suture is used to elevate the malar pad by using a 3-0 Vicryl to secure the malar pad vertically to the lateral inferior orbicularis oculi muscle (Fig. 158.4).

Deep Plane Face lift

- Extends a cheek sub-SMAS dissection so that the SMAS, skin, subcutaneous tissue is elevated as one myocutaneous unit (Figs. 158.5 and 158.6)
- The entry point for the deep plane is in a line drawn from the lateral canthus to the angle of the mandible.
- The inferior cheek is elevated sub-SMAS and transitions to supra-SMAS in the upper cheek.
- The plane of dissection is superficial to the zygomaticus major and

minor muscles.

- The zygomatic cutaneous ligaments are released at McGregor's patch. The flap extends medially to just beyond the nasolabial fold.
- The flap is elevated in a superolateral position.
- Sutures are used to anchor the entry point of the flap to the deep temporal fascia in the preauricular area.
- The inferior limit of the traditional deep plane face lift is the border of the mandible.

In the extended deep plane face lift, inferior dissection continues over the border of the mandible in the subplatysmal plane for 3 to 7 cm below the mandible. The cervical retaining ligaments are released between the platysma and the sternocleidomastoid muscle (see Fig. 158.5).[5,6]

Composite Face lift

- This combines the deep plane face lift and includes the orbicularis oculi muscle in the myocutaneous flap elevation.

Submentoplasty

- This can be combined with the face lift procedure or performed alone. A 3-cm horizontal incision is made in the submental crease. An inferior-based flap is undermined in the subcutaneous plane to the hyoid.
- Liposuction can be performed to remove the supraplatysmal adipose tissue. Subplatysmal adipose tissue can also be removed using liposuction through a midline opening in the platysma.

Various muscle plication procedures have been described, but a vertical approximation for support is a mainstay for tightening prominent platysma bands. The marginal branch of the facial nerve becomes more superficial as it enters the perioral muscles in the lateral chin area. Bipolar cautery may be useful in this area.

Platelet Rich Plasma

There has been increasing use of platelet-rich plasma mixed with thrombin in face lift surgery. This is sprayed under the flaps prior to closure. There is evidence that fibrin sealant has been shown to reduce the rate of hematoma in small studies. Other studies have shown no effectiveness.[7]

Common Errors in Technique

- Pixie ear
- Altered hairline
- Numbness resulting from injury to great auricular nerve
- Injury to stensen duct
- Injury to spinal accessory nerve
- Injury to the facial nerve
- Hematoma
- Button hole
- Skin slough
- Scarring
- Hair loss
- Cobra neck deformity

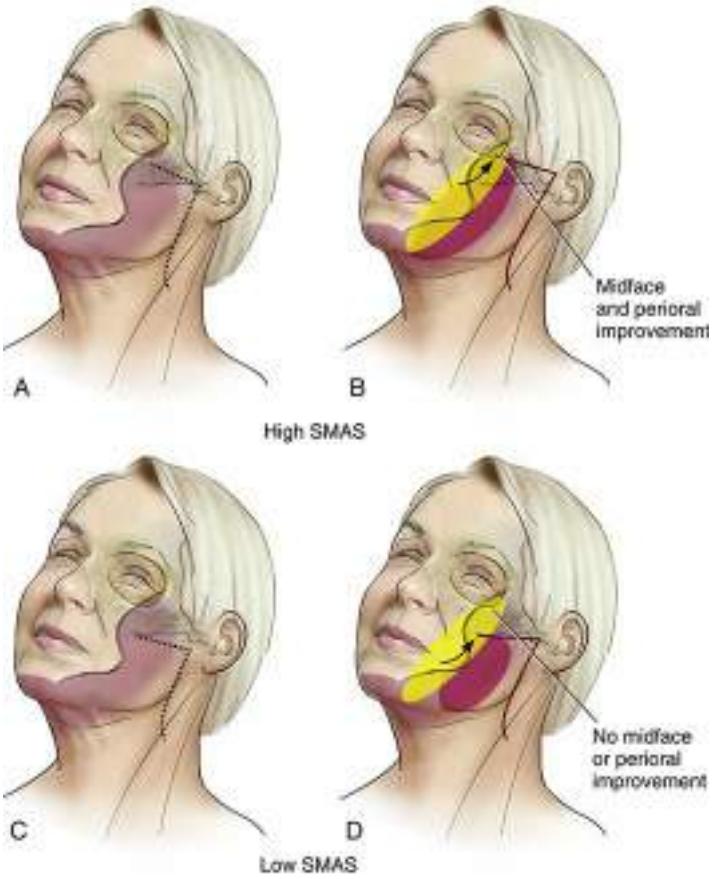

FIG. 158.4 (A) With the high SMAS lift, the SMAS is entered at the level of the zygomatic arch. (B) The suspension of the SMAS elevates not only the cheek and jawline jowling but also the anterior cheek and lower eyelid areas. (C) Care is required to preserve the temporal branch of the facial nerve. *SMAS*, Superficial muscle aponeurotic system. The low SMAS left does not have this good result (C/D).

Postoperative Management

- Patients have a head and neck wrap with gauze, Kerlex, and Coban wrapped circumferentially that is worn overnight. The patient returns the next day for removal of the dressing and to be evaluated for hematoma or motor nerve weakness. Some surgeons will place drains with more extensive face lifts.
- Incisions are cleaned with witch hazel, hydrogen peroxide, and topical

antibiotic ointment.

- Smokers are requested to refrain from smoking for 3 weeks following surgery.
- Sutures and/or staples can be removed at 1 to 2 weeks after surgery.
- Patients are advised to avoid turning their neck for 2 weeks and to sleep elevated on their back for 6 weeks.

Complications

- Unrealistic patient demands—The consultation is important to convey realistic expectations to the patient. Pointing out and documenting facial asymmetries prior to surgery can alleviate postoperative patient complaints. Limitations of an anterior hyoid/larynx should also be emphasized.
- Pixie ear—This can occur when too much tension is placed at skin closure around the ear lobule (see (Fig. 158.7).
- Altered hairline—Planning and closing the incision are essential to maintaining a natural hairline.
- Numbness—Cutting branches of the greater auricular nerve will lead to numbness of the ear and cheek. This typically resolves over time.
- Injury to the parotid duct—If identified intraoperatively, the duct can be reapproximated with 6-0 or 7-0 sutures. If a sialocele develops, repeat aspiration or opening the flap and ligating the duct may be required.
- Injury to the spinal accessory nerve—The nerve exits near Erb's point in the posterior triangle posterior to the mid-sternocleidomastoid muscle. Injury would cause a weakness of the trapezius muscle and loss of shoulder elevation.
- Injury to the facial nerve—The marginal and temporal branches are most likely to be injured. The marginal branch can be injured during sub-SMAS elevation over the upper neck. The temporal nerve courses over the mid-zygomatic arch and is vulnerable with the high SMAS lift or deep plane face lift or the S lift. Injury to the facial nerve occurs in 0.7% to 2.5%.[6]

- Hematoma—Use of aspirin, anticoagulants herbal products that can promote bleeding, and vitamin E should be stopped 2 weeks before surgery. Control of intraoperative and postoperative blood pressure, establishing meticulous hemostasis, placing drains, applying tissue sealant, and placing a compression wrap are techniques to prevent hematoma formation. However, a review of tliterature does not support a particular technique to avoid a hematoma following face lift surgery.[7] Meticulous cautery, compression post operatively, and even drains may help prevent hematomas. Small hematomas can be evacuated with syringe aspiration. However, large hematomas with significant ecchymosis will require return to the operating room to elevate the flap, evacuate the hematoma, and inspect for bleeding sites. Failure to evacuate an expanding hematoma promptly may cause necrosis of the skin flap (Fig. 158.8).

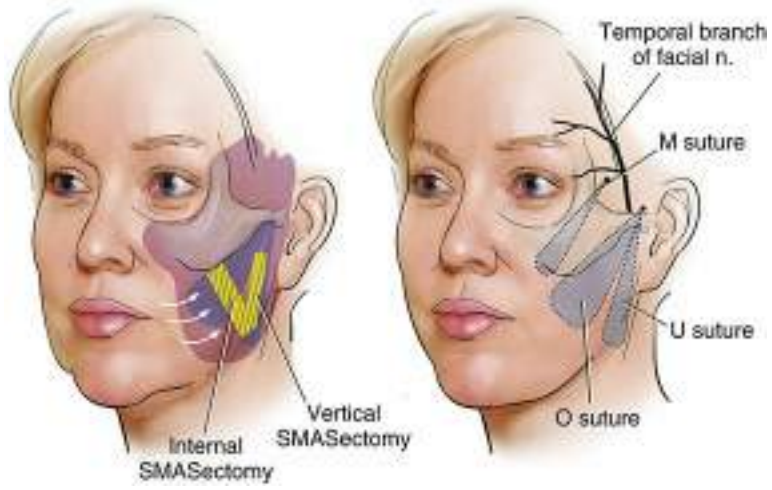

FIG. 158.5 The S lift modification is a short-flap technique using three purse string sutures to imbricate the SMAS. The "U" suture imbricates the SMAS vertically, and the "O" suture imbricates the SMAS laterally after a limited SMASectomy is performed. The "U" suture is anchored to the zygomatic arch periosteum and elevates the platysma at the angle of the mandible in a purse string "U" pattern. The "O" suture is placed at a 30-degree angle from the "U" suture and is anchored in the zygomatic arch periosteum. The "M" suture anchors the malar fat pad with a purse string suture secured to the

lateral canthal area of the orbicularis oculi muscle.

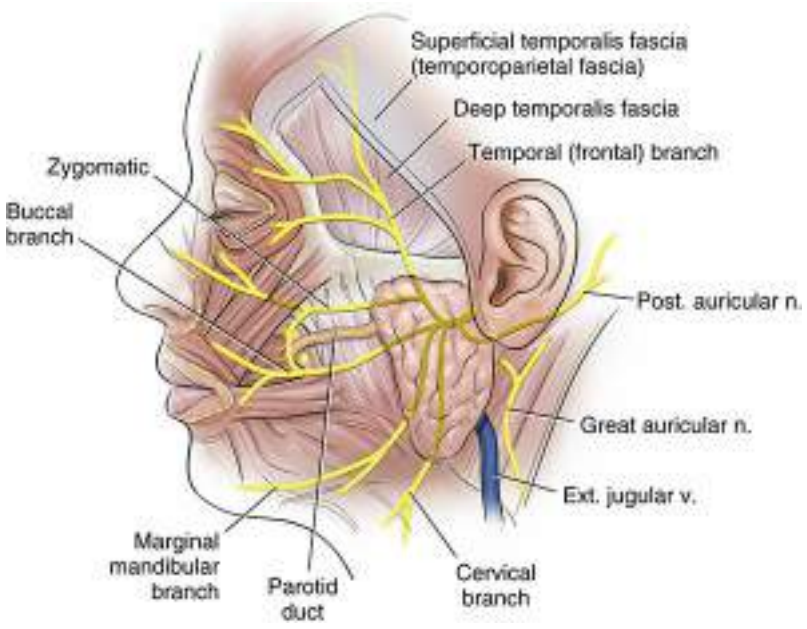

FIG. 158.6 Anatomy of the facial deep plane. The deep plane face lift uses a *sub*-SMAS dissection plane *in* the lower face combined with a supra-SMAS dissection plane in the upper cheek. The zygomatic cutaneous ligament McGregor patch and the mandibular ligament are released to improve suspension of the melolabial cheek.

- Button hole—Elevating the skin too superficial may create a button hole. This can occur when elevating the skin of the posterior neck over the sternocleidomastoid muscle in an effort to preserve the greater auricular nerve. It is best to suture the button hole immediately so that it does not expand. If the button hole occurs in an area where the skin will be resected, then it is not of a concern.
- Skin slough—This can occur from vascular compromise from smoking, creating a flap that is too thin, and too much tension on the skin. Typically when this demarcates, it will heal with conservative wound therapy.
- Scarring—An area of tension will result in hypertrophic or keloid scar. Some patients are prone to thickened scars. Straight head positioning when in bed for 4 to 6 weeks postoperative may help decrease tension

on the scar. The widened scars may be treated with topical silicone products or injected with steroids such as Kenalog 10 mg/mL or 40 mg/mL several times about 6 weeks apart.

- Hair loss—Alopecia may result when the incision is carried into the hairline. Beveling the incision in the direction of the follicles and avoiding tension along the closure may reduce this risk. Allow time for the follicles to regenerate hair. Topical minoxidil may help, or follicular hair transplants may be required after adequate delay for healing (see Fig. 158.9).
- Systemic complications—Deep vein thrombosis and pulmonary embolism are extremely rare following face lift surgery. Use of sequential compression for lower extremities during surgery and early ambulation decrease this risk.
- Cobra neck deformity—This occurs when insufficient subdermal adipose tissue is maintained on the submental skin flap. Overzealous platysma resection or plication may result in prominent bands or ridges vertically oriented that appear similar to a "cobra" (Fig. 158.10).

Alternative Management Plan

For patients who have an interest in facial rejuvenation but who are not candidates for surgery because of lack of tissue laxity or have a medical history that contraindicates a face lift, alternative options include soft tissue fillers, neurotoxin use in the forehead, glabella, or crow's feet area, facial peels, or laser resurfacing for rhytids. These options can also aid in improving the face lift results (A).

FIG. 158.7 Pixie ear is an unwanted stigma of face lift surgery. It is important to avoid any skin tension at the earlobe or a pulling down “pixie” ear web will result. A revision is required to release the ear lobule and advance skin closure without any tension.

FIG. 158.8 1-Lematomas are a dreaded complication of face lift surgery. Despite meticulous cautery, control of intraoperative and postoperative blood pressure,

avoidance of platelet-inhibiting medicines, and use of compression wraps, hematomas can still occur. It is paramount to identify the expanding hematoma as soon as possible to control the bleeding and preserve skin viability.

FIG. 158.9 Altered hairline results from poorly planned incisions, poor soft tissue handling, traumatic shock to the hair follicles with excess cautery, and excess tension on skin closure (arrows).

FIG. 158.10 Cobra neck deformity is depicted with the vertical band adherent to the skin. Excess liposuction of

the subdermal neck skin and plication of the platysma can create the cobra neck. Treatment requires releasing the contracture from the overlying skin, a z-plasty, and/or adipose tissue grafting to the neck (arrows).

Evidence-Based Medicine Question

Has the subperiosteal lift fallen out of favor?[9]

The subperiosteal lift first advocated by Tessier and then Ramirez provides for undermining the periosteum of the lateral and superior orbital rim and midface. However, the procedure is technically difficult, has a higher risk of motor nerve injury, and has prolonged postoperative recovery.

FIG. 158.11

Editorial Comment

Most current face lift techniques produce straight jawlines and good neck contours (Fig. 158.11). Proponents of extended SMAS and composite rhytidectomies stress that these techniques are needed to better correct midfacial ptosis and to improve the nasolabial folds. However, numerous clinical studies have also demonstrated that comparable clinical results are obtained up to 1 and 2 years when limited SMAS and standard SMAS procedures are compared with extended SMAS and composite

rhytidectomies. For a smoothing effect of the nasolabial fold and a lift of the midface, other techniques should be considered, such as fillers and lifting the malar adipose tissue pad.

Review Questions

1. Erb's point is a convenient landmark for locating which nerve(s)?

   a. Marginal mandibular nerve

   b. Greater auricular nerve

   c. Spinal accessory nerve

   d. A and B

   e. **B and C**

2. The cervicomental angle should be

   a. 90 degrees

   b. **105 to 120 degrees**

   c. 60 degrees

   d. 60 to 80 degrees

3. A patient calls the evening of her deep plane face lift surgery. She has throbbing pain, bleeding through her bandage wrap, and bruising intraorally. The pain medicine prescribed is not working. You advise her:

   a. Place ice on the cheek area and elevate the head of the bed.

   b. Have the caretaker release the dressing to determine if there is bleeding.

   c. **Assume she has a hematoma and arrange to meet her for evaluation and treatment.**

   d. Have her report to the local emergency room for evaluation and treatment by the Emergency room (ER) staff.

Facial Resurfacing

Peels and Lasers

Rebecca E. Fraioli

Introduction

Facial resurfacing with chemical peels and lasers is indicated for patients with photoaged skin. Photoaging is a term used to describe the changes that occur within the skin with aging and ultraviolet (UV) exposure, such as skin dullness due to loss of skin turnover and subsequent thickening of the stratum corneum, loss of elasticity due to breakdown of collagen and elastin, and pigmentary changes due to overactivity of melanocytes. Facial resurfacing is not appropriate for patients with deep rhytids or lax, sagging skin; patients with these characteristics will be better treated with surgery.

Facial resurfacing treatments work by damaging the skin and thereby triggering the wound healing process. Chemical peels cause exfoliation of damaged skin; the new skin that replaces it has better cellular organization, newly generated extracellular matrix, and a decrease in the number of cells with abnormal melanin deposits.[1]

Laser skin resurfacing may be ablative or nonablative. Ablative lasers damage and remove skin, similar to chemical peels. This is achieved by targeting water as a chromophore, resulting in heating and sloughing of skin. Traditional (nonfractional) ablative lasers affect all of the skin in the treatment area. Newer, fractional, ablative lasers treat only microcolumns of skin known as microthermal treatment zones (MTZs), sparing the skin between microcolumns. The spared adnexal structures allow faster skin regeneration, but with the compromise of less dramatic results.

Nonablative lasers used for skin resurfacing specifically target the

water in the dermis and thus heat, coagulate, and stimulate collagen remodeling in the dermis while leaving the stratum corneum intact. This feature allows for a shorter recovery period, although at the cost of less noticeable results. Fractional nonablative lasers can be used to penetrate deeper into the dermis and provide improved results compared to nonfractional lasers.

Key Operative Learning Points

- Chemical peeling agents are classified by the usual peel depth achieved.
- Very superficial peels are limited to the outermost layer of the epidermis, the stratum corneum.
- Superficial chemical peels are limited to the epidermis.
- Medium and deep peels penetrate the papillary and reticular dermis, respectively.
- In practice, many factors affect the depth of a chemical peel, and deeper than expected peeling can occur.
- Laser resurfacing can more precisely target the depth of the ablation.
- Lasers use an energy source to stimulate a lasing medium that then emits light waves of a single wavelength.
- Ablative lasers target water within the skin as a chromophore. Common ablative lasers are erbium:yttrium aluminum garnet (Er:YAG) with a wavelength of 2940 and carbon dioxide (CO_2) with a wavelength of 10,600. Common nonablative lasers are the 1320-nm neodymium:yttrium-aluminum-garnet (ND:YAG) laser and the 1064-nm ND:YAG laser.
- Ablative laser resurfacing removes the dermis and epidermis. Ablative lasers give the best result for wrinkle reduction but at the cost of a longer recovery period and increased risk of postprocedure complications.
- Fluence describes the energy per unit area of the laser beam. Higher fluence has more energy and penetrates deeper into the skin.

- Pulse width is essentially a measure of pulse duration.
- Spot size is the size of the laser beam. The larger the spot size, the higher the energy and the deeper the penetration of the laser beam.
- Melanin may also absorb some of the laser light; therefore patients with darker skin have a higher risk for laser burns. More conservative laser parameters should be used in patients with higher Fitzpatrick skin types (Table 159.1).[2,3]

Preoperative Period

History

History of Present Illness

- What are the patient's specific concerns (e.g., acne, skin dullness, dilated pores, rhytids)?
- Prior surgeries and treatments
- History of sun or tanning exposure
- Current skin care regimen
- Patient's psychologic motivation for facial resurfacing
- Are treatment goals and expectations realistic?

Past Medical History

- Medical comorbidities
  - Diseases with impaired wound healing (e.g., collagen vascular diseases or poorly controlled diabetes mellitus)
  - Immunosuppression
  - Coagulation disorders
  - Phenol peels in particular have systemic risks and should be avoided in patients with pre-existing cardiac, renal, or hepatic disease.
  - If a phenol-based peel is planned, the patient should have a complete

medical evaluation including cardiac, renal, and hepatic testing.

- History of herpes simplex virus (HSV) outbreaks should be noted.

TABLE 159.1

Fitzpatrick Skin Types

Fitzpatrick Skin Type	Skin Color	Ability to Tan	Tendency to burn
I	Very white or freckled	Never tans	Always burns
II	White	Tans minimally	Usually burns
III	White to olive	Tans moderately	Sometimes burns
IV	Light brown	Tans readily	Rarely burns
V	Dark brown	Tans profusely	Very rarely burns
VI	Black	Tans profusely	Never burns

- Skin history
  - A history of keloid or hypertrophic scarring is a contraindication to facial resurfacing.
  - History of skin cancer
  - Prior external beam radiation or burns to the skin are contraindications because they damage the adnexal structures in the dermis responsible for skin regeneration following resurfacing.
- Medications (current and past)
  - Antiplatelet agents and anticoagulants
  - Isotretinoin (Accutane) is a contraindication to chemical peels for 6 to 12 months after the medication has been discontinued. Isotretinoin downregulates adnexal structures in the dermis that are necessary for skin renewal following facial resurfacing.
  - Corticosteroids can impair wound healing.
  - Exogenous estrogen found in hormone replacement therapy or oral contraceptives increases the risk of postinflammatory hyperpigmentation following facial resurfacing procedures.
- Allergies
  - Allergy to any of the peel ingredients is a contraindication to using that peel. In particular, allergy to aspirin is a contraindication to any peel containing salicylic acid.

    - Lidocaine allergy should be noted.
- Social history
    - Smoking is not an absolute contraindication to chemical peel or laser skin resurfacing. However, caution should be used in a heavy smoker especially for deeper peels or ablative lasers.
- Family history
    - A family history of skin cancer should be noted.

Physical Examination

- A full examination of the face and neck should be performed, and the skin should be carefully assessed for texture, rhytids, pigmentary changes, acne lesions, open wounds, and scars.
- Pigmented skin lesions must be examined, and suspicious lesions should be biopsied. Facial resurfacing is not a treatment for skin cancer.
- Photodamaged skin must be differentiated from skin or muscle laxity and loss or descent of adipose tissue. The former is an indication for facial resurfacing; the latter are indications for surgery or injectable fillers.
- The degree of photodamage should be assessed and classified according to the Glogau scale (Table 159.2).[1]
- The patient's baseline skin pigment and response to UV exposure should be assessed and classified according to the Fitzpatrick scale (Table 159.1).[3]
- A lower eyelid "snap test" should be performed to assess for lower eyelid skin elasticity and recoil. Pull the lower eyelid skin inferiorly and release. If the skin does not return to its starting position within 3 seconds, laser resurfacing should not be performed in the area of the lower eyelid due to risk of postprocedure ectropion.

Imaging

- Radiographic imaging is not indicated in patients desiring facial resurfacing. However, pre- and posttreatment photodocumentation are essential.
- Lighting and patient positioning should be standardized and consistent between pre- and posttreatment photos.
- The five standard views are frontal, right and left lateral, and right and left oblique. Close-up photos should also be obtained of lesions or areas to be specifically targeted.

TABLE 159.2

Glogau Skin Types

Glogau Type	Degree of Photoaging	Description of Changes	Patient Age	Makeup
I	Mild	• Mild pigmentary changes • No keratoses • Minimal or no wrinkles	20s	Minimal to none
II	Moderate	• Early solar lentigines • Rare keratosis, mainly palpable • Wrinkles seen only with facial expression	30–40s	Wears some foundation
III	Advanced	• Obvious dyschromia and telangiectasias • Moderate actinic keratoses • Wrinkles seen at rest	50s	Always wears heavy foundation
IV	Severe	• Sallow (yellow–gray color) • Keratoses, skin cancer, severe actinic changes • Wrinkles throughout, little normal skin	60–70s	Can't wear makeup due to cakes and cracks

Indications

- General indications for facial resurfacing are: photodamaged or thick, rough skin, hyperpigmentation, dilated pores, acne, and acne scarring.
- Factors influencing the choice of resurfacing agent include: degree of photoaging, skin Fitzpatrick type, comorbidities, and willingness for postprocedure downtime.
- Superficial chemical peels are appropriate for mild to moderate photoaging (Glogau types I and II). Patients with more severe photoaging (Glogau types III and IV) are unlikely to see significant benefit.
- Superficial peels may be used in all Fitzpatrick skin types.
- Medium and deep chemical peels may provide benefit to patients with advanced photoaging; however, recovery period and risks are higher than with superficial peels, and laser resurfacing may be a better

option.

- Medium and deep chemical peels are contraindicated in patients with higher Fitzpatrick skin types due to the high risk of pigmentary complications.
- Nonablative laser resurfacing is appropriate for mild to moderate photoaging and rhytids (Glogau types I to III).
- Nonablative lasers have the advantage of limited postprocedure downtime, with the tradeoff of modest results. A series of treatments is usually necessary to see significant results.
- Fractionation increases depth of penetration and improves results; the tradeoff is increased healing time and increased risk of complications.
- Fractional nonablative lasers can be used in all skin types but should be used with caution in patients with darker skin types (Fitzpatrick IV to VI).
- Ablative laser resurfacing is indicated for patients with lower Fitzpatrick skin types (I to III) and more advanced photoaging, including static rhytids (Glogau IV). Patients must accept significant recovery downtime from this procedure.
- Fitzpatrick skin types IV to VI are not candidates for ablative laser resurfacing due to a high risk of pigmentary complications in these patients.

Contraindications

- Uncontrolled medical illness
- Bleeding disorder or anticoagulant use
- Active herpes simplex or other infection
- Open wound in the treatment area
- Damage to adnexal structures in the dermis that are responsible for regeneration of the epithelium, such as use of Isotretinoin (Accutane) within the preceding 6 to 12 months or a history of radiation treatment or burns to the face

- Medium to deep facial resurfacing in treatment area in the past 6 to 12 months
- Recent heavy sun exposure
- History of keloid or hypertrophic scarring
- Impaired wound healing
- Skin malignancy in the treatment area
- Pregnancy or nursing
- Body dysmorphic disorder or unrealistic patient expectations
- Allergy to chemical peel ingredients
- Ectropion is a contraindication to lower lid laser resurfacing.
- Tattoos in the treatment area are a contraindication to laser resurfacing, as a burn may occur in the skin under the tattoo.

Preoperative Preparation

- A standard skin preparation regimen should be initiated 6 weeks prior to skin resurfacing procedures
- Broad-spectrum sunscreen of SPF 30 and sun avoidance for 1 month prior to the treatment
- Topical retinoid should be started 6 weeks prior to chemical peeling. Preprocedure treatment with topical retinoids has been demonstrated to decrease time to reepithelialization following chemical peels.[4]
- Retinoid use also helps to modify the epithelium to a uniform thickness, which is helpful in achieving a standardized peeling depth. Retinoid use has not been shown to be beneficial prior to laser resurfacing.[5]
- Topical hydroquinone should be started 1 month prior to the procedure for patients with a history of hyperpigmentation or a high Fitzpatrick type.
- Antiviral prophylaxis should be started two days prior to the procedure and continued for 3 to 5 days following the procedure.

- Patch testing of chemical peels may be performed.
- All retinoid or AHA products should be stopped 2 weeks prior to the procedure to decrease skin irritation.
- Anticoagulant medications and supplements should be discontinued 2 weeks prior to the procedure. However, it is advisable to forgo facial resurfacing rather than to stop anticoagulant medications that are medically indicated.

Operative Period

Anesthesia

- Superficial chemical peels do not require anesthesia during the procedure.
- Nonfractional nonablative lasers often have built-in skin cooling that is sufficient for pain control for these procedures.
- Fractional nonablative laser treatments usually require a topical anesthetic. Cold-air cooling may also be beneficial. Regional nerve blocks may be used if necessary.
- Deeper peels and ablative laser resurfacing will require increased pain control. Options include strong topical agents, nerve blocks, anxiolytics, and/or narcotics. In certain cases, IV sedation or general anesthesia may be necessary.

FIG. 159.1 This photo demonstrates the setup for performing a superficial peel.

The peeling agents come premixed. A sterile specimen cup is used to decant a small amount of the peeling agent. Gauze sponges are folded up on sticks and used to apply the peeling agent to the face. Sterile saline is available to wash off the peeling agent if signs of undesirable clinical endpoints should occur.

Positioning

- For chemical peeling, the patient should be reclining with the head elevated 45 degrees. Head elevation helps to prevent pooling of the peel solution in dependent areas of the face.
- For laser treatments, the patient may be reclined in the treatment chair or lie flat in the supine position on the treatment table.

Perioperative Prophylaxis

- The risk of bacterial infection is low, and no antibacterial prophylaxis is indicated.
- Prophylaxis for HSV 1 and 2 should be given starting 2 days prior to the procedure.
- Because the rate of latent HSV infection is so high (up to 90% in some

studies), many providers provide prophylaxis regardless of prior infection history.[6]

Monitoring

- Cardiac monitoring is necessary for phenol-based peels.

Instruments and Equipment to Have Available

Chemical Peels

- Patient eye protection (moist gauze or adhesive eye pads)
- Handheld fan
- Peel solution
- Gauze sponges for application and removal
- Saline
- Neutralizing solution (if applicable)
- An example of the materials necessary for a superficial chemical peel is shown in Fig. 159.1.

Nonablative Laser Resurfacing

- Laser
- Protective eyewear: lead goggles for patient and wavelength-specific goggles for providers

Key Anatomic Landmarks

- Chemical peels are applied to the entire face, sparing the periorbital areas and the lips.
- The peel should be feathered into the hairline and under the jawline.

Prerequisite Skills

- Superficial peels should be mastered before progressing to medium and deep peels.
- General laser safety training and specific training on the particular laser to be used are prerequisites to performing laser resurfacing. Laser guidelines are manufacturer-specific, and device-specific training from the manufacturer should be obtained prior to using the device.

Operative Risks

Chemical Peels

- Risks are rare following superficial peels. Peels extending deeper into the dermis have a higher risk for complications.
- Infection, including bacterial, fungal (candidiasis), and viral (herpes simplex outbreak)
- Hyper- and hypopigmentation
- Scarring
- Eye injury
- Allergic reaction to peel ingredients
- Systemic toxicity from peeling agents, particularly phenol toxicity and salicylate toxicity. This risk is checked by limiting the total area being peeled in a single setting and peeling one aesthetic unit at a time.

Laser Resurfacing

- Burns
- Fire. It is critically important to cover hair and remove flammable materials from the laser field.[7]
- Petechiae and purpura may occur when the laser settings are too intense.
- Bacterial infection is rare but may occur. HSV infection is possible

despite prophylaxis.

- Atrophic, hypertrophic, and keloid scars. The risk of scarring is higher with ablative lasers.[7] Attention to proper laser technique during the procedure and meticulous wound care with prompt treatment of infection after the procedure are both critical to minimizing scarring.[8]
- Hyper- and hypopigmentation (temporary or permanent)
- Hair loss in or near treatment area
- Eye injury
- Ectropion is a risk when the lower eyelids are treated.

Surgical Technique

Chemical Peels

- The patient's hair and clothing are pulled away from the face and covered for protection from spills.
- Skin preparation is performed with a gentle cleanser and toner. Cleaning the skin allows for more even penetration of peeling agents and a more uniform depth of peel.
- Eye protection is placed.
- Rhytids and other depressed areas of skin are covered with petrolatum gel to prevent pooling of peel agents and increased depth of peeling.
- Cardiac monitoring is necessary for phenol-based peels.
- For medium and deep peels, the face should be divided by quadrants or aesthetic subunits, and the peel should be applied to one subunit at a time. Subunits with thicker skin (e.g., forehead) should be treated first and subunits with thinner skin (e.g., nose, chin, upper lip) should be treated last.[2]
- For peels with a risk of systemic toxicity, such as phenol-containing peels, a break of 10 to 15 minutes should be taken between each subunit. This spaces out the application of phenol and reduces the risk of toxicity. The full treatment time for a phenol-containing peel should

be 60 to 90 minutes.[9]

- Facial peels should be feathered just past the hairline and just under the jaw, to allow the peeled area to blend in with unpeeled surrounding skin. The peeling agent is not applied to the periorbital areas or lips.
- Some peels are applied in layers (e.g., Jessner's and trichloroacetic acid [TCA] peels). The skin should be monitored for 5 minutes prior to applying a second layer. Another layer should be applied only if clinical signs of adequate or excessive peel depth have not occurred.
- The face should be monitored for signs of peel progression and excessive peel depth. Signs of excessive depth are agent-dependent and are discussed below.
- Many peels will show frosting, a whitening of the skin, as a peel endpoint. An example of mild frosting is shown in Fig. 159.2.
- Some peels require neutralization at the end of the procedure.

Glycolic Acid Peel

- An alpha-hydroxy acid that can be used as a very superficial (concentration of 20% to 35%) or superficial (concentration of 50% to 70%) peel
- A timed peel that requires neutralization after 3 minutes (or sooner, based on clinical signs)
- Peel neutralization is performed using either water or a 10% to 15% sodium bicarbonate solution applied to a gauze sponge and wiped across the face. Neutralization should be repeated 2 to 3 times to ensure termination of the peel.
- Desired endpoints for a glycolic acid peel are mild erythema or a 3-minute peel duration.
- Clinical triggers for peel termination prior to 3 minutes are severe discomfort or blanching or blistering of the skin.

Salicylic Acid Peel

- Contraindicated in patients with allergy to aspirin
- A beta-hydroxy acid used in concentrations of 20% to 30% for a superficial chemical peel. Increasing the concentration increases peel depth.
- Apply peel and set timer.
- A thin white precipitate will form on the skin a minute or two following the application of the peel. Wait 2 to 3 minutes more and wipe off precipitate with gauze. If there is no erythema of the skin or significant patient discomfort, another layer may be applied.
- Increasing the number of layers applied increases the depth of penetration of the peel. A maximum of three layers should be applied per peeling session.
- Treatment area must be limited to less than 25% of total body surface area to avoid salicylate toxicity.
- Self-neutralizing; neutralization is not necessary at the end of the peel
- Signs of overly deep peeling include moderate to severe pain or severe erythema or blistering of skin. If these signs are present, the peel should be wiped off immediately with moist gauze rather than waiting for the peel to self-neutralize.

FIG. 159.2 **A,** Demonstrates mild frosting that occurred following a combination of a single layer of glycolic acid 35% peel and a single layer of Jessner's peel. **B,** Thirty minutes following the peel application, the frosting has resolved.

Jessner Peel (Lactic Acid 14 g, Salicylic Acid 14 g, Resorcinol 14 g and Ethanol to 100 mL)

- Contraindicated in patients who are allergic to aspirin
- Application and monitoring are as for salicylic acid peels.
- Results in a very superficial peel if applied with 1 to 3 layers or a superficial peel if 4 to 7 layers of solution are applied
- Neutralization is not necessary.
- Most commonly used as a very superficial peel with 1 to 3 layers and an endpoint of mild skin erythema
- An attempt should be made to remove the peeling agent with saline-soaked gauze if signs of overly deep peel are noted, including moderate to severe pain or skin blistering.

Trichloroacetic Acid Peel

- TCA can be used for superficial (concentration 10% to 25%), medium (concentration of 30% to 40%), or deep (concentration above 40%) peels. TCA is rarely used for deep chemical peels.
- Apply peel in quadrants, then set timer. The peel takes 2 to 3 minutes to achieve full effect.
- Assess skin for response to peel. Minimal skin erythema corresponds to a very superficial peel. Mild skin whitening accompanied by erythema indicates a superficial peel. Complete white frosting without erythema represents a medium depth peel involving the papillary dermis.[2]
- If desired skin findings are not seen, another layer may be applied. Increasing peel layers leads to a greater depth of penetration.
- Self-neutralizing, but peeling agent should be washed off if signs of

greater than desired peeling depth occur (e.g., severe pain, skin blistering)

- TCA peels have higher risk of pigmentary complications than glycolic or salicylic acid peels, and caution should be used in patients with darker skin types (Fitzpatrick IV to VI).

Fractional Nonablative Laser Resurfacing

- Each laser has device-specific guidelines set forth by the manufacturer. The laser operator must have training and familiarity with the specific device being used. The below steps should only serve as a general guideline for laser use.
- Clean the skin with a gentle cleanser and dry the skin.
- If necessary, topical anesthesia ointment is applied to the area to be treated and a waiting period should be observed for this to take effect.
- Cover tattoos with moist gauze. Less experienced operators should not perform laser resurfacing if there is a tattoo in the desired treatment area due to increased risk of burns.[2]
- Laser-specific eyewear must be given to everyone in the room to prevent eye injury. Fig. 159.3 demonstrates the array of safety goggles necessary, as each laser requires wavelength-specific goggles. The patient may wear lead goggles. The patient's contact lenses should be removed.
- Laser settings (spot size, fluence, density) should be chosen based on the Fitzpatrick skin type and patient history. Higher Fitzpatrick types require less aggressive settings.
- The handpiece is held perpendicular to and lightly touching the skin. An example of the technique is shown in Fig. 159.4.
- The skin should be treated in zones or facial units to ensure full coverage of skin.
- The handpiece is passed over the entire treatment area, with 20% to 50% overlap each time the handpiece is moved.
- Slow, continuous motion is preferred.

- Allow time for skin to cool between passes. Failure to do so may result in overheating and scar tissue formation.
- Assess skin after each pass of laser. Depending on the laser, multiple passes may be indicated if skin erythema has not occurred.
- Goals of treatment are mild to moderate erythema and darkening of skin. When these are achieved, no further passes should be performed.
- Signs of overly aggressive settings include petechiae, skin blistering, and development of a gray or white coloration of skin; these should trigger immediate termination of treatment, and ice packs should be applied to limit thermal damage to the skin.
- Ice packs and hydrocortisone cream may be applied to areas of erythema following treatment.
- Sunblock SPF 30 or greater should be applied before the patient is discharged.

FIG. 159.3 An array of protective laser eyewear. Each laser requires its own wavelength-specific safety

goggles.

Ablative Laser Resurfacing

- Each laser has device-specific guidelines set forth by the manufacturer. The laser operator must have training and familiarity with the specific device being used. The steps below should only serve as a general guideline for laser use.
- Anesthesia with topical cream, sedation, or nerve block.
- Remove patient's contact lenses, and apply lead goggles to patient and wavelength-specific protective eyewear to everyone in the treatment room.
- Providers in the room should wear a mask that can block aerosolized particles.
- A suction smoke evacuator should be held above the skin.
- A cool air blower may be positioned above the skin to aid with pain control.
- Laser settings (spot size, fluence, density) should be chosen based on the degree of facial aging.
- Perform trial pulses of laser at edge of area to be treated.
- Hold handpiece perpendicular to skin at distance recommended by manufacturer.
- Pass laser once over skin with no overlap between passes or as recommended by laser manufacturer. Lips and periorbital areas are not treated. Treatment should be feathered close to untreated areas and below the jaw.
- Skin should be assessed for response to treatment at all times. Erythema or slight skin whitening (seen as white dots for fractional lasers) are expected. Blistering or significant bleeding is a sign of overly aggressive treatment.
- Skin should be cooled at the end of the procedure with a cool air blower and ice packs.

- Apply occlusive ointment to skin following the procedure.
- Sunscreen should not be applied; however, patients must be counseled to wear a hat and avoid sun exposure.

FIG. 159.4 This photo demonstrates the positioning of the patient for an Erbium fractionated nonablative laser resurfacing procedure. The handpiece is at 90 degrees to the skin (A) and is gently touching the skin surface (B).

Common Errors in Technique

Chemical Peels

- Failure to standardize preparation and application steps may lead to deeper than expected peeling and a higher risk of complications.[9]
- Failure to feather the peel above the hairline and below the jawline may result in lines of demarcation between peeled and unpeeled skin.

Laser Resurfacing

- Laser resurfacing should not be performed over tattoos due to the risk of burns.

- Pigmented lesions that could represent malignancy should not be treated with laser resurfacing.
- Lower eyelid treatment is an advanced technique and should be performed only by providers with extensive laser resurfacing experience.
- Failure to feather laser adjacent to untreated areas may result in lines of demarcation between treated and untreated areas.

Postoperative Period

Postoperative Management

Superficial Chemical Peels

- The skin will begin to peel around day 3 to 5. A gentle skin cleanser and moisturizer should be used daily. Retinoids, hydroxy acids, and other products containing irritants should not be used.
- SPF 30 or greater sunscreen
- Topical hydrocortisone twice daily may be used if erythema is severe.
- The regular skin care routine may be resumed once the peeling has resolved, usually 2 weeks after the peel.

Nonablative Laser Resurfacing

- Ice packs may help with pain control.
- Gentle moisturizer may be used.
- Direct exposure to UV light should be avoided for 4 weeks.

Ablative Laser Resurfacing

- Cold compresses and occlusive (petroleum) moisturizer for the first 24 hours
- Days 2 to 5 clean skin with gentle cleanser

- Complete UV avoidance

Complications of Chemical Peel and Laser

- The appropriate choice of resurfacing agent based on Fitzpatrick and Glogau scales will minimize potential complications.
- Deeper than intended resurfacing may lead to pigmentary complications and scarring. Care must be taken to standardize peeling regimens, and close skin monitoring during treatment is essential.
- Severe postprocedure pain should prompt evaluation for infection.

Alternative Management Plan

- Microdermabrasion or dermabrasion
  - A mechanical skin exfoliation comparable to the chemical exfoliation achieved by chemical peels. A disadvantage is the potential for aerosolization of exfoliated skin, with associated risk for blood-borne pathogen exposure.
- Botulinum toxin and dermal fillers
  - Treat dynamic and static rhytids and volume loss, but do not rejuvenate photoaged skin.
- Surgical treatment of photoaging including brow lift, rhytidectomy, and platysmoplasty are complementary techniques but do not directly address the epidermal and dermal results of photoaging.

Discussion

Evidence-Based Medicine Question

Are CO_2 lasers effective in the treatment of hypertrophic scars?

Multiple prospective studies have demonstrated that CO_2 lasers may improve scar pliability and contour. Different lasers can be used to target specific goals. The 585- and 595-nm pulse dye lasers (PDLs) are best suited for the treatment of pruritus and erythema, whereas the CO_2 may

be used for the treatment of irregular scar contour.

Editorial Comment

When treating hypertrophic scars, the combination of CO_2 lasers and PDL may be superior to CO_2 laser alone. Because a PDL only penetrates about 1 mm, thick hypertrophic scars may not respond well to PDL. However, multiple split-scar randomized clinical trials have also shown that a PDL can improve scar height, pliability, and erythema, compared with untreated areas. PDL seems to be most effective treating immature hypertrophic scars, which are still hypervascular and erythematous, early in the remodeling phase.

Review Questions

1. Which facial resurfacing agent is most likely to show improvement in patients with high Glogau score?

   a. Superficial chemical peel

   b. Deep chemical peel

   c. Nonfractional ablative laser resurfacing

   d. **B and C**

   e. None of the above

2. Superficial chemical peels

   a. Are contraindicated in patients with higher Fitzpatrick skin types

   b. **Generally penetrate the epidermis but not the dermis**

   c. Are most likely to show effect in patients with higher Glogau score

   d. All of the above

   e. None of the above

3. Risk factors for postprocedure pigmentary complications include

a. Higher Fitzpatrick skin type

b. Excessive tanning prior to procedure

c. Use of oral contraceptive pills

d. **All of the above**

e. None of the above

4. Which of the following statements comparing fractional and nonfractional **ablative** laser resurfacing is true?

a. Nonfractional ablative laser resurfacing can be used in all Fitzpatrick skin types.

b. **Nonfractional ablative laser resurfacing carries a higher risk of complications.**

c. Fractional ablative laser resurfacing can provide superior results.

d. A and C

e. All of the above

5. Which of the following statements comparing fractional and nonfractional **nonablative** laser resurfacing is true?

a. Nonfractional nonablative laser resurfacing can be used in all Fitzpatrick skin types.

b. Nonfractional nonablative laser resurfacing carries a higher risk of complications.

c. Fractional nonablative laser resurfacing can provide superior results.

d. **A and C**

e. All of the above

Cosmetic Botox and Fillers

Robert J. Chiu

Introduction

Aesthetic procedures have gradually become more mainstream and popular over the past 15 years, largely led by the significant increase in minimally invasive procedures since the US Food and Drug Administration (FDA) approval of Botox Cosmetic treatment for glabellar rhytids in 2002.[1] In 2014, more than 15.6 million cosmetic procedures were performed, of which 13.9 million were minimally and noninvasive procedures (ASPS 2014 statistics). Of the minimally invasive procedures, more than 6.6 million botulinum toxin type-A (BoA) procedures were performed, representing a 748% increase since 2000. More than 2.3 million soft tissue filler injections were performed, representing a 253% increase since 2000.

A complete discussion of minimally and noninvasive cosmetic procedures would also include adipose tissue transfer/injections, chemical peels, laser skin resurfacing and other laser treatments, intense pulsed light (IPL), ultrasound and radiofrequency devices, sclerotherapy, microdermabrasion, and other procedures. This chapter will focus on the two most frequent noninvasive cosmetic procedures that prospective aesthetic patients seek: BoA neuromodulator injections and soft tissue filler injections. For simplicity, the BoA injections will be referred to as Botox (OnabotulinumtoxinA, Allergan), but it applies to other commercially available botulinum toxin-A products in the United States: Dysport (AbobotulinumtoxinA, Galderma) and Xeomin (IncobotulinumtoxinA, Merz; Table 160.1). The discussion of soft tissue filler injections will be limited to the hyaluronic acid (HA) product lines: Juvéderm (Allergan) injection procedure described can be applied to other HAs used in the United States: Restylane/Lyft/Silk (Galderma) and Belotero (Merz). The technique of Botox and filler injection procedures is

summarized in FDA-approved anatomic locations, as well as in more advanced, off-label areas.

Key Operative Learning Points

Preprocedure Period

Patient Selection

The importance of the doctor-patient relationship in aesthetic surgery and medicine should not be diminished, despite the increasing popularity of medi-spas, corporate aesthetic practices, Botox "parties," and the ease at which some minimally and noninvasive cosmetic procedures can be delivered. A patient who is interested in nonsurgical injectable procedures should have a consultation with a physician/surgeon specializing in aesthetic interventions/cosmetic procedures. During the consultation, the physician can ascertain the patient's concerns and goals and be able to offer appropriate recommendations and treatment options.

Patient Assessment

History of Present Illness/Chief Complaint (HPI/CC)

- Patient concerns and goals
  - Personal preferences
  - Gender, social, cultural, ethnic considerations
  - Work and/or family considerations
  - Downtime
  - Cost

History

- General health
- Aesthetic treatment history

- Past medical history
- Systemic disease
  - Autoimmune/collagen vascular disease
  - Bleeding tendencies/hematologic conditions
  - Reaction to anesthesia
- Localized disease/condition
  - Ocular conditions
  - Herpes simplex virus (HSV)/cold sores
  - Facial nerve weakness/disorders
- History of allergic reactions
  - Severe allergies/anaphylaxis
  - Food allergies: milk and egg products
- Current medications
  - Steroids and other immunosuppressive agents, muscle relaxants, pain medications, anticoagulants (Coumadin or Plavix), psychiatric medications
- Over-the-counter medications and supplements
  - NSAIDs, other blood thinning products
- Females: Pregnancy and breast feeding
- Social history: Smoking and alcohol use
- Psychiatric history and conditions
  - Bipolar disorder
  - Body dysmorphic disorder (BDD)
- Family history: Cardiovascular, psychiatric, hematologic disorder
- Occupation/work history

Physical Examination

- Skin quality and texture

- Facial sagging and laxity
- Loss of volume/contour deficiencies
- Dynamic and static rhytids
- Examination of face/neck at rest and with dynamic expression
- Scars and/or acne scars
- Pre-existing facial asymmetries/irregularities
- Eyebrow/upper eyelid complex ptosis
- Lower eyelid and cheek complex
- Facial nerve evaluation/facial weakness
- Cranial nerve examination
- Muscles of facial expression: Assess strength and size.
- Weight and height
- Fitzpatrick skin type
- Affect and psychologic presentation

Other

- Photo documentation
- Informed consent process
- Answer patient concerns/questions
- Follow-up

TABLE 160.1

Injectable Neuromodulators in the United States—Listed by Dates of US Food and Drug Administration Approval

Year of FDA Approval	Product Trade Name (Manufacturer)
2002	Botox (OnabotulinumtoxinA) (Allergan)
2009	Dysport (AbobotulinumtoxinA) (Galderma)
2011	Xeomin (IncobotulinumtoxinA) (Merz)
Pending	PurTox (Mentor)
Pending	RT001 (Topical and Injectable) (Revance)

FDA, US Food and Drug Administration.

The Ideal Patient for Nonsurgical Injectable Treatments

- Seeks nonsurgical options for rejuvenation
- Has aging changes mostly related to volume loss and/or dynamic rhytids
- Prefers minimal and/or no downtime
- Understands value of periodic ongoing treatments to maintain and achieve best results

Procedure/Treatment

Botox Cosmetic[2]

Indications

- Dynamic rhytids
- Static rhytids: Mild to moderate rhytids/younger patients
- Brow shaping and sculpting
- Facial sculpting
- Wrinkle prevention

Contraindications

Absolute Contraindications

- Known hypersensitivity to any botulinum toxin preparation components
- Ongoing presence of infection at the proposed injection site(s)
- Pre-existing neuromuscular disorders, such as peripheral motor neuropathic diseases, amyotrophic lateral sclerosis, or neuromuscular

junction disorders (e.g., myasthenia gravis or Lambert-Eaton syndrome)

- Pregnancy or lactation (category C)

Relative Contraindications

- Generalized muscle weakness
- Uncontrolled systemic disease and/or patients in poor health
- Pre-existing dysphagia or dysphonia
- Breathing difficulties
- Pre-existing cardiovascular disease
- Presence of inflammation at the proposed injection site(s)
- Baseline eyelid ptosis
- Diplopia
- History of excessive weakness or atrophy in the targeted muscle(s) to be injected
- Unrealistic expectations
- Psychiatric disease
- Drug interactions: Aminoglycosides, calcium channel blockers
- Recent administration of a different botulinum toxin preparation

Pretreatment Planning

- Selection of neuromodulator (patient and physician preference, clinical situation)
- Determine dose and volume to be injected
- Reconstitution and preparation
- Account for and/or limit other procedures performed at or around the time of injection (other nonsurgical injectable treatments, skin resurfacing procedures, surgical procedures).

Precautions Prior to Injection

- Notification of any rash or infection near or at the planned injection site
- Avoid blood thinning agents such as aspirin/NSAIDs, fish oils, vitamin E, herbal supplements, and/or alcohol a few days prior to treatment.
- Continue prescribed medications, including medically necessary blood thinners.

Recommended Materials

- Materials for mixing
  - 21- to 25-gauge needles
  - Preservative-free normal saline
- Digital camera
- Wipes
- Mirror
- Topical anesthetic (benzocaine/lidocaine/tetracaine [BLT] or lidocaine mixture)
- Gloves
- 30-gauge needle or tuberculin syringes
- 1-mL syringe
- Alcohol pads (or other disinfectant skin preparations)
- Bottle opener (to remove rubber stopper of vial)
- Marking pen/pencil
- Gauze pads (4 × 4 or 2 × 2)
- Ice pack
- Medical waste container

Preparation/Dilution/Storage

- Vacuum-dried powder form in single-use 50-Unit or 100-Unit vials
- 2.5 mL of preservative-free 0.9% sodium chloride diluent to reconstitute each 100-Unit vial, yielding a concentration of 4 Units per 0.1 mL
- Common off-label preparation
  - Preservative containing saline
  - Adjusting diluent quantity (1.0 to 4.0 mL) to yield the desired dose per 0.1 mL
- Stored in refrigerator (2°C to 8°C) and administered less than 24 hours after reconstitution
- Off-label storage: Multiple studies showing preservation of drug potency up to 2 weeks

Botox Injection Technique

General Considerations

- Botox Cosmetic effect/timeline
  - Chemical denervation of the injected muscles within the first several days post injection
  - Clinical detectable relaxation of muscles from a few days to 14 days
  - Maximum clinical effect within the first 4 to 6 weeks
  - Duration of effect ranging from 3 to 4 months
- FDA-approved indication/sites: glabella (2002), crow's feet (CF)/lateral canthal lines (2013)
- Off-label use in all remaining upper face, lower face, and neck areas
- Potency units of different neuromodulators not interchangeable
- Use 1:2.5 or 1:3 Unit conversion for Dysport and 1:1 Unit conversion for Xeomin.

Positioning

- Physician/injector preference
- Recumbent

FIG. 160.1 Botox treatment for FDA-approved glabella indication: 4 Units/0.1 mL of reconstituted Botox Cosmetic is injected intramuscularly into each of five sites, two in each corrugator muscle at its inferomedial and superolateral aspect and one in the procerus muscle at the midline, for a total dose of 20 Units. Adapted from Botox package insert, Allergan, Inc.

- Semirecumbent
- Sitting up

Anesthesia

- Topical anesthesia—lidocaine based
- Nerve/intraoral blocks
- Cooling devices—Zimmer

Monitoring

- Possible vasovagal reaction

Key Anatomic Landmarks

- Muscles of facial expression and neck
- Eyebrow position and shape
- Bony orbit
- Facial vessels

Upper Face Indications for Botox Cosmetic

- Injections of glabella/frown lines/11's (corrugator/procerus muscles)[4]
  - On-label FDA-approved glabellar indication: 4 Units injected intramuscularly into each of five sites, 2 in each corrugator muscle and 1 in the procerus muscle for a total dose of 20 Units (Fig. 160.1)[2]
  - 10- to 40-Unit range for desired clinical effect/relaxation of the glabella
  - Higher doses needed for active muscles and male patients
- Injections of lateral canthal/CF lines (orbicularis oculi muscle):[3]
  - On-label FDA-approved CF indication: 4 Units are injected intramuscularly into each of six sites, 3 on each side, into the orbicularis oculi muscle for a total dose of 24 Units (Fig. 160.2).[2]
  - Two variant patterns of injecting lateral canthal lines are provided in the trial (see Fig. 160.2).
  - 10- to 30-Unit range for desired clinical effect/relaxation of the CF
  - Concurrent treatment of glabellar lines and lateral canthal lines can be performed with an on-label suggested dose of 44 Units.
- Injections of horizontal forehead rhytids/lines (frontalis muscle):
  - 5 to 20 Units injected intramuscularly into the frontalis muscle
  - Variable pattern and number of injection sites—individualize treatment
  - Counsel patients before injection regarding the possibility of brow

position changes and brow ptosis.

- Use in conjunction with treatment of orbicularis oculi to alter brow shape and position.

- Injections for chemical browlift (orbicularis oculi/corrugators/procerus muscle):
  - 5 to 20 Units total injected into the superolateral portion of the orbicularis oculi in the lateral third of the brow
  - Keep injections superior and lateral to the orbital rim to minimize ptosis.
  - May need to treat brow elevator to achieve desired brow height and shape
  - Can achieve a modest nonsurgical browlift of up to a few millimeters
- Treatment of bunny lines (overactive procerus muscle):
  - Indicated for patients with excessive horizontal nasal lines
  - Can be unmasked by Botox treatment and relaxation of glabellar rhytids
  - In addition to treating the procerus, use small doses (1 to 2 Units Botox or 3 to 5 Units Dysport per side) injected directly over the bunny lines.
  - Injecting too low and lateral can affect the levator labii superioris.
- Injections for "jelly rolls" in the lower eyelid (hypertrophied orbicularis oculi)
  - 1 to 2 Units injected into the lower eyelid pretarsal orbicularis muscle
  - Decreases hypertrophied orbicularis muscle and increases the palpebral aperture
  - Reduced blinking can lead to corneal exposure and related symptoms.
  - Other potential complications include epiphora and edema of the lower eyelid.

Lower Face Indications for Botox Cosmetic

- Treatment of perioral lip lines (orbicularis oris), oral commissures (depressor anguli oris), and medial chin rhytids (mentalis muscles)
  - Can be used in conjunction with dermal fillers
  - Results are usually less dramatic and duration of effect shorter than those in the upper face.
  - Discuss the possibility of oral incompetence with your patient.
  - Contraindicated for patients who depend on use of muscles in perioral region (i.e., singers, musicians who play wind instruments)
- Injections of perioral (vertical) lip lines (orbicularis oris):
  - Inject the orbicularis oris muscle in small amounts, maximum 1 to 1.5 Units Botox or 3 Units Dysport per site, two to six sites in the upper lip and two to four sites in the lower lips.
  - Stay close (within 5 mm) to the vermilion border.
- Injections of oral commissures (depressor anguli oris muscles):
  - One to two injections (2 to 3 Units Botox or 6 to 9 Units Dysport) each side directly into the depressor anguli oris muscle overlying the mandibular body
  - Avoid injecting medial to the perpendicular line to the oral commissure.

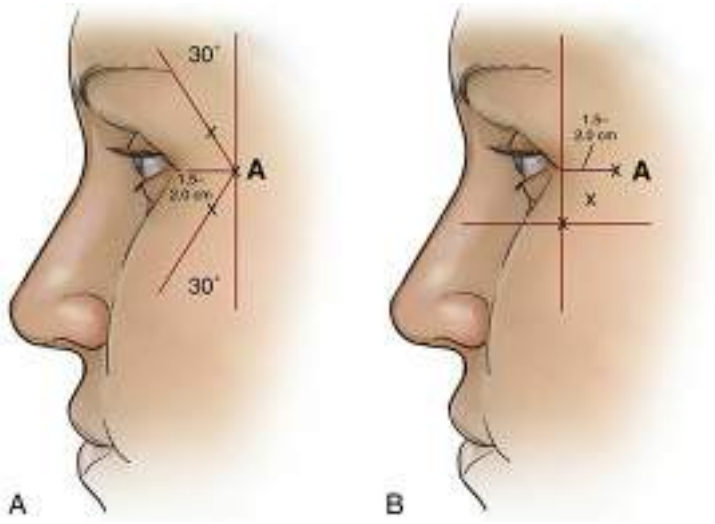

FIG. 160.2 Botox treatment for FDA-approved lateral canthal lines (crow's feet/CF) indication: 4 Units/0.1 mL of

reconstituted Botox Cosmetic is injected into three sites per side (six total injection points) in the lateral orbicularis oculi muscle for a total of 24 Units/0.6 mL (12 Units per side). **A,** Standard CF injection pattern—the first injection *(A)* should be approximately 1.5 to 2.0 cm temporal to the lateral canthus and just temporal to the orbital rim, with the second and third injection *(X)* above and below the lateral canthus. **B,** Modified CF injection pattern—the first injection *(A)* should be approximately 1.5 to 2.0 cm temporal to the lateral canthus and just temporal to the orbital rim, with the second and third injection *(X)* below the lateral canthus. Adapted from Botox package insert, Allergan, Inc.

- Avoid injecting close to the mouth to minimize complications related to oral incompetence and/or lower lip ptosis.
- Improves marionette lines and lifts mouth corners (Fig. 160.3)

- Treatment of dimpled chin (mentalis muscle):
  - Two injection sites in a paramedian position near the inferior mandibular border: total of 2 to 8 Units Botox or 6 to 20 Units Dysport
  - Avoid injecting too far lateral or superiorly.

Other Lower Face and Neck Indications for Botox

- Treatment of gummy smile (depressor septi muscle):
  - Indicated for patients with with "gummy smiles" gingival show upon smile
  - Use small doses (total 1 to 3 Units Botox or 3 to 9 Units Dysport) injected just below the nose into the lip elevator complex (one to two injections).
  - As a nonsurgical treatment option for dynamic ptotic noses
- Treatment of nasolabial folds (NLFs; levator labii superioris alaeque nasi muscle)
  - Patients with short upper lips and/or strong elevation of upper lip upon smile are potential candidates.
  - Use small doses (maximum 1 Unit Botox or 3 Units Dysport per side)

injected just below the nose into the lip elevator complex and the levator labii superioris alaeque nasi muscle.

  - Advise patients that their smile pattern may be altered.
  - The area is best treated with dermal fillers.

- Treatment of neck bands (platysma muscle):
  - Consider in older patients who are not candidates for surgery
  - Younger patients who are not candidates yet for facelift surgery
  - Patients with good skin elasticity and minimal submental fullness
  - Botox has no effect on skin laxity or redundancy, laxity, or adipose tissue deposits
  - Requires higher dosages than the lower face
  - Use 10 Units Botox or 30 Units Dysport per platysmal band.
  - Can inject multiple sites per band from the mandible to the lower neck, or inject the band only at the cervicomental angle to recreate it
- Treatment of square jaw (masseter muscle):
  - Injected into the masseter muscle to alter shape of the jawline
  - Popular application in East Asian countries
  - 10 to 25 Units Botox or 30 to 75 Units Dysport used per side (two to four injections)
  - Treatment effect may require multiple sessions, and treatment onset is slower but effects tend to last longer.
  - Adverse effects include mastication difficulty, muscle pain, dysarthria, and awkwardness with smiling.
  - Patients with Temporomandibular Joint Disorders (TMJ) and/or grinding tendency may benefit.

Facial Sculpting Techniques Using Botox Cosmetic

Upper Face

- Chemical brow lift/elevation

- Brow shaping
- Increase eye opening/aperture

Lower Face

- Treatment of square jaw (masseter muscle)
- Lifting corners of mouth (depressor anguli orismuscle)
- Alteration of lip size and position (orbicularis oris muscle)

Postprocedure Period

Postprocedural Care

- Avoid lying flat or inversions for 4 hours following injection treatment.
- Avoid strenuous exercise or activity for 24 hours.
- Avoid alcoholic beverages and other blood thinning agents.
- No sun exposure for 7 days

Complications

Potential Risks/Adverse Effects[4]

General Information

- Can occur within hours to weeks after injection with Botox Cosmetic

FIG. 160.3 Patient before and after Botox and HA filler treatment.

- Generalized reactions: malaise, headaches, Upper Respiratory Infection (URI) symptoms, nausea
  - 5% to 10% of first-time Botox Cosmetic users may experience reactions.
- Pregnancy category C and has not been studied in nursing mothers
- Safety and effectiveness not established in patients younger than 18 years or older than 65 years

Adverse Effects

- Bruising
- Pain
- Upper eyelid ptosis
- Brow ptosis
- Hematoma (rare)
- Infection

- Loss of facial expression (overtreatment)
- Unsatisfactory reduction of rhytids (undertreatment)
- Unwanted muscle paralysis in distant sites ("distant spread")
- Neutralizing antibodies and loss of therapeutic effect
- Adverse neurologic effects
- Complaint of metallic taste after injections
- Adverse ophthalmic effects
  - Reduced blinking leading to corneal exposure, especially with injection to the medial part of the lower eyelid
  - Diplopia
- Interaction with aminoglycosides, agents interfering with neuromuscular transmission, and may exaggerate the effects of anticholinergic drugs and/or muscle relaxants
- Administering different botulinum neurotoxin products, which are not interchangeable with one another, in close proximity, should be performed with caution.
- Botox contains albumin and carries an extremely remote risk for transmission of viral diseases or Creutzfeldt-Jakob Disease (CJD).

Serious Adverse Effects

- Rare serious adverse reactions, including some with fatal outcomes, include:
  - Excessive weakness, dysphagia, aspiration pneumonia, respiratory failure, arrhythmia, and myocardial infarction
- Serious hypersensitivity reactions including anaphylaxis

Eyelid Ptosis—Prevention

Glabellar Rhytids

- Avoid injection near the levator palpebrae superioris, particularly in patients with larger brow depressor complexes.

- Lateral corrugator injections should be placed at least 1 cm above the central bony supraorbital ridge.

Crow's Feet/Lateral Canthal Rhytids

- Injections should be placed 1 to 2 cm lateral to the bony orbit and directed laterally, not toward the eyeball.
- Injection volumes should be kept below 0.1 to 0.2 mL per injection point, with dose per injection less than 5 Units (Botox Cosmetic) or less than 12.5 Units (Dysport).

Eyelid Ptosis—Management

- Reassure patient as to transient nature of condition.
- Regular follow-up to address patient's concerns
- Photo documentation
- Prescribe treatment of affected eye with eyedrops.[4]
  - Apraclonidine 0.5% (Iopidine)
  - Phenylephrine 2.5% (Neosynephrine)
  - Eyedrops work on the Müller muscle of the upper lid and can lift the lid up to 1.0 mm.

Eyebrow Ptosis—Prevention

- Understand that forehead injections can have variable results and require experience.
- Consider injecting brow depressor muscles to offset possible brow ptosis from injecting frontalis muscle.
- Before forehead injections, counsel patients appropriately regarding the possibility of brow ptosis and/or the sensation of heavy brows.
- Consider injecting glabellar and forehead muscles at separate treatment settings.

Eyebrow Ptosis—Management

- Limited treatment available
- Consider brow depressor muscle treatment.
- Reassurance and support
- Regular follow-up to address patient's concerns
- Photo documentation

Distant Spread of Botulinum Toxin Products

- Postmarketing surveillance led to reports of events relating to spread of the products' effects beyond the area of injection to other areas of the body, causing symptoms similar to those of botulism.
  - Mostly reported in children with cerebral palsy being treated off-label
  - Some cases also reported in adults treated both for approved and unapproved uses
  - Symptoms can occur several hours to several weeks after treatment.
- In 2009, FDA mandated safety label changes.
  - Boxed warning to all botulinum toxin products alerting to possible distant spread
  - Designed to also highlight the difference in strength and potency of different botulinum toxin products
- Botox Cosmetic for approved indications at recommended doses has not been definitely associated with any serious and/or fatal outcome related to distant spread of toxin effect.

Fillers—Hyaluronic Acid

Overview

- HA fillers have proven to be very safe and effective, as shown by postmarketing safety data and clinical experience.
- Classified as medical devices

- Designed to be implanted/injected into the mid to deep dermis, submucosa, subcutaneous layer, and/or deep (such as periosteum)
- Safe for use in all skin types
- Potentially reversible
- May stimulate collagenesis
- Restylane and Juvéderm, the two most used fillers in the United States, FDA approved in 2003 and 2006, respectively[5]
- Current marketed HA fillers, with FDA-approved indications (Table 160.2)

Indications

- Improve moderate to severe rhytids (wrinkles) and folds (such as NLFs)
- Restoration of volume loss
- Facial sculpting and shaping
- Nonsurgical aesthetic rejuvenation

Contraindications and Adverse Reactions

Absolute Contraindications

- Known hypersensitivity to gram-positive bacterial proteins
- Ongoing presence of infection at the proposed injection site(s)
- Pregnancy or lactation (category C)

Relative Contraindications

- History of anaphylaxis or multiple severe allergies
- History of lidocaine allergy
- Uncontrolled systemic disease and/or patients in poor health
- Pre-existing cardiovascular disease

- Pre-existing collagen vascular/rheumatologic disease
- Patients on immunosuppressive therapy
- Presence of active inflammation at the proposed injection site(s)
- History of keloid formation, hypertrophic scarring, and/or pigmentation disorder
- Unrealistic expectations
- Psychiatric disease

Pretreatment Considerations

Planning

- Selection of filler material
  - Patient preference (previous treatment, age, goals, cost, time)
  - Physician preference
  - Clinical indication/situation
  - Site of injection
- Determine amount/volume to be injected.
- Consider filler dilution and/or mixing with lidocaine/epinephrine (off-label).
- Selection of sharp needles versus blunt-tipped microcannulas (off-label)
- Assess for combination therapy (e.g., with Botox treatments) to enhance treatment result and longevity (Fig. 160.4).
- Account for and/or limit other procedures performed at or around the time of injection (other nonsurgical injectable treatments, skin resurfacing procedures, surgical procedures).

Patient Precautions Prior to Injection

- Notification of any rash or infection near or at the planned injection site
- Avoid blood thinning agents such as aspirin/NSAIDs, fish oils, vitamin

E, herbal supplements, and/or alcohol a few days prior to treatment.

- Continue prescribed medications, including medically necessary anticoagulants.
- Avoid smoking.

Recommended Materials

- Materials for mixing (optional, off-label)
  - 21- to 25-gauge needles
  - 1% lidocaine or 1% lidocaine with 1:100,000 epinephrine
  - 3-mL syringes or 1-mL syringes
- Digital camera
- Wipes

TABLE 160.2

Injectable Fillers Listed by Dates of US Food and Drug Administration Approval

Year of FDA Approval	Product Trade Name (Manufacturer)	Duration of Action	Product Description
2003	Restylane (Galderma)	6–12 months	HA
2004	Sculptra (Galderma)	up to 2 years	PLLA
2006	Juvéderm Ultra (Allergan)	6–12 months	Nonanimal HA
—	Juvéderm Ultra Plus (Allergan)	6–12 months	Nonanimal HA
—	Belafill (formerly Artefill) (Suneva Medical)	up to 5 years	PMMA
—	Radiesse (Merz Aesthetics)	6–12 months	CaHA
2007	Restylane Lyft (formerly Perlane) (Galderma)	6–12 months	Nonanimal HA
—	Sculptra Aesthetic (Galderma)	up to 2 years	PLLA
2010	Juvéderm XC (Allergan)	6–12 months	Nonanimal HA with lidocaine
—	Restylane-L (Galderma)	6–12 months	Nonanimal HA with lidocaine
—	Restylane Lift-L (formerly Perlane-L) (Galderma)	6–12 months	Nonanimal HA with lidocaine
2011	Belotero (Merz Pharmaceuticals)	6 months	Nonanimal HA
—	LaViv (Fibrocell Technologies)	6 months	Autologous fibroblasts
—	Restylane-L for lips (Galderma)	6–12 months	Nonanimal HA with lidocaine
2013	Juvéderm Voluma (Allergan)	up to 2 years	Nonanimal HA
—	Juvéderm Voluma-XC (Allergan)	up to 2 years	Nonanimal HA with lidocaine
2015	Juvéderm XC for lips (Allergan)	6–12 months	Nonanimal HA with lidocaine
2016	Juvéderm Volbella XC for lips and perioral lines	up to 1 year	Nonanimal HA with lidocaine

CaHA, Calcium hydroxylapatite; *FDA*, US Food and Drug Administration; *HA*,

hyaluronic acid; *PLLA,* poly-L-lactic acid; *PMMA,* poly(methyl methacrylate).

FIG. 160.4 Patient before and after Botox and HA filler treatment.

- Mirror
- Topical anesthetic (BLT or other lidocaine mixture)
- Gloves
- 25- to 30-gauge needle
- Microcannula
- Alcohol pads (or other disinfectant skin preparations)
- Marking pen/pencil
- Gauze pads (4 × 4 or 2 × 2)
- Ice pack
- Medical waste container
- Eyewash
- Hyaluronidase

Preparation/Dilution/Storage

- HA filler supplied in individual sterilized packages and ready to use
- Most products today supplied with lidocaine
- Common dilution/mixing (off-label)
  - Diluents containing lidocaine and/or lidocaine with epinephrine
  - Increased comfort
  - Titration of filler viscosity: Allow for more superficial injection
- Off-label storage: Anecdotal

Filler Injection Technique

General Considerations

- Vary injection depth, quantity, and technique/pattern strategies.
- Topical/injectable anesthesia and/or cold air treatment to minimize discomfort
- Aseptic technique
- Prime the needle/plunger.
- Correct with quantity sufficient to achieve desired volume effect.
- Following injection, gentle massage can be performed (depending on product).
- Mild to moderate injection-site responses, such as swelling and bruising, are to be expected and typically resolve within a few days to few weeks.
- Tailor treatment to individual needs and concerns.
- Proper patient counseling and informed consent process
- Subsequent follow-up to assess the results of the treatment and/or for further treatments

Injection Precautions.[6]

- The product should not be injected into blood vessels.

- Refrain from product use in vascular rich areas, such as the glabella and nose.
- Injector should be look for signs and symptoms of vascular occlusion and embolization: pain disproportionate to the procedure, immediate blanching, skin color changes that reflect ischemia.
- If blanching occurs, the injection should be stopped immediately with massage of area. Massage until it returns.
- Intravascular injection and embolization can lead to symptoms/signs consistent with vessel occlusion/compromise: infarction, ischemia, blindness.
- Dermal filler procedures carry a risk of infection, and standard precautions associated with injectable materials should be followed, not limited to skin disinfection.
- Superficial injections have higher risk of visible lumps and/or discoloration.

Filler Injection Pattern Strategies.[7]

- Serial puncture: Deposition of filler material in small boluses along closely spaced entry points along rhytids
- Linear threading: Filler injected gradually and evenly in the area of desired enhancement as needle is withdrawn (retrograde) and/or advanced (anterograde)
- Serial threading: Combination of serial puncture (small bolus depots) and linear threading techniques (retrograde and/or anterograde)
- Fanning: Linear threading but with needle direction change without needle withdrawal to form a fanlike pattern
- Cross-hatching: Linear threading technique applied in a series of threads that creates a injection pattern grid (at right angles) over the area of desired enhancement
- Depot: Deposition of filler material in medium to larger boluses

Filler Injection Techniques–Cannula/Microcannula

- Common areas of use

    - Tear trough/infraorbital hollow
    - Cheek
    - NLFs
    - Temples
- Theoretic advantages
    - Decreased discomfort and sequelae versus sharp needle
    - Decreased risk of intravascular injection
- Deep threading and fanning techniques
- Deeper plane of injection (subdermal, subcutaneous, preperiosteal)

Filler Injection Techniques–Filler Dilution

- Common off-label use
    - Mixing with saline, lidocaine, and/or epinephrine
    - Prior to introduction of lidocaine containing filler products
- Improved ability to inject more superficially
- Can vary dilution and viscosity

Positioning

- Physician/injector preference
- Recumbent
- Semirecumbent
- Sitting up

Anesthesia

- Topical lidocaine-based anesthesia
- Nerve/intraoral blocks
- Cooling devices—Zimmer

Monitoring

- Possible vasovagal reaction

Key Anatomic Landmarks

- Facial vessels
- Cheeks/midface
- Lips—pink and white lip
- Eyelid/cheek junction
- Eyebrow
- Jawline
- Temples

Hyaluronic Acid Fillers—On-Label Uses

Correction of Moderate to Severe Facial Wrinkles and Folds

- Dermal implantation/injection
  - Juvéderm Ultra XC, Restylane Silk
  - Lip lines/perioral rhytids
- Mid to deep dermal implantation/injection
  - Restylane/Restylane-L, Juvéderm Ultra/Ultra XC, Juvéderm Ultra Plus/Ultra Plus XC, Belotero Balance
  - NLFs, marionette lines, mouth corners
- Deep dermal to superficial subcutaneous layer
  - Restylane Lyft/Restylane Lyft-L (formerly Perlane/Perlane-L)
  - NLFs, marionette lines, mouth corners
- Submucosal implantation/injection
  - Restylane/Restylane-L, Juvéderm Ultra XC, Restylane Silk
  - Lip augmentation

Correction Midface Contour Volume Loss

- Deep dermal to superficial subcutaneous layer
  - Restylane Lyft/Restylane Lyft-L
  - Cheek/midface
- Subcutaneous to periperiosteal (deep) injection
  - Juvéderm Voluma XC
  - Cheek/midface

Anatomic Sites for Hyaluronic Acid Filler Injection/Correction (On-Label)

- NLFs (parenthesis/smile lines)
- Marionette lines
- Mouth corners
- Lip augmentation
- Lip lines/perioral rhytids
- Cheeks/midface contour

Anatomic Sites/Uses for Hyaluronic Acid Filler Injection/Correction (Off-Label)

- Forehead/glabellar rhytids
- Eyebrows
- Temples
- Periorbital
- Nasojugal grove/tear trough/infraorbital hollow (lid/cheek junction) (Fig. 160.5)

FIG. 160.5 Patient before and after Botox treatment to depressor anguli oris muscle.

- Malar smile lines
- Prejowl area
- Jaw shaping
- Earlobe
- Neck lines
- Nose (nonsurgical rhinoplasty)
- Chin (nonsurgical chin augmentation)
- Scars/acne scars

Facial Sculpting Techniques Using Hyaluronic Acid Filler

- Cheek/midface contouring
- Brow augmentation/shaping
- Upper and lower lid contouring
- Jawline contouring

- Jaw shaping
- Nose reshaping
- Chin augmentation/contouring
- Earlobe shaping

Postprocedure Period

Postprocedural Care

- Within the first 24 hours, patients should avoid strenuous exercise or activity.
- Avoid blood thinners such as alcohol and NSAIDs to minimize ecchymosis.
- Minimize excessive sun or heat exposure to avoid irritation and swelling.
- Minimize manipulation or trauma to injected/filled areas.

Complications

Complications/Adverse Reactions

- Local injection-site responses usually mild or moderate in intensity
- Most common immediate responses are redness, swelling, pain/tenderness, firmness, swelling, lumps, bruising, itching, and discoloration.
- Most symptoms resolve within 7 days.
- Delayed responses include persistent erythema, nodules/bumps, infection/biofilms, granulomas, telangiectasias and/or other skin discoloration/changes, and Tyndall effect (filler visibility).
- Dryness and peeling of skin
- Pivotal phase III trial of Juvéderm injectable gel (vs. Zyplast), multiple randomized studies, and postmarket safety surveillance of Juvéderm

injectable gel showed a similar adverse event profile.

Serious Complications/Adverse Reactions

- Serious allergic reactions (1:5000)
- Prolonged lumpiness/irregularities
- Prolonged swelling, commonly in the undereye/periorbital area
- Permanent discoloration
- Vascular occlusion/compromise leading to skin necrosis/tissue loss
- Vascular compromise leading to blindness and/or other visual compromise

Vascular Occlusion—Blindness and Visual Compromise

Overview

- The most serious complication with filler injection procedures
- Vascular occlusion/embolism can lead to tissue compromise/necrosis and/or blindness.
- FDA recent 2015 communication released alerting to risk of intravascular injection with soft tissue fillers

Literature Review.[8]

- Ninety-eight cases of vision changes from filler identified, including one case of death, in association with blindness after 5 mL of autologous adipose tissue injected into the glabella
- Risk of devastating complication of blindness is exceedingly low, considering that more than 5.5 million filler procedures/treatments were performed worldwide in 2014
- Most large case series from South Korea
  - Available data collected from major medical centers with retinal

specialists
    - Cultural popularity of volumizing high-risk central portion of the face
- Virtually every anatomic location on the face at risk for blindness
- Highest risk sites
    - Glabella (38.8%)
    - Nasal region (25.5%)
    - NLF (13.3%)
    - Forehead (12.2%)
- Every filler type used
    - Autologous adipose tissue (47.9%) was the most common filler type to cause this complication, followed by HA (23.5%).
    - HA complications had better outcomes than autologous adipose tissue, but vision loss was still seen in 39.1% of cases.
- Most common symptoms: Immediate vision loss and pain
- Most cases of vision loss did not recover.
- Central Nervous System (CNS) complications seen in 23.5% of cases

Mechanism

- Multiple mechanisms proposed for vascular compromise/occlusion
    - Intravascular occlusion
    - Embolization
    - Vessel compression/ischemia
- Intravascular injection mechanism
    - Filler material injected intravascularly can travel in retrograde fashion.
    - Injected bolus can move proximally or distally, in or against the direction of blood flow.
    - Ophthalmic artery has multiple branches and anastomoses to facial

vessels in the nose and forehead

- When filler reaches the ophthalmic artery, the bolus can travel to the retinal artery and cause partial or complete blindness.
- Further retrograde transport to the internal carotid artery and possible cerebral vascular compromise

Prevention Strategies

- Know the facial anatomy well.
- Track depth and plane of injection.
- Inject slowly and in small aliquots.
- Aspirate and look for flashback.
- May mix the filler with epinephrine
- Avoid injecting higher risk areas such as the glabella and nose.
- Consider using a cannula in the following anatomic areas: medial cheek, tear trough, and NLF.
- Use extreme caution when injecting in areas that have previously undergone previous surgical and/or nonsurgical procedures.

Management Strategies

- If a patient complains of ocular pain or vision changes, stop the injection.
- Contact an ophthalmology or oculoplastics colleague and urgently transfer the patient directly.
- Consider treating the injected area and surrounding location with high-dose hyaluronidase.
  - Possible retrobulbar injection of high-dose hyaluronidase
- Monitor the patient's neurologic status and consider brain imaging.
- Other treatment options: warm compresses, digital massage, intraocular pressure-lowering agents (acetazolamide and mannitol), intravenous (IV) and/or oral steroids, aspirin, nitroglycerin paste,

hyperbaric oxygen, antibiotics, mechanical and chemical thrombolysis, anterior chamber paracentesis, and/or anticoagulants

Hyaluronidase

- Makes HA filler treatments theoretically reversible
- Can remove/reverse partial and/or total treatment
  - Bumps/irregularities
  - Prolonged swelling (e.g., lower lid puffiness)
- Variable effect
- Commercially available products
  - Vitrase (bovine)
  - Hylenex (recombinant)
- High-dose hyaluronidase most efficacious treatment for severe vascular complications

Discussion

Evidence-Based Question

Is there a proven difference in the efficacy of different neuromodulators?

Review of existing literature on the three major botulinum toxin-A products (Botox, Dysport, and Xeomin) shows few head-to-head studies, with no definitive advantage of one product over the other. The generally accepted conversion factor between the products are 3:1 for Dysport:Botox and 1:1 for Xeomin:Botox, but consideration should be given to factors not limited to different diffusion properties, as well as modifying techniques to achieve consistent results.

Editorial Comment

Noninvasive rejuvenation procedures are too often promoted as alternatives and/or replacements of surgical rejuvenation, to the detriment of the patients' needs and reflecting misunderstanding of the

central components of the aging process. Patients with aging changes predominantly involving descent, tissue laxity, and/or excess skin would benefit more from consultation focusing on surgical options.

Frederic W.B. Delayiannis

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. When injecting fillers, which of the following anatomic areas is at high risk for vascular compromise complications?

   a. NLFs

   b. Marionette lines

   c. **Nose**

   d. Lip

2. Which of the following is NOT a branch of the external carotid artery system?

   a. Labial artery

   b. Lateral nasal artery

   c. Angular artery

   d. **Ophthalmic artery**

3. Of the following, select the one statement that is true:

   a. Botox injections are contraindicated in the lower face.

   b. Filler injections are contraindicated in the upper face.

   c. **Combination therapy with Botox and fillers in certain clinical situations can enhance therapy efficacy.**

   d. None of the above

Management of Skin Cancer of the Head and Neck

John Zitelli, and Amanda J. Tschetter

Introduction

Cancer of the skin is the most common form of cancer in humans. The incidence of skin cancer is greater than that of all other forms of cancer combined and is increasing more rapidly than any other, largely because of an aging population and an increased exposure to ultraviolet radiation. Skin cancer is most common in the 60- to 80-year-old age group, and as our life expectancy and this segment of the population have increased, the incidence of skin cancer has risen dramatically. In addition, since discovery of the health benefits of vitamins in the early 20th century, particularly the role of sunlight and production of vitamin D, sun exposure was advocated for its health benefits. As leisure time increased and convenient transportation offered warm and sunny vacations to those living in colder climates, the lifetime exposure to ultraviolet light increased as well. These and other epidemiologic factors such as the use of tanning beds and a deteriorating ozone layer have, together, resulted in a virtual epidemic of skin cancer affecting an expanded age range of patients. Because the majority of skin cancers arise on sun-exposed areas of the head and neck, it is an important part of operative Otolaryngology.

There are numerous forms of skin cancer as malignant neoplasms may arise from any cell type in the skin.

- Epidermis
  - Epidermal precursor cells → basal cell carcinoma (BCC)
  - Differentiated epidermal cells → squamous cell carcinoma (SCC)

- Melanocytes → melanoma
- Neuroendocrine cells → Merkel cell carcinoma (MCC)
- Adnexal skin cells
  - Sebaceous glands → sebaceous carcinoma
  - Eccrine glands → eccrine carcinoma and microcystic adnexal carcinoma
  - Apocrine glands → extramammary Paget's disease
- Fibroblasts → dermatofibrosarcoma protuberans (DFSP), atypical fibroxanthoma (AFX), and malignant fibrous histiocytoma (MFH)
- Endothelial cells → angiosarcoma
- Smooth muscle → leiomyosarcoma

Key Operative Learning Points

1. Each type of skin cancer has a unique appearance, biologic behavior, prognosis, and response to treatment.

2. Knowledge of the biology of each type of cancer and the optimal operative approach are important prior to beginning treatment.

Preoperative Period

History

1. History of present illness
   a. How long has the lesion been present? Lesions that have not undergone change for many years tend to be benign.
   b. Has the lesion changed in size? Increasing size or growth is a signal to consider malignancy and biopsy.
   c. Are there associated symptoms? Bleeding commonly indicates malignancy. Dysethesias, paresthesias, anesthesia, or loss of motor function (uncommon) may indicate perineural invasion.

d. Has the lesion been treated previously? Previous treatment is a signal that the original treatment was inadequate, usually secondary to unrecognized positive margins. Routine pathologic examination only samples the surgical margins, therefore a report of clear margins is only an estimate. In the face of recurrence, retreatment with routine surgery is associated with much higher recurrence rates. Consider Mohs surgery.

2. Past medical history

a. Medical illness

Predisposing syndromes that influence management

1) Basal cell nevus syndrome

a) Features: multiple BCCs, palmoplantar pits, frontal bossing, hypertelorism, odontogenic keratocysts, skeletal abnormalities, and calcification of the falx cerebri

b) Relevance: Tumors often appear before puberty and number in the hundreds over a lifetime. Patients typically become discouraged by the need for frequent treatment, are often lost to follow-up, and ultimately reappear with multiple difficult-to-treat lesions.

c) Management: Counsel to prevent discouragement and lack of regular follow-up. Plan treatments to minimize loss of work/school and quality time. Select treatments with a high cure rate to prevent repeat treatments and minimize deformity.

d) Adjunctive therapy: Chemoprophylactic treatment with retinoids (topical or systemic) has no long-term benefit. The smoothened receptor inhibitor, vismodegib, is food and drug administration (FDA) approved for advanced cases but is typically limited by intolerable side effects at standard dosing (dysgeusia, gastrointestinal disturbance, weight loss, myalgias, alopecia).

2) Muir-Torre syndrome (Subset of Lynch syndrome)

a) Features: at least one cutaneous sebaceous neoplasm (usually a sebaceous carcinoma/adenoma/epithelioma;

sometimes a keratoacanthoma) and one visceral malignancy (most commonly colorectal or urogenital)

b) Relevance: A single cutaneous sebaceous neoplasm warrants further investigation. Truncal lesions are most commonly associated with the syndrome; periocular are more likely sporadic. Testing the pathology specimen for defective mismatch repair proteins via immunohistochemistry is a sensitive screen (detects loss of protein expression of MLH1, MSH2, MSH6, or PMS2 within the tumor) and should be requested. If loss is noted, refer the patient for colonoscopy and genetic counseling.

c) Management: Most patients have only a few cutaneous cancers (curable if treated early) and should be screened regularly during their lifetime (professional and self-examination). Routine gastrointestinal and primary care appointments for visceral malignancy screening are key. Family members should also be tested.

3) Syndrome of multiple trichoepitheliomas

a) Features: Trichoepitheliomas, benign neoplasms of the hair follicle, appear as small papules on the medial aspect of the cheeks, nose, and upper lip (also, ears and elsewhere); these lesions increase in number and size over the patient's lifetime. Cylindromas and spiradenomas may also be present.

b) Relevance: Management difficulties arise.

i) Trichoepitheliomas resemble BCC clinically and histologically; misdiagnosis may occur if an accurate clinical description is not given or if an expert pathologist is not available.

ii) BCCs often develop within benign trichoepitheliomas and require adequate treatment.

iii) Pathology examination is complex because of confusion between benign trichoepithelioma and malignant BCC at the margin.

c) Management: A lesion that is enlarging, ulcerated, or looks

different from the others should be biopsied and sent to a dermatopathologist.

4) Dysplastic nevus syndrome; atypical mole syndrome

a) Arises spontaneously or as an autosomal dominant trait with incomplete penetrance

b) Features: dozens of clinically atypical nevi, usually greater than 6 mm in diameter, and often with nonuniform pigmentation. Borders appear to diffuse into the surrounding skin (normal nevi have clearly distinct borders). Highest density of nevi on the trunk, head, neck and scalp. Biopsied lesions are labeled as dysplastic nevi (DN) based on pathologic architecture.

c) Relevance: associated with an increased risk for melanoma

i) 5% lifetime risk (1% for the average population)

ii) A single DN may increase the risk.

iii) Having multiple nevi and a family history of melanoma confers the highest risk, approaching 100%.

d) Management: Controversy exists regarding diagnosis and treatment.

i) DN resemble melanoma in some ways (clinically and histologically).

ii) Biopsies are common because of the irregular clinical appearance.

iii) Pathologists may have difficulty distinguishing the morphologic and cytologic atypia characteristic of DN from melanoma.

iv) Margins are often positive.

v) Ambiguous pathology reports leave management decisions to the clinician, who may be confused about the unresolved controversy.

vi) DN with mild atypia are benign and do not require excision, regardless of biopsy margin status.

vii) DN with moderate atypia are also benign. If removal

was attempted on biopsy and pathology reports clear margins in the plane examined, we do not recommend re-excision. If biopsy margins are positive, the patient may be followed clinically or re-excision may be performed.

viii) DN with severe atypia should be conservatively re-excised as one pathologist's DN with severe atypia may be another's melanoma or melanoma in situ (MIS).

e) Importantly:

i) DN may be found in patients with or without DN syndrome.

ii) Melanomas may appear in pre-existing nevi but often develop in normal skin.

iii) Elective removal of DN does not decrease the risk for melanoma.

iv) A recurrent nevus may falsely resemble a melanoma on histopathology; a history of previous biopsy or lesion at the biopsy site should be noted in the pathology requisition.

v) Counsel patients to minimize lifetime exposure to ultraviolet light, to perform regular skin self-examinations, to have yearly checkups by dermatologists, and to understand the genetics for children and close family members.

Diseases associated with skin cancer

5) Oral lichen planus

a) Chronic inflammatory condition of skin and mucous membranes

b) Whitening of the vermilion lip, ulceration, thickening of the epidermis, and induration caused by the inflammatory response can simulate SCC clinically and histologically.

c) Predisposes to development of true invasive SCC

d) Clinicopathologic correlation is imperative.

6) Solid organ transplant

a) Skin cancer (majority are SCC) is a serious, nearly universal long-term sequela.

b) Emphasizes the important role of immune surveillance in the prevention of skin cancer

c) Patients often become discouraged with the overwhelming number of skin cancers, the need for frequent treatment, and the time and effort required to keep up with therapy.

d) Neglected or recurrent disease may be life-threatening and is often the cause of death in transplant patients.

e) Coordinating medical management with the transplant team to optimize the immunosuppressive drug regimen is often advisable.

f) Early effective treatment, constant surveillance, follow-up, and patient education are imperative.

7) Chronic immunosuppression

a) Human immunodeficiency virus–positive patients with low CD4 lymphocyte counts have a higher risk for SCC (and other skin cancers). Chronic human papillomavirus infection plays an important role.

b) Compromises the prognosis of patients with known metastases or those at high risk for metastases

b. Surgery

c. Family history

d. Medications

8) Many medications increase the risk of postoperative bleeding.

a) Antiplatelet drugs

b) Vitamin K antagonists

c) Direct thrombin inhibitors

d) Factor Xa inhibitors

e) High dose Vitamin E

f) Herbal products (garlic, gingko, feverfew, ginger, and saw palmetto)

9) The risk of postoperative bleeding or hematoma (<1%) is a minor concern in comparison to consequences of myocardial infarction or cerebral vascular accidents; therefore it is ill-advised to stop physician-prescribed anticoagulants for skin cancer surgery.

10) Self-prescribed supplements should be stopped 10 to 14 days prior to surgery.

e. Social history

1) Alcohol

a) Increases risk of postoperative bleeding

b) Advise abstinence for 24 hours leading up to and 48 hours postprocedure.

2) Tobacco

a) Increases risk of flap/graft failure

b) Adversely effects cosmesis

c) Patients should be counseled to quit (or decrease consumption as feasible).

3) Living situation/support system

a) One repair option may be favored over another based on postsurgical needs.

b) May determine ability to pursue adjuvant therapies

Physical Examination

1. Crucial to preoperative planning and decision making
2. Evaluating tumor size and margins

a. Nonmelanoma skin cancers:

1) Tightly stretch the skin under light-emitting diode (LED)

examination or operating room lights.

2) Clues to tumor extension of BCC and SCC

a) Subtle pink color (vascular response induced by inflammation)

b) Scar-like white or yellow color (fibrosis and tumor infiltration)

c) Shiny or pearly appearance (underlying tumor lobules obscuring normal fine skin wrinkling)

d) Dermatitis-like appearance

i) Extension of superficial BCC or SCC in situ beyond invasive disease may simulate dermatitis, appearing totally different from the primary tumor (must distinguish from dermatitis due to bandaging).

3) Tumor depth

a) Difficult to estimate beyond simple palpation and movement over underlying structures (Mobile? Attached to bone?)

b. Melanoma of the head and neck

1) Margin assessment is more difficult compared to the trunk/extremities.

2) Lentigines, freckles, seborrheic keratoses, and actinic keratoses (AKs) may all camouflage the margin.

3) In situ extensions at the edge are often amelanotic, simulate dermatitis, or may be totally invisible.

3. Evaluating for local, regional, or metastatic cancer

a. Palpate the regional skin, soft tissues, and lymph nodes to determine the presence of satellite metastases, in transit metastases, or lymph node metastases.

b. Important in SCC, melanoma, MCC, undifferentiated pleomorphic sarcoma (UPS) (previously MFH), and sebaceous carcinoma

Imaging

1. Adjunctive testing to evaluate lymph nodes for metastatic cancer has limited value.

2. Imaging may be useful in obese patients in whom palpation of early clinical disease is difficult.

3. Preoperative imaging to determine the extent of invasion is minimally helpful.

   a. Only estimates the likelihood of bone invasion, orbit invasion, or involvement of vital structures of the neck

   b. Estimates the extent of *gross* tumor involvement but cannot detect *microscopic* extensions of skin cancer in soft tissue that often extend many millimeters from the main tumor mass

Indications

1. Most are surgical candidates.

2. Most skin cancers are small (<2 cm) and can be treated under local anesthesia in the office, ambulatory surgery center, or hospital outpatient setting with or without sedation.

3. Common contraindications to surgery often do not apply to smaller procedures.

   a. Anticoagulants may be safely continued (see "Medications" above).

   b. Age is generally not an issue.

      1) Most tumors require simple, low-risk operative procedures.

      2) A short, 1-day procedure is less disruptive to fragile, elderly patients than managing chronic, nonhealing ulcers from untreated skin cancer.

Contraindications

1. True contraindications to skin cancer surgery are rare.

2. *Life expectancy* is more important than age.

   a. Consider the biologic behavior of the skin cancer and the patient's health and life expectancy.

1) BCC is a slowly growing cancer that may be asymptomatic for years. There may be no need to treat a small, nonulcerated BCC in a patient with other metastatic disease and a life expectancy of less than 1 year.

2) Treatment of nodular melanoma in an independent 95-year-old patient may be curative and allow the family to celebrate the potential 100-year mark.

3. Extent of disease and the impact of surgery

a. Very rarely, extensive or invasive cancers may require surgery that has a significant mortality rate, impacts quality of life after surgery, or is unlikely to achieve cure. The balance of risks and benefits must be weighed carefully.

1) Is it worthwhile to remove one eye because of a slowly growing BCC in an elderly patient who has little or no vision in the other eye?

2) Is temporal bone resection for management of a "close positive margin" after excision of SCC worth the mortality risk?

4. Informed consent must include the probability of results from treatment versus no treatment, alternative forms of therapy, and palliative treatment options.

Preoperative Preparation: Determining Surgical Margins by Histologic Tumor Type

Histopathology

1. Distinguishes tumor from benign diseases that may mimic cancer

FIG. 161.1 Nodular basal cell carcinoma of the inner canthus.

2. Pathology results should correlate with the clinical picture.
   a. Biopsies are often small samples of a larger lesion and may not represent the entire tumor.
   b. Microscopic appearance of one skin cancer may simulate another (melanoma may be confused with a superficial BCC, and a MCC can be confused with cutaneous lymphoma).
   c. If the patient's history, tumor appearance, and histopathology results do not all correlate, another biopsy is indicated.
3. Histologic diagnosis of tumor type is essential to surgical planning.
   a. Determines the need for evaluation of metastases
   b. Determines width of the surgical margin

Complete removal of skin cancer is achieved through careful patient selection, surgical planning, and extensive examination of the margins by a pathologist. The approach differs according to tumor type. The best chance for cure is the first operation.

1. BCC (Fig. 161.1)
   a. Five-year cure rates of 90% to 95% are achievable by careful selection and planning.
   b. Primary BCC with a diameter ≤2 cm and clearly visible margins requires a 4-mm wide surgical margin.[1]

1) 1 to 2-mm margins cure some BCCs, but 5-year cure rates are only 50% to 60% (inadequate).

c. Margin depth is more difficult to estimate and depends more on the location of the tumor and clinical judgment.

d. High-risk lesions and certain situations require margins wider than 4 mm or careful intraoperative frozen section control:

1) Morpheaform/sclerosing/infiltrative

2) Micronodular

3) Superficial

4) BCC greater than 2 cm in diameter

5) Recurrent cancer

2. Cutaneous squamous cell carcinoma (cSCC) (Fig. 161.2)

a. cSCCs are associated with a significant risk for metastases; however, extra wide margins, excised in the hope of including microscopic satellite metastases, do not improve survival or local control.

b. Risk for tumor persistence is minimized to an acceptable level when histopathologic sampling confirms negative margins with the following clinical margin widths[2]:

1) Low-risk cSCC → 4-mm margin

FIG. 161.2 Squamous cell carcinoma of the auricle.

a) Less than 1 cm in diameter

b) Location: cheek, neck, and similar

c) Not invading adipose tissue

d) Histologic grade 1

2) Moderate-risk cSCC → 6-mm margin achieves a clear surgical margin in 95% of cases

a) 10 to 19 mm in diameter

b) 2- to 6-mm Breslow thickness

3) High-risk cSCC → 9-mm margin

a) ≥2 cm in diameter

b) Greater than 6-mm Breslow thickness

c) Invasion of subcutaneous adipose tissue

d) Perineural invasion of nerves with a diameter greater than 0.1 mm

e) Location: temple, vermilion lip, scalp, ears

c. Keratoacanthoma → 5-mm margin

1) Variant of cSCC

2) Often grows extremely rapidly

3) May appear as a dome-shaped, crateriform nodule

4) Spontaneous involution without treatment has been reported

5) Can be aggressive, destructive, and indistinguishable from true cSCC, including the ability to metastasize

6) Treatment of choice is complete removal

d. Squamous cell carcinoma in situ (SCCIS)

1) A small or large scaly macule or patch

2) Malignant atypical cells are limited to the epidermis

3) Squamous atypia extending down hair follicles into the dermis makes treatment more difficult. Deep destruction or full-thickness skin excision is required.

4) In lesions with minimal or no follicular extension, superficial destruction (curettage, cryosurgery, or laser surgery) is quite effective.

5) Untreated or inadequately treated SCCIS often progresses to true invasive cSCC with metastatic potential.

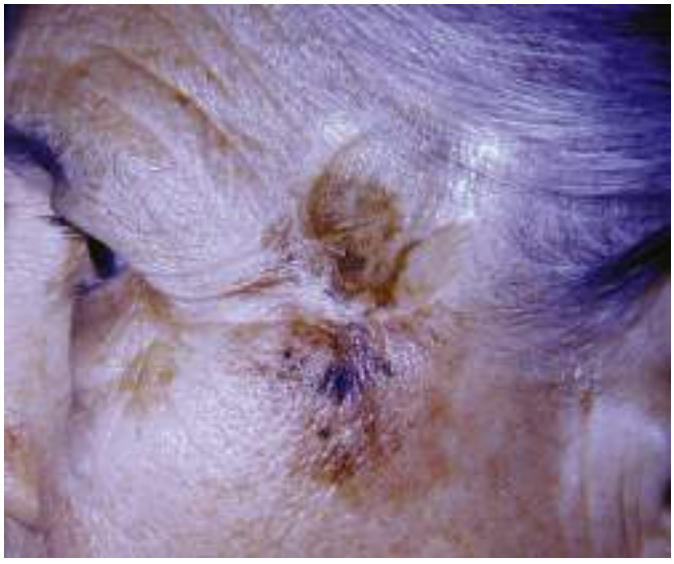

FIG. 161.3 Locally recurrent melanoma on the temple.

3. Melanoma (Fig. 161.3)

a. Successful excision of melanoma on the head and neck is more difficult than excision on the trunk and extremities.

1) Margins are more difficult to visualize.

2) Amelanotic melanomas are more common.

3) Surgical margins are often reduced for cosmetic or functional reasons.

4) 9% to 18% of cases recur at the surgical margin because of inadequate excision.

b. Surgical margins:

1) A 5-mm margin (consensus statement[2i]) for MIS has no scientific basis and often results in inadequate excision and recurrence of both in situ and invasive melanoma.

2) 1.2-cm margins cleared melanomas of all thicknesses on the head and neck in 97% of cases.[3]

3) 1.5-cm margins cleared MIS on the head and neck in 97% of cases.[4]

4) 5-mm margins clear more than half of MIS on the head and neck, but up to 2.4-cm margins are required to clear 100%.[3,4]

5) Given that margin requirements may vary greatly from one tumor to the next (an MIS lesion may require 2.4-cm margins whereas an invasive melanoma with a Breslow depth greater than 4 mm may be cleared with a 6-mm margin in more than 50% of the cases), melanomas of the head and neck are best treated by Mohs surgery to confer the highest cure rates possible while preserving tissue to maximize both cosmetic and functional outcomes.

c. Surgical technique

1) There is high-level evidence for treating both invasive and in situ melanomas, especially those located on the head and neck, with Mohs surgery.

2) Interdisciplinary care coordination is possible and effective.

a) Excision of the primary melanoma by the Mohs surgeon followed by surgical nodal exploration by the head and neck surgeon prior to reconstruction can produce exceptional results with a local recurrence rate of less than 1%.[5]

d. Recurrent melanoma

1) Due to inadequate excision

a) Occurs along the previously treated surgical margin

b) Histopathology of the biopsy specimen generally shows an intraepidermal component.

c) Much better prognosis than metastatic recurrence

d) Prognosis still accurately related to tumor thickness

2) Due to metastasis

a) Histopathology of the biopsy specimen generally shows only dermal or subcutaneous components.

e. Sentinel lymph node biopsy (SLNB)[6]

1) Slight improvement in estimating a patient's prognosis in comparison with Breslow thickness alone for melanomas 2 to 4 mm thick

2) Breslow thickness is more accurate than SLNB in melanomas less than 1 mm and greater than 4 mm thick.

3) Early detection of microscopically positive lymph nodes with complete lymph node dissection may aid in improved regional control, which can be an important benefit in the head and neck, especially in patients who may otherwise neglect regular follow-up or self-palpation of lymph nodes and be seen instead with advanced regional lymph node metastases.

f. Completion lymph node dissection (CLND)

1) Value remains unproven

2) Final results of the Multicenter Selective Lymphadenectomy Trial I (MSLT I) (no SLNB vs. SLNB ± completion

lymphadenectomy) showed no survival benefit for SLNB and CLND in patients with microscopically positive disease.[7]

3) Results of the MSLT-II trial (SLNB-positive patients received completion lymphadenectomy vs. observation with nodal ultrasound), expected in 2022, will hopefully provide further evidence to guide clinical decisions about SLNB and CLND.

g. Gene expression profiling (GEP)

1) Test performed on the original formalin-fixed, paraffin embedded tumor

2) Tumor classified as class 1 (low risk) or 2 (high risk) for the 5-year risk of distant metastasis

3) More accurately stratifies high- and low- risk patients compared to SLNB

4) Assay combined with SLNB status can help identify SLNB(−) patients with high-risk disease as well as SLNB(+) patients who are unlikely to show disease progression.

h. Radiation therapy (RT)

1) Adjuvant regional RT may decrease local recurrence but does not improve overall survival.

i. Systemic therapies

1) Traditional chemotherapy such as dacarbazine showed durable response rates less than 2%.

2) There has been a relative explosion in melanoma-specific drug therapies in recent years. Advanced therapies are prolonging survival in patients with stage IV melanoma. Numerous ongoing phase III trials are investigating the effects of immunotherapies and cell-signaling effectors in the adjuvant setting for stage III melanoma patients.

3) Therapies to watch include the following:

a) Immunotherapies: programmed cell death 1 (PD-1) and cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) immune checkpoint inhibitors

b) Cell-signaling effectors: BRAF, MEK and cyclin-dependent

kinase 4/6 (CDK4/6) inhibitors

c) Intralesional therapies: Talimogene laherparepvec (T-VEC), Interleukin-12 (IL-12), and rose bengal (PV-10) intratumoral injections

j. Final points:

1) Primary management remains a surgical issue.

2) Early, complete removal of primary disease is the most important factor.

3) Teaching patients to palpate nodes and soft tissue is important.

4. Adnexal neoplasms

a. Sebaceous carcinoma

1) Malignant tumor of sebaceous glands

2) Commonly occurs on eyelids; also in other sites of the skin of the head and neck

3) Malignant potential similar to cSCC and should be treated as such

4) See section on Muir-Torre syndrome.

b. Microcystic adnexal carcinoma and eccrine carcinoma

1) Clinical appearance similar to BCC

2) Often show extensive subclinical invasion

3) Wider margins are more necessary than for BCC.

4) Complete margin examination or Mohs surgery will minimize the high rate of recurrence.

c. Trichoepithelioma

1) Benign tumor of the hair follicle (see syndrome of multiple trichoepitheliomas)

5. Merkel Cell Carcinoma (MCC)

a. Arises from neuroendocrine cells

b. Nondescript pink or red papule or nodule (rarely diagnosed clinically)

c. Biologic behavior is similar to melanoma

d. Very high risk of metastatic cancer

e. Microscopic extensions of MCC are much wider and deeper than clinical estimates.

f. Wide and deep margins (i.e., 2 cm) are recommended.

g. Careful histologic examination of the surgical margins is important to validate complete excision.

h. Mohs surgery can ensure total excision.

i. If negative margins are not possible or are in question, MCC is very radiosensitive, and RT may improve local control.

j. The role of SLNB and elective lymph node dissection may be similar to that in melanoma, although there is no proven survival benefit.

6. Dermatofibroma Sarcoma Protuberans (DFSP)

a. Tumor of fibroblast origin

b. Presents as a dermal subcutaneous, scar-like mass

c. Often a nodular tumor greater than 2 cm in diameter

d. Invades dermis and fibrous septa between lobules of adipose tissue so microscopic extent is much wider and deeper than is visible or palpable

e. Rarely metastasizes but has high local recurrence rates due to difficulty of clinically estimating microscopic tumor extension

f. Imaging studies are of limited value.

g. Wide lateral margins of 2 to 2.5 cm of normal-appearing skin may be adequate to clear the surgical margins.

h. The deep margins are often the most difficult to estimate.

i. Careful histologic margin control is important.

j. Mohs surgery is very effective and produces the lowest recurrence rates with the narrowest margins possible.

7. Angiosarcoma

a. Malignant tumor of blood vessels

b. Early on it is a purple papule or nodule but is most often detected as a large flat plaque resembling a bruise covering a wide area of the scalp and forehead.

c. Clipping the hair is necessary to see the full extent of disease in hair-bearing areas.

d. Surgical management is difficult:

1) Margins are difficult to evaluate histologically because growth of the malignant vessel is subtle.

2) Small lesions may be excised, but local recurrence and regional metastatic rates are high.

3) Large lesions are often not amenable to surgery because of their extreme size.

e. Radiation Therapy (RT):

1) It is a radiosensitive tumor so that treatment of small lesions improves local control.

2) Employed as the primary treatment for large lesions not amenable to surgery

f. Adjuvant chemotherapy has no proven value for the primary tumor.

8. Atypical Fibroxanthoma (AFX) and Undifferentiated Pleomorphic Sarcoma (UPS)

a. Often present as a pink papule or erosion in sun-exposed areas

b. Resemble SCC or BCC; usually diagnosed only after biopsy

c. AFX

1) Involves only the dermis and superficial adipose tissue

2) Rarely metastasizes

3) Excise with margins similar to those for cSCC

d. UPS

1) Previously "malignant fibrous histiocytoma"

2) Deeper than AFX; involves subcutaneous tissue or muscle

3) High risk of metastasis

4) Excise with a width and depth similar to that for MCC or melanoma

e. Elective regional lymph node dissection

1) Unnecessary for AFX

2) No proven value for UPS

9. Tumors of uncertain behavior

a. Surgeons are often faced with tumors on the head and neck with uncertain biologic behavior.

b. Ultimately, the clinician must process the information described by the pathologist along with the clinical picture to decide whether to manage it as a benign or malignant lesion.

c. Spitz nevi

1) Benign nevi

2) Usually enlarging, red papules in children or young adults

3) Resembles nodular amelanotic melanoma clinically and histologically

4) A classic lesion in a child 16 years or younger with a histologic diagnosis of Spitz nevus from a dermatopathologist does not require excision.

5) Uncertain lesions (lesions arising in adults, those showing cellular atypia or nonclassic histology) should be excised and treated as though they were melanoma (negative surgical margins documented by careful histologic examination).

d. DN

1) See "management" under dysplastic nevus syndrome section.

e. Many cutaneous lesions have overlapping features with their benign and malignant counterparts.

1) Desmoplastic trichoepithelioma can resemble morpheaform BCC clinically and histologically.

2) Other tumors of follicular origin may be difficult to distinguish from BCC with follicular differentiation.

Operative Period

Anesthesia

General: rarely necessary

Conscious sedation: occasionally necessary (benzodiazepines ± opiates)

Local: preferred as it minimizes the risk to the patient

Positioning

Supine

Prone

Lateral recumbent

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Second-generation cephalosporin

Clindamycin if allergic to penicillin

Instruments and Equipment to Have Available

1. 15-blade and blade handle
2. Forceps:
   a. Straight, serrated dressing (aid in margin-controlled excisions to decrease tissue damage)
   b. Adson, Brown-Adson (suturing)
3. Skin hooks (hemostasis, suturing, reconstruction planning)
4. Hemostats

5. Scissors:
    a. Straight iris (serrated or tungsten carbide)
    b. Suture cutting
6. Gauze
7. Cotton-tipped applicators
8. Desiccator or bipolar electrocautery
9. Needle driver
10. Suture
    a. Deep tissue and dermal approximation:
        1) Polyglactin 910/polyglecaprone 25/polydioxanone
    b. Epidermal approximation:
        1) Fast-absorbing surgical gut/polypropelene/polyglecaprone 25
    c. Tissue marking for pathology: any
    d. Securing a bolster:
        1) Silk or polyglactin 910
11. Special site considerations
    a. Eyelid:
        1) Anesthetic drops and eye shield (stainless steel or plastic)
        2) Beaver blade and handle
        3) Scissors
            a) Gradle
            b) Castroviejo curved iris
        4) Castroviejo needle driver
        5) Forceps
            a) Bishop-Harmon
            b) Paufique

Key Anatomic Considerations, Common

Errors, and Surgical Repair Techniques by Tumor Location

1. Surgical approach to skin cancer must consider
    a. Tumor type
    b. Anatomic location
        1) Incidence and biologic behavior vary according to location.
    c. Margin verification
        1) Prior to repair there must be reasonable certainty that excision margins are tumor-free via:
            a) Use of evidence-based surgical margin width around a well-defined primary lesion
            b) Negative margins by extensive histopathologic frozen examination of all margins or Mohs surgery for large, deep, recurrent, or poorly defined tumors
                i) Alternatively, delay reconstruction until margins have been determined to be negative by permanent paraffin sections.
        2) Re-excision for positive margins becomes especially difficult after local flaps, complex reconstruction, or repair with extensive undermining of tissue.
    d. Reconstruction options
        1) Each defect is unique with its own challenges, but in most locations, reconstructive choices are predictable and yield reproducible results.
        2) The repair method depends on the likelihood of negative margins, laxity and availability of adjacent skin for closure, and patient's desire for a good cosmetic outcome.
2. Eyelids/periocular region
    a. BCC, SCC, melanoma, and sebaceous carcinoma are most common.
    b. *Anatomic considerations:*

1) Inner canthus region

a) BCC tends to invade deeply.

b) A cancer that appears to be fixed to bone often involves the lacrimal drainage system or extends into the orbit.

c) The reason for deep extension of small BCCs is not the "embryonic fusion plane" theory but rather that growth of BCCs is stromal dependent.

i) Only invades tissue with appropriate stromal components

ii) Show poor, slow growth in adipose tissue

iii) Grow more quickly in fascia and muscle

iv) With little protective adipose tissue in the periocular region, BCC quickly invades through the dermis into the deeper tissues of the medial and lateral canthus and orbital septum.

d) Microscopic extensions are invisible, hard to predict, and not identifiable by MRI or CT.

c. *Common errors:*

1) Very difficult to achieve negative histologic margins with narrow surgical margins as clinical margins are often indistinct, especially in superficial BCC on thin eyelid skin and in tumors infiltrating into the lid margin and tarsal plate

2) Mohs surgery or careful complete margin examination is important for successful management of periocular skin cancers.

d. Surgical repair techniques

1) Keys

a) Protect the eyes, especially the cornea.

i) Poorly planned repairs may result in ectropion with exposure-induced desiccation of the conjunctiva or keratitis from drying of the cornea.

b) Suture must be placed in a manner that prevents irritation of the globe.

c) After the key suture(s) is/are placed, have the patient open the eyes and mouth and look up (placing the eyelid under maximal tension) to check for distortion and to ensure apposition of the lid against the globe.

2) Eyelid defects

a) Defects crossing the eyelid margin are often best repaired by an oculoplastic surgeon.

b) Primary closure

i) Is easily performed on eyelid skin within the orbital rim

ii) Care must be taken to move tissue horizontally, even when ellipse orientation is somewhat oblique.

c) Inferiorly and laterally based rotation flap

i) Is appropriate for larger defects of the lower lid

ii) Extend the lateral incision superiorly so that during rotation, when the superior portion of the flap moves medially and inferiorly, the eyelid is not pulled down.

d) Full-thickness skin graft

i) Provides excellent cosmesis in the medial and lateral canthal regions

ii) Secondary choice for lower lid defects as the inevitable shrinkage of the graft increases the risk of ectropion

3) Brow defects

a) Must move hair-bearing skin to maintain brow continuity, even if brow length is shortened

b) Vertically oriented primary closures are appropriate for small defects.

c) V-to-Y flaps are good for larger defects.

d) Hair-bearing, full-thickness composite grafts, harvested from the temples, are rarely necessary.

i) Proper orientation of the hair follicles must be maintained (even to the point of a double graft).

1. Top graft of hair faces inferior and lateral.

2. Bottom graft of hair faces superior and lateral.

3. Ears

a. BCC, SCC, AFX, and melanoma are most common.

b. *Anatomic considerations:*

1) Tumors of the antihelix, conchal bowl, and the external auditory canal tend to invade through the thin skin quickly down to perichondrium and spread laterally with little visual surface change.

2) Sacrificing cartilage may be necessary to achieve negative surgical margins, but tumors rarely invade cartilage.

3) Lack of adipose tissue in the preauricular and postauricular sulcus allows for quick invasion, often making deep negative surgical margins difficult to achieve.

c. *Common errors*:

1) Margins are difficult to outline with certainty so recurrence rates are high.

2) Chondrodermatitis nodularis helicis (focal pressure dermatitis) of the ear can simulate malignancy (biopsy prior to excision).

d. Surgical repair techniques

1) Helical defects

a) Are typically the most challenging to reconstruct

b) Full-thickness skin graft

i) Useful when cartilage and perichondrium (vascular base) are preserved

ii) Donor site: postauricular skin

iii) Provides very good cosmesis

c) Helical rim advancement flap (Fig. 161.4)

i) For defects greater than 1 to 1.5 cm extending to or including cartilage

ii) Cut anteriorly through the skin and cartilage but not

through the posterior skin.

1. Undermining/separating the posterior skin from cartilage leaves a large vascular base for the flap.
2. Cutting through anterior skin, cartilage, and posterior skin leaves only a small base of the helix to provide the vascular supply so the tip is often compromised.

d) Advancement flap from the postauricular surface through the postauricular sulcus

i) For large defects on the helical rim

ii) Can be performed as a one- or two-stage procedure

iii) Very reproducible repair

iv) May require cartilage replacement from the ipsilateral conchal bowl if cartilage from the helical rim is missing

2) Scapha defects

a) Split-thickness skin graft

i) For superficial defects

ii) Donor site: postauricular mastoid skin

b) Second intention healing

i) Defects inside the rim of the scapha heal nicely.

3) External canal defects

a) Should be grafted if more than half of the circumference is involved to prevent stenosis of the canal

4) Very large defects involving more than half the ear

a) A prosthesis is often better than reconstruction. Salvaging the tragus helps camouflage the prosthetic border.

b) Wedge resection often yields inferior cosmetic results compared with other reconstruction choices and should be avoided.

4. Lips

a. BCC (upper lip) and cSCC (lower lip) are most common.

b. *Anatomic considerations and common errors:*

1) cSCC is often associated with a dense inflammatory infiltrate making depth of invasion difficult to assess (tumor frequently feels deeper than is seen microscopically).

2) Invasive cSCC of the lower vermilion lip with extensive SCCIS along lateral portions of the vermilion is common (SCCIS often extends much wider laterally than appears clinically).

c. Surgical repair techniques

1) Please see Chapter 27.

5. Nose

a. BCC, SCC, melanoma, and MCC are often seen.

b. *Key anatomic considerations and common errors:*

1) Depth of tumor invasion is difficult to estimate, especially on the lower third of the nose.

a) Underlying cartilage makes it difficult to adequately palpate.

b) Lack of adipose tissue allows early invasion of muscle and fibrous tissue.

c) SCC of the nasal septum frequently invades into the bone of the nasal spine.

2) Recurrence rates for all skin cancers are high; careful margin examination or Mohs surgery is helpful.

c. Surgical repair techniques

1) Please see Chapter 163.

6. Cheeks

a. All forms of skin cancer are seen, including DFSP and angiosarcoma.

b. *Key anatomic considerations and common errors:*

1) Adipose tissue is often a barrier to invasion of deeper structures until the cancer becomes very large.

2) Tumor invasiveness is enhanced by superficially located muscle and aponeurotic layers along the medial portion of the cheek

adjacent to the nose and the lateral preauricular cheek. Negative margins are most difficult to achieve at these sites.

c. Surgical repair techniques

1) Please see Chapter 171.

7. Forehead, temple, and scalp

a. All forms of skin cancer are seen.

b. cSCC tends to be aggressive; satellite metastases are common with large tumors.

1) Management of multiple satellite and in transit metastases

a) Surgical excision preferred when possible

b) Adjuvant wide-field radiation for widespread metastasis can be utilized for local/regional control.

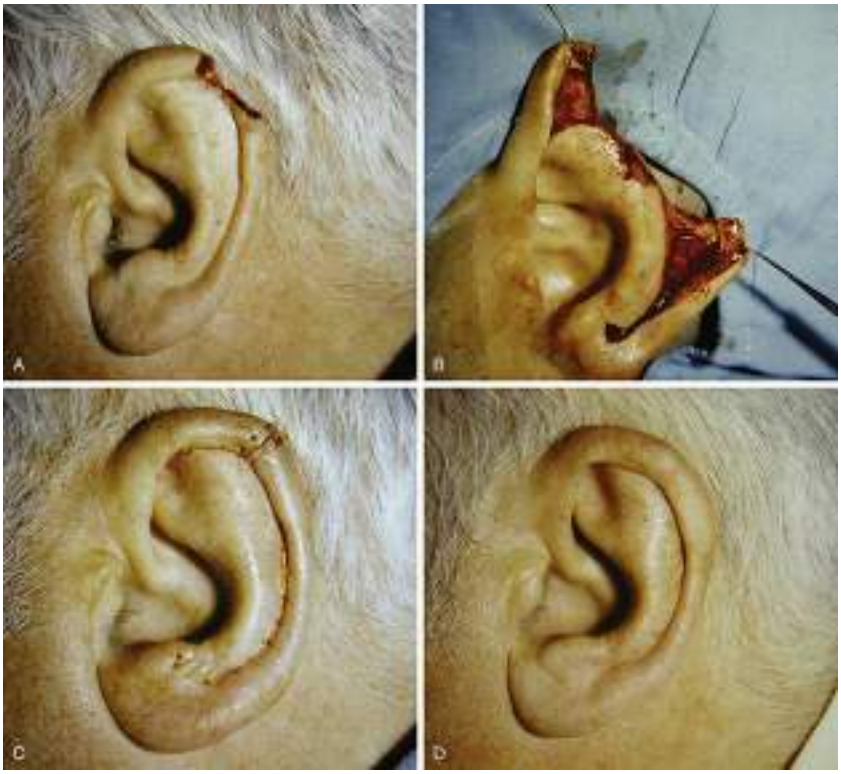

FIG. 161.4 **Helical rim advancement flap.**

A, Defect after excision of basal cell carcinoma. **B,** Bilateral helical rim advancement flaps elevated with a broad posterior base. **C,** Immediate postoperative result. **D,** Cosmetic result after

6 months.

c. Key anatomic considerations

1) Skull

a) Acts as a strong barrier to invasion

b) If bone appears pitted upon removal of periosteum it is assumed that early bone invasion has occurred, and the outer cortex should be removed (via osteotome, bur, or excision). Cover with a split-thickness skin graft.

c) If bone is exposed but not involved, burring to improve survival of the reconstruction should be performed only as a last resort.

i) Burring the outer cortex destroys its barrier function to tumor invasion.

ii) The tumor can then easily invade the bone, making treatment of recurrences a high-risk operation.

2) Temple

a) Care should be taken to avoid the temporal branch of the facial nerve during excision and undermining.

d. Common errors:

1) Early bone invasion is not easily seen with imaging studies and must be assessed intraoperatively.

e. Surgical repair techniques

1) Please see Chapter 164.

Managing Open Wounds

1. Wounds best managed without reconstruction:

a. Small biopsy wounds

b. Wounds after excision of small cancers at the medial canthus, alar crease, ear, forehead, and scalp

c. Large graft donor sites

2. Predictable events can inform decision making about which wounds can heal and which should be repaired.

a. Wounds in concave areas heal with better cosmesis than do wounds on convex surfaces.

b. Scars on pigmented skin or a red, ruddy complexion will be more noticeable than the same scar in pale, white skin.

c. Scars are better camouflaged in skin with other lesions like lentigines or keratoses than in flawless skin.

d. All wounds contract; distortion of nearby structures during healing (eclabion and ectropion) is possible.

Evaluation of Surgical Margins and Pathology Report Interpretation (Prerequisite Skills)

1. The major goal of treating skin cancer is to excise or destroy the tumor completely.

2. Destructive techniques, including RT, rely on a certain amount of guesswork in estimating the margin without the benefit of a tissue specimen to accurately evaluate the success of removal.

3. One advantage of surgical excision is the ability to evaluate the margins to assess completeness of removal.

4. If the goal of surgery is complete excision, and if the surgeon relies on the pathologist to measure the success of excision, the surgeon must understand the process of margin examination.

5. *Routine tissue processing* by pathologists:

a. Involves only margin sampling

b. Most "bread-loaf" specimens. This technique examines less than 0.1% of the margin.

c. At best, only an estimate of surgical margin status is reported.[8]

d. Biopsy of a malignant lesion that was not removed with the intent to include standard surgical margins may be reported by the

pathologist to have negative margins, even when visible tumor remains.

e. Surgeons must keep this in mind when interpreting pathology reports.

f. It is critical to excise skin cancer with adequate margins of normal skin and only then use the pathologist's report to validate excision results.

6. Intraoperative frozen sections

a. Give a quick estimate of margins.

b. Are technically difficult to cut

c. Intraoperative examination usually samples far less than the 0.1% examined by permanent sections.

d. Results are followed by more accurate results from permanent sections (better quality for visualization), but these are typically only available days later.

7. *Peripheral in-continuity tissue examination (en face tissue sectioning)*

a. Some pathologists are willing to examine a greater portion of the margin.

b. Strips of tissue from lateral and deep margins are processed from tangential cuts.

c. Provides a more complete margin assessment

d. Useful in evaluating a high-risk infiltrating skin cancer or those with clinically indistinct margins

8. *Mohs surgery*

a. Method of complete histologic control of the surgical margin[9]

b. Literally examines 100% of the margin providing the most complete margin examination possible

c. Excisional method performed under local anesthesia that differs from routine excision by surgical technique and tissue processing

d. Tissue is excised in a way that allows the entire margin to be flattened into a two-dimensional, one-plane tissue "patty."

e. This “patty” is cut into pieces for processing like a puzzle, the edges are dyed and numbered for individual identification, and a corresponding puzzle-like map of the specimens is drawn.

f. Each specimen is processed so that the entire outer surface is examined microscopically.

g. Results of the microscopic examination are marked on the map.

h. Any remaining cancer at the margin can be located within the wound by using the map.

i. The remaining cancer is re-excised in the positive area, reprocessed in the same fashion, and repeated if necessary until a true tumor-free plane is reached.

j. The initial surgical margin is narrower than traditional margins (because complete margin examination is possible) and is often negative resulting in smaller wounds than those after traditional excision.

k. Benefits:

1) A negative margin is ensured with almost certainty.

2) Recurrence rates are low.

3) The rate of skin cancer cure is the highest of any method.

4) Often preserves valuable normal skin for reconstruction by removing tumor with very narrow margins

l. Mohs surgery as an alternative to routine excision becomes most useful in certain cases:

1) Skin cancers that might be at higher risk for recurrence

2) Those in the midface and ears (depth and lateral margins are difficult to estimate)

3) Previously treated skin cancers (recurrent or those excised with positive margins)

4) Cancer in areas where the smallest possible wound is important to achieve the best cosmetic or functional result

5) Infiltrative tumors

6) Tumors with poorly defined margins

7) Tumors with high risk histopathologic characteristics that make negative margins difficult to achieve by routine excision

8) Excisions requiring complex reconstruction

a) Otherwise, routine surgery should be followed by delayed reconstruction until negative margins are confirmed by permanent paraffin pathology sections.

m. Like routine excision, it usually requires a half- or full-day time commitment for patients.

n. Requires special fellowship training because the surgeon also acts as the pathologist to better correlate the pathology results with the clinical tumor margin

o. Mohs surgeons are an important part of the multispecialty team for the treatment of skin cancer.

1) Often contribute by completely excising the cancer and working with colleagues for reconstruction after Mohs surgery

2) Can clear soft tissue margins and identify any remaining tumor near vital structures of the head and neck, such as invasion of bone; perineural invasion extending into the infraorbital, supraorbital, or other important foramen; and invasion of the parotid gland close to the facial nerve

p. Its costs compare favorably with other office procedures.

1) In times of limited health care dollars, cost consideration is critical.

2) TABLE 161.1 compares costs for the most common treatment options, including the cost from the time of initial evaluation up to and including 5 years of follow-up screening.[10]

9. Positive pathology report

a. A pathology report with a final diagnosis of a positive margin should be taken seriously.

b. Approximately 10% to 12% of excision specimens of head and neck cancer are positive for tumor at the margin.

c. Without further treatment, at least a third will recur and may be difficult to cure after recurrence.

TABLE 161.1

Average Cost of Treating Skin Cancer by Different Methods

Method	Cost, $, Mean (Range)
Destruction (electrodessication and curettage)	392–652[a]
Office excision/permanent section	1,025.83 (438.22–13,459.09)
Mohs surgery	804.72 (544.67–8,397.67)
Office excision/frozen section	1,199.82 (693.49–13,702.18)
Ambulatory surgery/frozen section	2,507.10 (1,141.99–16,761.27)
Radiation therapy	2,559–4,558[a]

[a] Based on other reports referenced in this study.

From Ravitskiy L, Brodland DG, Zitelli JA. Cost analysis: Mohs micrographic surgery. Dermatol Surg 2012, 38(4):585–594.

d. When margins are positive, re-excision or Mohs surgery should be attempted.

e. When repeat surgery is not an option, RT may be considered, but the chance for cure is lower than with pathologically documented negative margins.

Operative Risks

1. Postoperative hemorrhage or hematoma
2. Pain
3. Sensory and motor nerve injury
   a. Temporal branch of facial nerve
   b. Marginal mandibular nerve
   c. Greater auricular nerve
   d. Spinal accessory nerve
   e. Branches of supratrochlear and supraorbital nerves
4. Skin and soft tissue infection

Postoperative Period

Postoperative Management

1. Immediate concerns

a. Pain

1) Most patients claim that the aching after skin cancer surgery is handled well by acetaminophen (smaller procedures) and minor narcotic pain relievers (larger procedures, especially wounds under tension or those involving muscle). Combination therapy with acetaminophen and ibuprofen may be more effective than narcotics.

b. Bleeding

1) Often occurs in the first 6 to 8 hours postoperatively

2) Minimized by careful intraoperative hemostasis, a well-placed dressing that applies pressure over the wound and undermined areas, and instructions to the patient to minimize physical activity

3) Patients should be instructed that if bleeding occurs, continuous pressure for 20 minutes will stop most bleeding.

2. Patient education

a. Is an important part of postoperative management

b. Inform of prognosis and risk for recurrence locally, regionally, and systemically. Differs according to tumor type, size, location, and treatment

c. Advise about family risks as family members may require screening (see earlier sections on tumor types and syndromes).

d. Instruct on self-palpation of skin and lymph nodes for patients at risk for recurrence by emphasizing:

1) The method of palpation (for in transit, satellite, and nodal disease)

2) That nodes are not usually painful

3) That most regional recurrances is discovered first by the patient (possibly prior to regularly scheduled follow-up)

e. Encourage sun protective measures.

1) Most skin cancers are associated with ultraviolet light exposure.

2) Minimize exposure by:

a) Liberal application of a broad-spectrum (Ultraviolet A and B [UVA, UVB] protection) sunscreen

i) Most people do not apply liberally enough to get the absorption indicated by the sun protective factor (SPF) value, so UVB protection ratings of SPF 30 or higher are better than a rating of 15.

b) Use of protective clothing

3. Oncologic follow-up

a. Patients with a history of skin cancer have at least a 40% risk of a second skin cancer within the first 5 years after surgery (higher risk if they have cSCC or a history of multiple skin cancers).

b. Patients should be instructed in monthly skin self-examinations with a description of the appearance of the skin cancer.

c. They should undergo full-body examination of the skin by a dermatologist at least yearly for early detection of new skin cancers.

d. Follow-up schedules to observe for signs of local, regional, or distant disease depend on the tumor type and stage.

1) High-risk tumors such as MCC, thick melanomas, or deep cSCCs may be monitored every 2 months.

2) Patients with uncomplicated, low-risk BCC should be seen annually.

4. Cosmetic follow-up

a. At 1 month:

1) Tensile strength has developed so patients may massage their wounds to minimize swelling and scar firmness.

2) Repairs at risk of contraction and distortion (lower eyelid, upper lip, etc.) may benefit from intralesional triamcinolone (40 mg/mL) injection.

b. At 3 months: Dermabrasion of suture lines (or second intention sites) on thick sebaceous skin of the nose is beneficial.

c. At 6 months: Re-evaluation for any other revisions can be

considered.

Complications

1. Aside from pain and bleeding, most appear in the first few weeks.
2. Surgical site infections are:
   a. Detected as early as 48 hours
   b. Most commonly seen 5 to 7 days postoperatively
   c. Almost always *red* and *painful*
   d. Not always purulent
   e. Defined by the surgeon alone (clinical diagnosis)
      1) There is no absolute set of criteria for infection.
      2) Culture results do not define infection but serve as a guide for appropriate antibiotic therapy once a diagnosis is made.
3. Causes of "redness":
   a. Normal wound healing
   b. Wound infection
   c. Tight closure
   d. Excess intraoperative electrocoagulation
   e. Poor tissue handling or suturing technique
4. Hematomas at the surgical site should be drained if possible.
   a. Usually achievable through a 1- to 2-cm opening in the incision line
   b. Local anesthesia is necessary if the blood is coagulated, and pressure is necessary.
5. Interstitial hematomas:
   a. Occur when blood and fluid infiltrate the tissue without a pooled collection
   b. Cannot be drained
   c. Fortunately, these resolve quickly and completely.

6. Necrosis of flaps and grafts

   a. May begin to occur at 1 week and develop over the subsequent few weeks

   b. It is difficult to estimate the true extent of tissue loss at weeks 1 to 2.

      1) Delay any decision to débride tissue until the full extent of necrosis is evident by the appearance of a black eschar or autolysis and separation of fully necrotic skin.

   c. Dark or violaceous tissue often heals nicely without the need for débridement.

7. Open wounds that fail to heal are very frustrating.

   a. Often caused by one of three conditions:

      1) Overgrowth of *Candida albicans* (most commonly)

         a) Due to topical application of antibiotics and continuous use of occlusive dressings for 3 weeks or longer

         b) Clinical evidence of infection by yeast may be sparse.

         c) Simply adding or switching to a topical anti-yeast medication can promote healing.

      2) Erosive pustular dermatosis

         a) Suspected if the wound does not respond to anti-yeast medications

         b) Commonly occurs on the scalp and forehead (can be seen elsewhere) as superficial erosions with thick, yellow, greasy crusts

         c) Responds quickly to potent topical corticosteroids

      3) Exuberant granulation tissue

         a) If elevated over the wound edges, scraping it with a curette or scalpel may promote wound healing (local anesthesia with epinephrine plus a pressure dressing controls bleeding).

         b) Granulation tissue that is minimally elevated does not interfere with healing; no manipulation is necessary.

c) Topical treatment with silver nitrate or other caustic agents delays wound healing and should be avoided.

Alternative Management Plan

1. Although surgery usually offers a simple treatment with little pain, delivers specimens for a pathologist to evaluate the success of removal, and is usually accompanied by an aesthetic reconstruction, there are significant reasons to consider alternative methods.

2. In properly selected patients, after considering variables such as tumor type, size, location, and patient expectations of cosmetic results, alternatives can offer cure rates similar to those of surgical excision.

3. *Curettage with electrodesiccation*

a. Commonly used for small, noninvasive BCC less than 2 cm and very small cSCC or SCCIS

b. Under local anesthesia, a circular knife 2 to 6 mm in diameter is used in a scraping motion to remove the majority of tumor (soft compared to the normal surrounding dermis).

c. Scraping is followed by electrodessication of the wound, which destroys an additional 3 to 4 mm of skin and soft tissue.

d. After removal of the tumor and wider destruction with electrodesiccation, the wound heals by second intention.

e. A pale but acceptable scar is often left in carefully chosen locations.

f. Not useful:

1) If tumor involves adipose tissue, cartilage, or tissue for which one cannot feel the contrast between tumor and normal skin with the curette

2) In scar tissue, recurrent skin cancers in scar tissue, or infiltrating tumors that cannot be separated from normal dermis

4. *Laser destruction*

a. For superficial skin cancers confined largely to the epidermis and superficial dermis (superficial BCC, Bowen's disease, or microinvasive cSCC)

b. Wounds are left to heal by second intention, and pale white scars often result.

c. Advantages

1) The ability to destroy very superficial layers of skin with less destruction than occurs with curettage and electrodesiccation

2) The ability to detect focal invasive areas of tumor during vaporization by their unique "bubbling" reaction (normal dermis simply shrinks)

5. *Cryosurgical treatment*

a. Liquid nitrogen (a coolant) freezes tumor and adjacent skin.

b. Kills cells by dehydration or the formation of intracellular ice crystals that then burst the cell

c. It is often claimed as a method to kill cancer cells and preserve a viable framework of collagen that heals with less scarring.

1) In practice, the cosmetic result is similar to that achieved with other destructive techniques.

2) Results are operator dependent (no way to accurately judge the depth of destruction without significant experience).

6. Radiation Therapy (RT)

a. Was once a popular alternative to surgery that was used by dermatologists and radiation oncologists alike

b. Operator dependent; experience is needed to estimate not only the width of the surgical margin but also, with more difficulty, the depth of tumor invasion

c. Ten to thirty visits are required (inconvenient for most patients).

d. The most expensive treatment option

e. The advantage is that it provides a cure rate similar to that of surgery without most of the risks and complications of surgery.

f. It is most useful as an adjunct to surgery:

1) When surgical margins are positive but the tumor is inoperable

2) If margins are questionable and there is high risk for recurrence

3) To provide local control if there is a high risk for satellite metastases (applied around the surgical site)

7. Topical therapy

a. Topical chemotherapy (5-fluorouracil) and a topical immunomodulator (imiquimod) have been tried with some success.

b. Food and Drug Administration approval

1) Both approved only for superficial skin cancers

2) Imiquimod is not approved for use of skin cancers on the head (AKs only).

c. Current studies show short-term success rates of 80%; long-term cure rates will likely be lower.

d. Some consider topical therapy for widespread superficial disease that would otherwise be inoperable or for very superficial tumors that with excision might result in significant cosmetic deformity.

e. Cost is high, results are interim, and use is limited.

8. Actinic Keratoses (AKs)

a. Skin colored and erythematous macules with gritty yellow scale

b. Detection on physical examination by inspection and palpation (often easier to "feel" than to see)

c. Marker of chronic sun damage; indicates an increased risk of the formation of skin cancer

d. Considered premalignant: Lesions may self-resolve, persist, or evolve to skin cancer (approximately 10% of lesions over a 10-year period). Treatment is recommended as the course cannot be predicted.

e. Treatment includes destruction by liquid nitrogen cryotherapy, curettage, shave removal (if hypertrophic), or field therapy.

f. Field therapy will reduce the number of precancerous lesions and, by this reduction, may prevent formation of invasive skin cancers.

1) 5-fluoruracil (thymidylate synthase inhibitor; 5-FU) cream or solution

2) Imiquimod (immune response modifier) cream

3) Photodynamic therapy ("blue light treatments"; PDT)

a) Aminolevulanic acid is applied to the skin causing an accumulation of photoactive porphyrins within AKs; upon exposure to blue light a cytotoxic reaction occurs causing the AKs to slough.

g. Treatment selection

1) Liquid nitrogen is best for isolated and hyperkeratotic AKs.

2) PDT is most effective on flat and nonkeratotic AKs.

3) 5-FU is most effective for widespread and mildly hyperkeratotic AKs.

Discussion

Evidence-Based Medicine Question

What is the most important aspect of Mohs surgery?

Mohs surgery is a method of complete histologic control of the surgical margin; the technique literally examines 100% of the surgical margin. Traditional "bread-loaf" pathologic processing allows the pathologists to examine less than 0.1% of the surgical margin. Complete margin examination by Mohs surgery affords the highest cure rates and lowest tumor recurrence rates of any method (negative margin is ensured with near certainty) while allowing as much normal skin to be spared from the excision as possible. Mohs surgery as an alternative to routine excision becomes most useful in certain cases (see above *"Evaluation of Surgical Margins and Pathology Report Interpretation: Mohs Surgery*).

Editorial Comment

Although they are benign neoplasms, Spitz nevi sometimes have histopathologic features that overlap with those of melanoma. This has led to controversies regarding appropriate strategies for the diagnosis and treatment of this type of nevus. Children are much more likely to develop Spitz nevi than melanomas. Some dermatologists have endorsed the option of longitudinal follow-up for Spitz nevi with classic clinical

and dermatoscopic features in children younger than 12 years of age, with subsequent routine evaluations. However, recently proposed guidelines also recommend that a biopsy be done for a Spitz nevus with atypical features such as large size (e.g., >8 to 10 mm), excessive growth, asymmetry, or ulceration in patients of any age.

Frederic W.B. Deleyiannis

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. What percent of the margins have been examined when a routine pathology report of a cancer excision reports "negative margins"?

   a. **<0.1%**

   b. <1%

   c. <10%

   d. 100%

2. What is the value of prophylactic neck dissection in cutaneous tumors as opposed to intraoral/mucosal tumors?

   a. Mixed value—improves disease-free survival, but adds significant morbidity

   b. Great value—improves disease-free and overall survival, outweighing any added morbidity

   c. **No value—no survival benefit is conferred by prophylactic lymph node dissection in any solid tumor (including cutaneous tumors)**

3. What is the appropriate management of a biopsy-proven dysplastic nevus with mild atypia?

   a. Excise with 1-mm margins to ensure complete removal.

   b. Excise with 5-mm margins to ensure complete removal.

   c. Excise with 1-cm margins to ensure complete removal.

   d. **Clinical monitoring with a dermatologist; excision is not required for this benign lesion**

Microvascular Reconstruction of the Head and Neck

Frederic W.B. Deleyiannis

Introduction

Free tissue transfer offers a well-accepted, superior ability to restore form and function to certain major defects of the head and neck. Microvascular surgery provides distinct advantages for reconstruction of osseous defects of the mandible, large glossectomy defects, total or near-total pharyngeal defects, and complex defects of the midface and skull base. Theoretically, any tissue with a defined vascular circuit (i.e., perforator) can be transferred as a free flap, but for reconstruction of defects in the head and neck, there are six free flaps which are particularly useful: the radial forearm free flap (RFFF), the anterolateral thigh (ALT) flap, parascapular and scapular free flaps, rectus abdominis and deep inferior epigastric perforator (DIEP) flap, fibula free flap (FFF), and jejunal free flaps.

Key Operative Learning Points

1. When possible, resected tissue should be reconstructed with tissue that duplicates both the appearance and the function of the resected tissue. Epithelium can be used to resurface mucosal or skin defects. Muscle can be used to restore bulk and motion, and palatal and mandibular skeletal defects can be reconstructed with bone.

2. The ALT free flap, the flap most commonly used for reconstruction of defects in the head and neck, is routinely designed from perforators from the descending branch of the lateral circumflex artery/vein.

3. Multiple options (i.e., medial thigh free flap, tensor fascia lata free flap)

from the thigh are available for soft tissue reconstruction, in addition or instead of an ALT free flap.

4. The fibula will provide up to 26 cm of bone vascularized by the peroneal artery and its two venae comitantes.

Preoperative Period

History

1. History of present illness

   a. Successful reconstruction begins with planning the extirpation of the tumor based on Tumor Node Metastasis (TNM) stage and anticipating the impact of both the extirpation and reconstruction on the patient's quality of life.

   b. Prognosis, dental rehabilitation goals, the need for postoperative radiation therapy, and the type of neck dissection may impact surgical choices (i.e., recipient vessels, type of free flap).

2. Past medical history

   a. Cardiac, vascular, and pulmonary disease, as well as alcoholism, are common in patients with cancer of the head and neck and may independently impact survival and limit reconstructive options.

   b. Radiation induces soft tissue fibrosis, in particular perivascular fibrosis. Therefore, a history of prior radiation and the anticipated decreased vascularity may guide reconstructive options toward using a pedicled or free flap instead of a skin graft.

   c. Previous surgery, such as open abdominal surgery or open reduction and internal fixation of a radius fracture or a tibial fracture, may limit the choice of an extremity or of the abdomen as a donor site.

Physical Examination

1. An Allen test should be performed prior to harvesting an RFFF to ensure the postoperative viability of the hand.

2. Determine whether a patient has a pre-existing hernia of the

abdominal wall before harvesting a rectus abdominis, iliac crest free flap, or jejunal free flap.

3. Confirm the presence of a palpable dorsalis pedis and posterior tibialis pulse prior to harvesting a fibular free flap.

4. Palpate the thickness of the thigh to determine its suitability for tissue transfer as an ALT flap.

Imaging

1. Preoperative imaging with a computed tomography (CT) scan and/or magnetic resonance imaging (MRI) to determine the extent of the tumor

2. Pre-bent plates and CT-guided templates can be fabricated prior to surgery to assist in designing and insetting osseous flaps.

3. The need for preoperative vascular assessment prior to fibular transfer is controversial. Large series done without preoperative imaging have reported no adverse sequelae, yet given the prevalence of the risk factors for peripheral vascular disease in the cancer of the head and neck population, others have stressed the need for vascular evaluation. Ankle-arm index screening and color flow Doppler imaging may be more economical and efficient ways to evaluate the vasculature of the lower extremity than angiography or magnetic resonance angiography.

Indications

1. Mandibular defects

The morbidity of mandibular resection upon function is highly variable.[1,2] The level of postoperative disability depends on (1) the preoperative condition of the oral cavity (including the presence or absence of viable teeth), (2) the extent of mandible to be included in the resection, (3) the site of the tumor (anterior vs. lateral), and (4) the soft tissues to be resected.

a. When the mandible is resected with an accompanying large amount of soft tissue, the mandibular defect is sometimes “incidental” to the rest of the wound. Closure of the soft tissue defect with restoration of function and coverage of the planned mandibular reconstruction

become the primary goals.

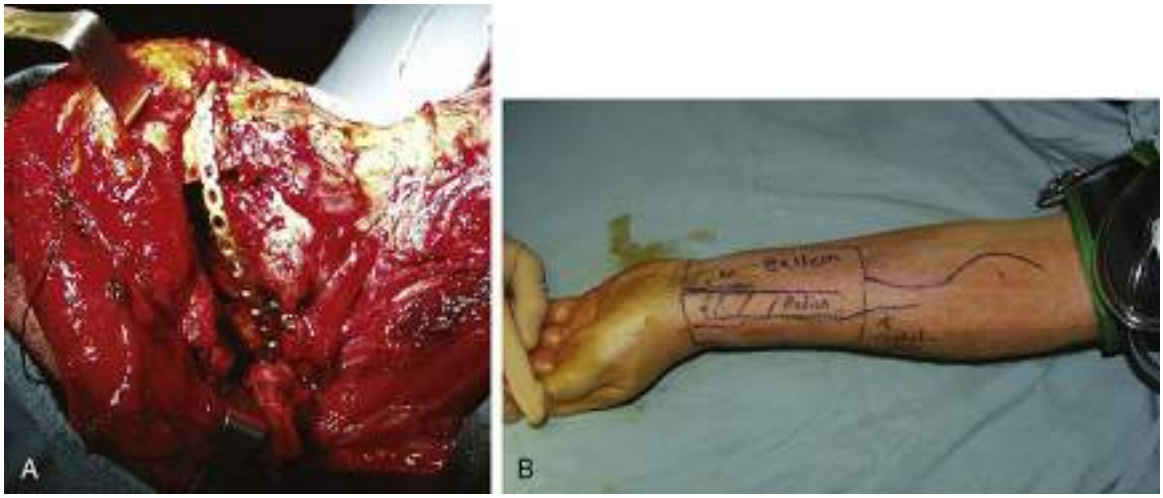

FIG. 162.1 Osteocutaneous radial forearm free flap for a lateral mandibular defect.

A, Lateral mandibular and floor of mouth defect after resection of a T4 carcinoma. **B,** Flap design with radius, skin paddle, cephalic vein, and radial artery marked.

b. Some patients following a segmental lateral mandibulectomy function well without restoration of mandibular continuity. However, a contour deformity of the lower third of the face will develop in patients who have not been reconstructed, and the pull of the contralateral muscles of mastication displaces the remaining mandible toward the side of the defect. In patients with dentition, this results in malocclusion. For these reasons, most surgeons offer patients primary reconstruction of lateral mandible defects with an osseous free flap (i.e., FFF or osteocutaneous RFFF; Fig. 162.1).

c. Numerous reports have supported the use of a reconstruction plate with soft tissue coverage to reconstruct pure lateral mandibular defects (Fig. 162.2). Soft tissue coverage has been generally provided by a pectoralis myocutaneous flap or a soft tissue free flap.

d. Delayed reconstructive failure secondary to external plate exposure or plate fracture has been generally reported to be between 7% and 30%, with soft tissue coverage provided only with a pectoralis flap. These rates of failure would likely be much higher if patients

survived longer than 3 years. (Three-year survival of patients selected for reconstruction with a pectoralis flap is 11%.)[2]

e. Resection of the anterior mandible can leave a patient an oral cripple. When reconstruction is not attempted, the retained segments of the mandible tend to collapse toward the midline. This lack of support results in the Andy Gump deformity, with the associated oral incontinence and cosmetic deformity.

f. Free tissue transfer of a composite, osteocutaneous flap is the reconstructive method of choice for anterior defects (Fig. 162.3).

2. Glossectomy defects

a. It is unrealistic to expect a unidirectional, reinnervated muscle, such as the rectus abdominis, to mimic the complex, pattern of muscle contraction in the native tongue.

b. The attainable goals of tongue reconstruction are to preserve the mobility of the remaining tongue and to restore bulk so that the neotongue can contact with the palate to assist in articulation and swallowing.[3]

c. Because of the different functions of the two regions, the tongue is divided into the mobile anterior part and the base of the tongue. The mobility of the anterior tongue is critical for articulation, mastication, and the oral phase of swallowing. The base of the tongue is critical in completing the pharyngeal phase of swallowing.

d. The approach to reconstructing the mobile tongue should involve the use of thin, sensate, pliable tissues (i.e., RFFF or ALT free flap) that maintain maximum mobility and potentially restore sensation.

e. Defects of the base of the tongue present a separate problem. Volume of the base of the tongue must be restored so that the base of the tongue can contact the pharyngeal walls and generate a force to drive the food bolus through the pharynx.

f. Two flaps, in particular an ALT (or a RFFF, rectus abdominis free flap, or pectoralis flap) with a fibular flap, may be necessary for complex composite defects involving a segmental mandibulectomy defect with a glossectomy defect.

3. Pharyngectomy defect

a. The major goal of pharyngeal reconstruction is the restoration of swallowing. It is important to choose a flap that is not too bulky in order to avoid obstruction.

b. ALT (Fig. 162.4), RFF (Fig. 162.5), and jejunal free flaps are the primary options for pharyngeal reconstruction.

c. Laryngeal preservation in the setting of a major pharyngeal defect is especially challenging because aspiration is inevitable. In addition to the patient's preoperative function, designing a reconstruction that can minimize aspiration may be the critical issue that determines whether a patient will require a laryngectomy.

d. In most cases of advanced laryngopharyngeal or pharyngeal cancer, the larynx is resected.

e. If the cervical esophageal resection extends below the thoracic inlet, gastric pull-up continues to be the most reliable way to avoid a salivary leak in the chest.

4. Midface and maxillectomy defects

a. Defects in the midface occur after resection of tumors that arise from the paranasal sinuses, palate, overlying skin, nasal cavity, skull base, orbital contents, or oral mucosa. As a result, extensive reconstruction of the midface may require independently reconstructing the palate, orbit, cheek, and bony midface (maxilla and zygoma).

FIG. 162.2 Scapular fasciocutaneous flap.

A, Composite resection of lateral mandible, floor of mouth, and cheek skin. **B,** Mandibular continuity restored with a reconstruction plate. **C,** Flap design. **D,** Flap inset with strip of skin de-epithelialized to allow for two skin paddles—one for cheek skin and one for floor of mouth reconstruction.

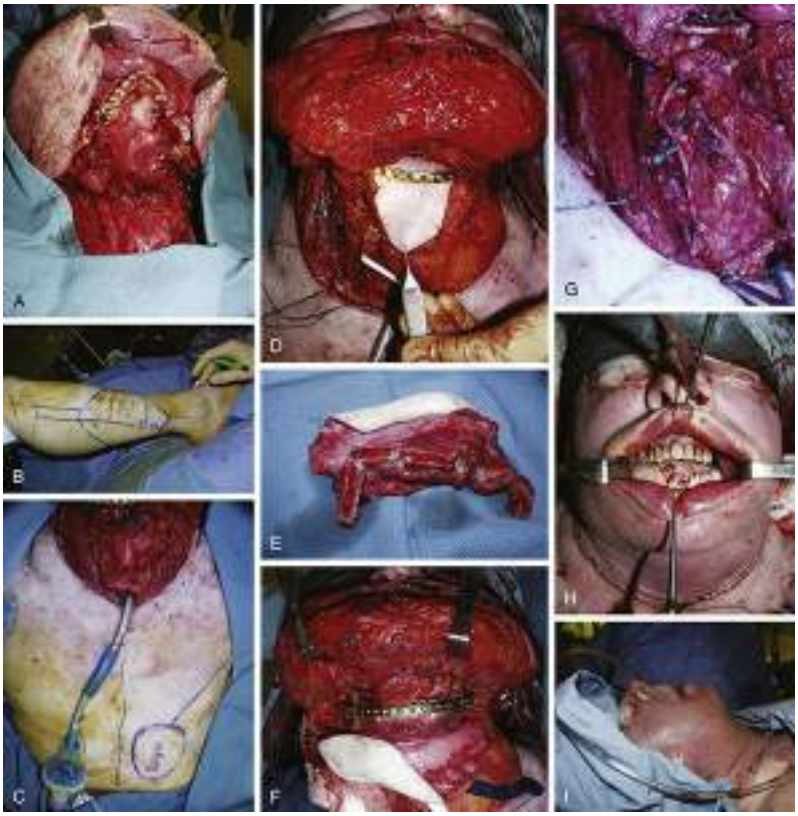

FIG. 162.3 Fibular osteocutaneous free flap and pectoralis major myocutaneous flap for near total mandibulectomy and total glossectomy.

A, Near-total mandibulectomy and total glossectomy defect. **B,** Osteocutaneous fibular free flap design: skin perforators *(P)* marked. Skin paddle to be used for floor of mouth and anterior tongue reconstruction. **C,** Pectoralis flap for posterior tongue reconstruction. **D,** Inset of the pectoralis flap. **E,** Closing wedge osteotomies of the fibula. **F,** Inset of the fibular free flap with the skin paddle to be rotated over the plate and to be sewn to the pectoralis flap. **G,** Inset of greater saphenous vein graft into the proximal internal jugular vein stump. Both internal jugular veins had been ligated during the resection. **H,** Final inset—oral cavity. **I,** Final inset—lateral view.

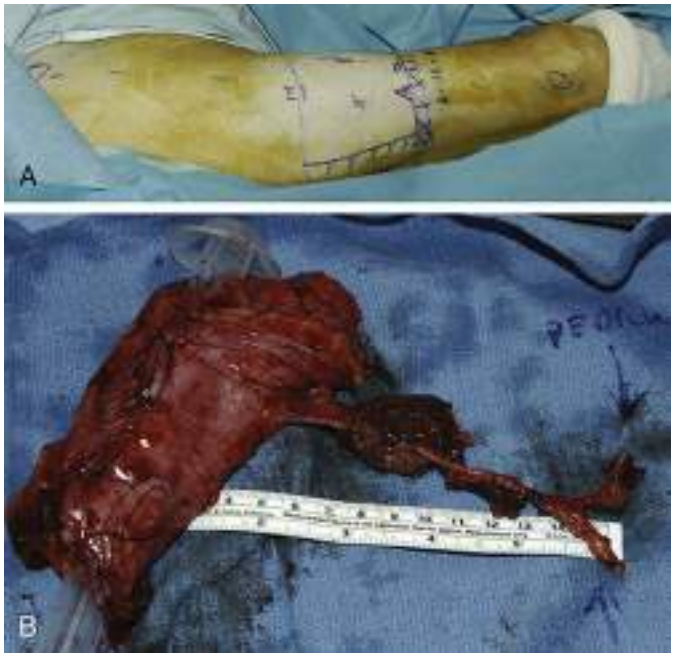

FIG. 162.4 Anterior lateral thigh flap.

A, Flap design based on location of perforator. **B,** Total pharyngeal reconstruction using the anterior lateral thigh flap (ALTF). The fascia lata has been wrapped around the reconstruction for an additional layer of closure.

FIG. 162.5 Total pharyngeal reconstruction with a radial forearm free flap (RFFF) harvested with a monitor paddle. Flap design with monitor paddle.

b. Cordeiro and Santamaria proposed a classification system and algorithm for reconstruction of maxillectomy and midfacial structures.[4] The temporalis muscle, soft tissue free flaps (rectus abdominis and radial forearm), nonvascularized bone (rib or calvarium), and vascularized bone flaps (osteocutaneous RFFF) were

used to construct a variety of maxillectomy defects. Palatal defects were closed only with soft tissue. The nonvascularized and vascularized bone were used for the osseous reconstruction of the zygoma, maxilla, and orbital floor.

c. The use of an FFF for midface reconstruction allows for the osteointegration of implants for dental rehabilitation.

d. The ALT can be designed with multiple skin paddles, based on separate perforators, to reconstruct many midface/maxillectomy defects.

e. In cases of combined midface and lip resection, oral competency can be restored by using local flaps, such as the Abbe lip-switch flap, in combination with free tissue transfer.

5. Skull base defects

a. Although small defects can and should be reconstructed with local flaps, such as pericranial or temporoparietal fascial flaps, many defects in the expanding spectrum of extirpative endeavors will require free tissue transfer.

b. The main reconstructive needs of skull base defects include separating the intracranial and extracranial spaces to avoid intracranial infections, obliterating the dead space with coverage of vital structures, preventing brain herniation, diminishing the risk of cerebrospinal fluid (CSF) leakage, and restoring cosmesis.

c. The rectus abdominis, ALT, latissimus myocutaneous (or myofascial), and serratus free flaps are some of the flaps commonly chosen.

Contraindications

1. An expectation of a poor quality of life or of limited survival, regardless of the ability to successfully extirpate the tumor, may change the reconstructive recommendation.

2. Severe peripheral vascular disease and lack of recipient vessels in the neck following previous surgery may make the harvest and anastomosis of a free flap impossible.

FIG. 162.6 Venous outflow obstruction and restoration (postoperative day #1, same patient as in Fig. 162.3).

A, Venous congestion of fibular free flap: bluish blood with pinprick of flap skin paddle. **B,** Saphenous vein graft and internal jugular vein clotted. **C,** Clots in venae comitantes of fibular flap cleared with #3 Fogerty catheter.

Preoperative Preparation

1. Plan for the possible need for a second or backup free or pedicled flap. Protect an extremity so that no venipuncture is done in this extremity.

2. Be sure the tumor margins are clear before finalizing flap design.

3. Determine the recipient cervical vessels likely for anastomosis. If the neck is without recipient vessels, prepare for the possibility of vein grafts from the extremities.

Operative Period

Anesthesia

General

Positioning

Supine: The bed is turned 180 degrees, allowing simultaneous access to the head and neck by the extirpative team and to the extremities by the reconstructive team. Sequential compression devices are placed on the contralateral leg if a fibula is being harvested and on both legs if an ALT is being harvested.

Lateral decubitus: Used for a scapular free flap and latissimus free flap

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin: For cutaneous defects without communication to the oral cavity or pharynx

Unasyn or clindamycin (if allergic to penicillin): For defects of oral cavity and/or pharynx

Monitoring

None for flap harvest

Instruments and Equipment to Have Available

1. Basic microvascular instrument set and operating microscope

2. Doppler to detect and monitor perforators

3. Craniofacial and mandibular hardware for mandibular and midface bony reconstruction

4. Venous coupler system

5. Implantable Doppler (optional)

Key Anatomic Landmarks

1. Specific to each free flap (see "Surgical Technique")

2. For recipient vessels: Facial, superior thyroid, and transverse cervical arteries; external carotid artery

3. Veins include veins in zones I and V of the neck and the external jugular vein.

Prerequisite Skills

1. Advanced training in microvascular surgery (i.e., a head and neck fellowship and/or plastic surgery fellowship with an emphasis on microvascular reconstruction of the head and neck)

Operative Risks

1. Flap failure: This risk in experienced hands should be well less than 5%.

2. Deep neck infection; oral-cutaneous (or oral-pharyngeal) fistula

3. Pharyngeal stenosis

4. Donor site morbidity: Tendon exposure, failure of skin graft, hernia, extremity swelling, deep venous thrombosis (DVT), decreased ankle, or wrist flexion/extension

5. Harvest of a fibular free flap in patients with peripheral vascular disease (an ankle arm index <1.0) but with three-vessel runoff may still lead to delayed wound healing at the harvest site.

Surgical Technique

1. RFFF

   a. The RFFF is a fasciocutaneous flap deriving its blood supply from branches of the radial artery and venae comitantes that run in the intermuscular septum between the brachioradialis and flexor carpi radialis muscle.

   b. The major advantage of the RFFF is the large amount of thin forearm skin that can be harvested for reconstruction of any associated intraoral and/or external skin defect.

   c. A segment of radius vascularized by vessels passing from the radial artery through the lateral intermuscular septum and perforating

vessels through the muscle belly of the flexor pollicus longus may be transferred with the radial forearm flap (see Fig. 162.1A and B).

d. Approximately 10 cm of bone can be harvested between the insertion of the pronator teres and the insertion of the brachioradialis. A "boat-shaped" osteotomy in preference to right-angle bone cuts may help avoid the complication of a fracture. Only 30% of the cross-sectional area of the radius should be removed to avoid a fracture of the radius.

e. Provided that the periosteum is carefully preserved on the volar and radial aspects of the segment of the radius, one or two osteotomies may be performed from the medullary aspect to allow reconstruction of anterior symphyseal and parasymphyseal defects.

f. Whereas the anterior projection of the anterior mandible can be recreated using the osteotomized radial forearm osteocutaneous flap, the vertical height of the anterior mandible cannot be created, and the bony segment is usually too thin to allow placement of osseointegrated implants.

g. The antebrachial cutaneous nerves of the forearm can be incorporated to create a sensate flap.

2. Anterolateral thigh free flap

a. An ALT flap is a perforator flap, derived from the descending branch of the lateral circumflex femoral artery.

b. Its advantages include a long pedicle (8 to 16 cm) with a suitable vessel diameter and the possibility of harvesting the flap with thigh musculature (the vastus lateralis muscle, rectus femoris muscle, and/or the tensor fasciae lata) or as a sensate flap (by incorporating the anterior branch of the lateral cutaneous nerve of the thigh).[5]

c. To increase the width or length of the flap, an ALT may be harvested with multiple perforators or may be supercharged and/or venous augmented with separate pedicles from the medial, superior, and posterior-lateral thigh (i.e., perforators respectively from superficial femoral artery, ascending or transverse branch of the lateral circumflex artery, and the profundus femoral artery).

d. Because of its distance to the head and neck, its harvest can be performed simultaneously with tumor extirpation.

e. Flap elevation begins by mapping the cutaneous perforators with a pencil Doppler probe. These perforators are located by first marking the midpoint between the anterior superior iliac spine and superolateral corner of the patella (see Fig. 162.4B and D). A circle centered at this midpoint is then drawn with a radius of 3 cm. The majority of the cutaneous perforators are located in the inferolateral quadrant of this circle. The flap is then harvested with its center over these perforators and its long axis parallel to that of the thigh.

f. The skin and subcutaneous tissue are raised until the perforator(s) to the skin is defined. Once the skin perforator is seen, it is dissected until the main pedicle is reached. If the skin vessel (or skin vessels) is a musculocutaneous perforator (the majority of patients), then the harvest includes an intramuscular dissection through the vastus lateralis muscle. If the skin vessel is a septocutaneous perforator, the dissection is simpler and proceeds between the vastus lateralis and rectus femoris muscles.

g. A skin defect less than 9 cm in width can be closed primarily without any reported evidence of compartment syndrome. Larger defects require skin grafting.

h. A distinct disadvantage is the thickness of the flap in overweight individuals. However, the flap can be trimmed to the subdermal adipose tissue level for use as a thinner flap (4 mm).

i. Although the vastus lateralis muscle is a major constituent of the quadriceps femoris, near-normal quadriceps function has been reported when it is taken for reconstruction.

3. Scapular and parascapular fasciocutaneous and osteocutaneous flaps

a. The branching pattern of the circumflex scapular artery and vein permits the harvest of a number of fasciocutaneous and osteocutaneous flaps for reconstruction of the oral cavity.

b. The scapular flap is based on the horizontal cutaneous branch of the circumflex scapular artery (see Fig. 162.2 A-D). The parascapular flap is based on the descending cutaneous branch of the circumflex scapular artery.

c. Up to 14 cm of the lateral border of the scapula vascularized by periosteal branches from the circumflex scapular artery and vein can

be isolated.

d. Unlike other osteocutaneous flaps, the scapular bone and the two skin paddles can be orientated independently of one another for reconstruction of complex three-dimensional defects.

e. In addition, the latissimus dorsi and serratus anterior muscles vascularized by the thoracodorsal artery and vein can be harvested with the scapular flaps based on the common vascular pedicle of the subscapular artery and vein.

f. The disadvantages of these flaps are that they require harvesting in the lateral position; the lateral border of the scapula is quite thin and may preclude secondary osseointegrated implants, and the segmental periosteal blood supply may be compromised if multiple osteotomies are required to shape the scapula for anterior defects.

4. Rectus abdominis free musculocutaneous flap and DIEP flaps

a. The rectus abdominis free musculocutaneous flap is based on periumbilical perforators from the deep inferior epigastric arteries. Incorporation of the periumbilical perforators permits an orientation of the skin paddle virtually in any direction from the midline.

b. After the perforators are identified, the anterior rectus sheath is incised medial to the linea semilunaris and lateral to the linea alba. To preserve the strength of the abdominal wall, the anterior rectus sheath should not be harvested below the arcuate line. Inferiorly the anterior rectus sheath is incised vertically to completely expose the rectus muscle.

c. The deep inferior epigastric pedicle is identified after the rectus muscle is bluntly dissected free from the posterior rectus sheath. The vascular pedicle, up to 15 cm in length, is exposed all the way to the origin of the vessels from the external iliac artery and vein.

d. A DIEP flap is a perforator flap raised by dissecting a skin perforator (usually a dominant medial or lateral perforator) through the rectus abdominis muscle without harvesting the muscle itself. By not harvesting the rectus abdomnis muscle with the flap, one can preserve the strength of the abdominal wall.

e. Closure of the abdominal wall can be accomplished with direct approximation of the residual anterior fascial margins.

f. Harvest of a unilateral rectus muscle has little impact unless the patient is involved in vigorous physical activities.

5. Fibular free flap

a. The FFF is the first-line choice for reconstruction of the mandible (Fig. 162.3A to I).

b. The fibula can be transferred as a free osseous, free osteocutaneous, or osteomuscular flap.

c. The skin of the lateral calf is supplied by septocutaneous perforators that traverse the posterior crural septum between the posterior compartment muscles, the gastrocnemius and the soleus, and the lateral anterior compartment muscles, the peroneus longus and brevis. Musculocutaneous perforators that run through the flexor hallucis and soleus may also supply the skin.

d. The fibula will provide up to 26 cm of bone vascularized by the peroneal artery and its two venae comitantes. The peroneal artery provides both an endosteal and periosteal blood supply to the fibula, allowing multiple bony segments of the fibula to maintain their blood supply after multiple osteotomies of the fibula.

e. The cross-sectional area of the fibula is ideally suited for placement of osseointegrated implants for dental rehabilitation.

f. Criticisms of the use of the FFF include height discrepancy between the fibular bone and the native mandible and the inability to reconstruct associated large soft tissue defects (i.e., large glossectomy defects or through-and-through defects).

g. A "double barrel" technique in which the fibula is folded on itself can effectively double the height of the neomandible.

h. In conjunction with a FFF, large soft tissue defects can be reconstructed with a second flap, either an ALT or pectoralis myocutaneous flap.

i. Following FFF harvest, most patients will have some slight decrease in range of motion of ankle plantar and dorsiflexion and a loss of ankle strength. If the flexor hallicus longus is also harvested with the flap, the patient will have loss of dorsiflexion of the great toe. These decreases are usually not severe enough to impact on the patient's

daily activities.

6. Jejunal free flap

   a. The jejunal free flap was the first free tissue transfer in the literature in 1959. Over the past several years, the use of fasciocutaneous free flaps (RFFF, ALT) has replaced jejunal free flaps in the reconstruction of certain defects.

   b. This flap can be used as a mucosal tube or as a patch. Its advantages for pharyngeal reconstruction include a diameter that matches that of the cervical esophagus, the potential for peristalsis, and an innate secretory ability.

   c. Some of the relative disadvantages of this flap include abdominal complication rates as high as 5.8%. Tracheal esophageal puncture (TEP) speech can be less discernable versus other flaps due to the intrinsic moistness of the jejunum.

   d. Flap harvest is usually performed by qualified general surgeons (possibly laproscopically) and may be done simultaneously with the extirpative procedure. Preoperative bowel preparation is not necessary.

   e. The jejunal arteries arise from the superior mesenteric artery and form a series of vascular arcades that run in the mesentery. Large segments of jejunum can be harvested by dividing proximally a single jejunal vessel that feeds multiple arcades.

   f. To limit ischemia to the jejunum, one should only divide the pedicle after the pharyngeal defect and recipient vessels have been prepared.

   g. During the inset if there is a size mismatch at the level of the base of the tongue, the antimesenteric border may be divided to “open” up the proximal end. Any redundancy in the jejunum after inset may cause it to fold on itself and become a barrier to food transport. To prevent this redundancy, we perform the inset into the base of the tongue first and then the vascular microanastomosis. With perfusion reestablished, the jejunum expands, and after this expansion, we resect any redundant jejunum prior to completing the mucosal anastomosis to the cervical esophagus.

Common Errors in Technique

1. The length of the pedicle of a rectus abdominis flap may be insufficient to reach the neck, especially when the mandible is intact. Careful planning of the skin paddle and intramuscular dissection of the pedicle from the rectus muscle may be necessary to ensure adequate length.

2. Aggressive harvest (>40%) of the radial bone may lead to pathologic fracture. Prophylactic plating of the radius is advised to prevent a fracture.

3. Irreversible ischemic changes of the jejunum can occur within 2 hours. The jejunal vessels should only be divided and transferred from the abdomen once the recipient vessels have been isolated and prepared for microanastomosis.

4. Failure to recognize venous congestion will lead to total loss of the flap. Leeches should only be used as a treatment for venous congestion after problems with the microanastomosis and pedicle have been excluded by surgical exploration.

Postoperative Period

Postoperative Management

1. Free flap monitoring

   a. The most reliable way of assessing the viability of a free tissue transfer remains clinical examination. We prefer nursing assessment of all flaps (with Doppler of the pedicle) every hour for the first 72 hours, with a physician assessment every 6 hours.

   b. Color, turgor, temperature, evidence of edema, quantity and quality of blood extravasation after pinprick, and quality of the Doppler sound are all basic methods of assessment. The arterial signal should increase in strength during subsequent postoperative days. The venous signal should be augmentable.

   c. Signs of venous congestion include bluish discoloration, increased warmth and swelling, and quick and bluish blood return after pinprick (see Fig. 162.6).

d. With arterial compromise, the flap appears pale, feels cool, and has a loss or delay of bright red blood with pinprick of the flap.

e. If there is any concern about vascular inflow or outflow obstruction, the patient should be returned to the operating room immediately for surgical exploration.

f. Most fasciocutaneous flaps that are buried, such as for pharyngeal defects, can allow for a small skin paddle to be separately incorporated into the cervical skin closure. This allows for clinical assessment and a pinprick examination. Later, as an outpatient under local anesthesia, this skin island can be removed, and the cervical skin suture line can be reapproximated.

g. Implantable Doppler systems are also available for monitoring flaps.

Complications

1. Flap failure secondary to a thrombosis at a microvascular anastomosis, vessel kinking, or flap design exceeding the vascular territory of the flap pedicle/perforator (i.e., partial skin flap necrosis)

2. Donor site morbidity: Refer to specific flaps.

Discussion

Evidence-Based Question

When a strip of hypopharyngeal mucosa remains after a total laryngopharyngectomy, should the remaining mucosa be resected to convert the defect into a circumferential defect?

The preservation of the remaining mucosa and the incorporation of this mucosa in the reconstruction may reduce the risk for stenosis. However, the additional suture lines may place the reconstruction at a greater risk for fistula compared to a tubed free flap. In the case of a circumferential defect, the jejunal free flap has been the most reliable flap. It requires no tubing and thus one less suture line. Most studies report that the jejunal free flap has stenosis and fistula rates that are lower or equal to those of tubed fasciocutaneous flaps. The major alternative to the

jejunum is the tubed RFFF (see Fig. 162.5). Its advantages over the jejunum include the lack of an abdominal harvest, better TEP speech, and the ability to create separate skin paddles for cervical skin reconstruction. The use of a Montgomery stent may lower fistula and stenosis rates.

Editorial Comment

The anterolateral thigh free flap may also be used for pharyngeal reconstruction with the additional advantage that the fascia lata may be included to provide an additional layer of closure to the neopharynx (see Fig. 162.4B).

Review Questions

1. Which of the following flaps is a perforator flap?

   a. RFFF

   b. Fibular free flap

   c. Jejunal free flap

   d. **An anterolateral thigh free flap**

2. The septocutaneous perforators to the skin paddle of a fibular free flap traverse which septum of the leg?

   a. Anterolateral septum

   b. **Posterolateral septum**

   c. Interosseous septum

   d. Medial septum

3. To reduce the risk of fracture, what is the recommended limit of the cross-sectional area of the radius that should not be harvested in an osteocutaneous RFFF?

   a. No more than 10% of the radius should be harvested.

b. No more than 20% of the radius should be harvested.

c. **No more than 30% of the radius should be harvested.**

d. No more than 40% of the radius should be harvested.

Nasal Reconstruction

Frederic W.B. Deleyiannis

Introduction

The nose is of critical aesthetic and functional significance. Mastery of nasal reconstruction requires not only a knowledge of flaps and grafts but also an appreciation of facial aesthetics and functional rhinoplasty. A skin graft or local flap will close most nasal defects, but without a comprehensive evaluation of the nasal defect and of anticipated reconstructive outcome, the reestablishment of facial balance and nasal breathing can be lost.

Nasal defects represent tissue loss, often the result of tumor resection or trauma. To reconstruct a nasal defect aesthetically and functionally, one must understand the layers and volumes missing from the defect, the nasal subunits involved, the cartilage support structures required, and the color and thickness of the proper skin replacement. This chapter describes the basic principles of nasal reconstruction as applied to acquired nasal defects.

Key Operative Learning Points

1. Reconstruction of the nose begins with an analysis of the facial and nasal subunits involved and the nasal layers that are missing.

2. Cartilage grafts support skin flaps to prevent contraction. The septum, concha of the ear, and the ribs (sixth through ninth ribs) are the best donor sites for cartilage.

3. A forehead flap transfers skin of ideal quality to reconstruct the nasal skin defect in patients of all ages. A paramedian flap based on an ipsilateral supratrochlear vascular pedicle is located approximately 1.2 to

1.5 cm from the midline.

4. Reconstruction with a forehead flap should be done in three stages. Secondary cartilage grafting and flap thinning should be done at the second stage.

Preoperative Period

History

1. History of present illness
   a. Most nasal reconstruction is done to repair defects created by the excision of basal cell or squamous cell carcinomas. These cancers usually present with a long history of a nodular or ulcerative lesion of the nose.
   b. It is critical to explain the significance and extent of an acquired nasal deformity to the patient. As in many aspects of plastic surgery, congruence between what is perceived by the patient and observed by the physician is essential.
   c. Because of the importance of the nose for body image, most nasal defects are reconstructed. The patient's age is generally not a contraindication for nasal reconstructive procedures.
2. Past medical history
   a. The surgeon should insist that smoking be stopped at least 3 weeks prior to reconstruction. Smoking will increase the risk of partial or total loss of a skin flap; this risk should be discussed with the patient and documented.
   b. The patient's general medical condition as well as the extent of the procedure may influence the decision for or against surgery. Sometimes a nasal prosthesis is a valuable and recommended option (Fig. 163.1).
   c. If the nasal defect is the result of a cancer resection, the pathology as well as the need and the timing of any adjuvant therapy (i.e., radiation therapy) should be discussed in the context of tumor surveillance, recurrence, wound healing, and overall prognosis.

Physical Examination

Analysis of the Defect—By Adjacent and Underlying Facial Structures

Extended nasal defects are those that extend beyond the nose and involve the cheek, upper lip, and/or underlying maxilla. Large cheek and lip defects may require free tissue transfer prior to nasal reconstruction (Fig. 163.2) to replace missing volume and skin. Small defects of the medial cheek and upper lip can be repaired with cheek advancement flaps or nasolabial flaps at the first stage. A foundation of skin and adipose tissue should exist or be reconstructed along the region of the piriform aperture (i.e., the nasal platform) to support the reconstructed alar bases and columella and to position the new nose anterior to the maxilla so that it does not extend beyond its normal borders and flow onto the cheek. Cheek advancement flaps can be used as a foundation for the nasal base before median forehead flap reconstruction and can be used for replacement of the nasal sidewall (Fig. 163.3). The nasal platform and base should be in harmony with the eyes (i.e., the alar base width should approximate the intercanthal distance).

Analysis of the Defect—By Nasal Subunits

The nose is often divided into subunits (Fig. 163.4), which define areas of dissimilar skin texture and depth.[1,2] Borders between these areas are sites of shadows and highlights. The convex subunits of the nose are the tip, dorsum, alae, and columella. Application of the subunit principle is mainly practical for reconstruction of the convex subunits with flaps, not for the concave subunits—the nasal sidewalls and soft triangles. As skin flaps heal, they contract in response to the collagen and myofibroblasts in the recipient bed. This contraction pulls the flap centripetally (i.e., trapdoors) into the convex shape of the unit it covers. The subunit principle is not suitable for repair with skin grafts because skin grafts do not undergo trapdoor contraction. These grafts lie flat and do not bulge with wound contraction, likely because they lack a layer of subcutaneous adipose tissue. If more than 50% of the subunit is missing, the entire subunit (in particular the tip or ala) should be replaced with a flap.

The nose in a young child is smaller, flatter, and less defined than that in an adult.[3] The subunit's borders are less distinct, but even in children the subunit principle can be used as a technique to hide scars and harness flap contraction.

FIG. 163.1 Nasal prosthesis.

An 83-year-old male status post a total rhinectomy, before, **A,** and after, **B,** coverage with a nasal prosthesis.

Analysis of the Defect—By Nasal Layers (Skin, Cartilage, and Mucosa)

Accurate analysis of the defect with regard to the component layers of the nose is essential. In general, when only skin is missing, reconstruction can be done reliably with local flaps and, if the underlying framework has been resected, with cartilage grafts. The difficulty of the reconstruction increases as the amount of nasal lining diminishes.

The nose has three distinct zones of skin thickness with differing degrees of subcutaneous adipose tissue, sebaceous gland content, and mobility (Fig. 163.5).[4] The skin of zone 1 is nonsebaceous and mobile and covers the upper dorsum and sidewalls of the nose. Zone 2 contains thick, sebaceous, nonmobile skin and covers the supratip area, tip, and alar lobules. Zone 3 skin is thin, nonsebaceous, and fixed to the

underlying alar cartilages or fibroadipose tissue structures of the alar margin, soft tissue triangles, infratip lobule, and columella.

Imaging

Imaging is generally not indicated for cutaneous carcinomas unless possible invasion of the underlying structures (i.e., bone destruction, perineural invasion) or regional metastasis is suspected. In these cases computed tomography (CT) or magnetic resonance imaging (MRI) may be indicated.

Indications

1. Nasal defects caused by cancer resection or trauma

Contraindications

1. Congruence between what is perceived by the patient and observed by the physician is essential. Discrepancies in form or function are best addressed before any consideration can be given to surgical intervention.

2. Preoperative counseling is also crucial to best define anticipated cosmetic results and limitations. This might include demonstrating certain procedures in a mirror for the patient and outlining schematic figures of the intended surgeries. If multiple staged surgeries are needed, their timing should be emphasized. If a patient is unwilling to proceed with a multistage plan, the surgical options/recommendations should change.

3. Medical comorbidities increase the risks of general anesthesia.

Preoperative Preparation

1. Be sure the surgical margins are clear before proceeding with reconstruction.

2. Discontinue antiplatelet drugs if possible.

3. In designing a flap to reconstruct the defect or subunit, one should use

a template based on the contralateral, uninjured side. If the contralateral side is also injured, a plaster or clay model of an ideal nose can serve as the template.

Operative Period

Anesthesia

- General: Although some skin flaps (i.e., bilobed, nasolabial, forehead) can be developed under local anesthesia or with sedation, general anesthesia is preferred for patient comfort, especially if cartilage grafts are being harvested.

Positioning

- Supine: The bed is turned 90 degrees, allowing access to both sides of the face (so that symmetry can be checked) and to the ears (so that cartilage grafts can be harvested if needed).

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin

Monitoring

- None

Instruments and Equipment to Have Available

1. Basic septoplasty and rhinoplasty surgery set

2. Needle-tip cautery

3. Plastic surgery soft tissue tray containing small double-pronged skin hooks, iris scissors, and 0.5 skin pickups

FIG. 163.2 Reconstruction of the cheek and nose with free tissue transfer.

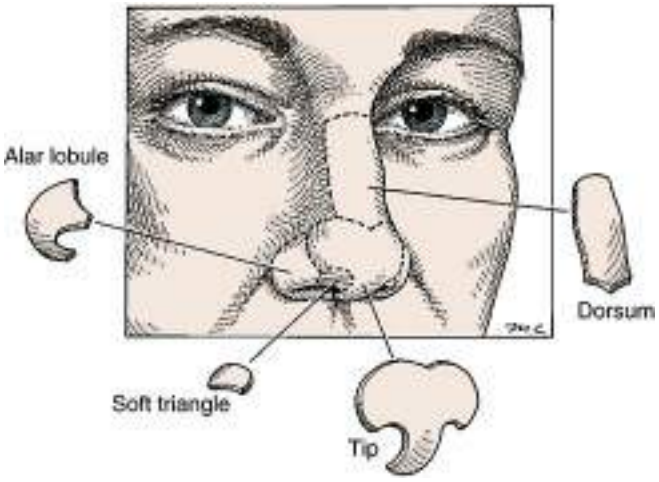

FIG. 163.4 Nasal subunits.

The surface of the nose can be divided into distinct anatomic regions corresponding to sites of natural lines of shadow, curvature, and differing skin characteristics. The convex subunits of the nose are the tip, dorsum, alae, and columella. From Burget GC: Aesthetic restoration of the nose. Clin Plast Surg 12:463-480, 1985; with permission.

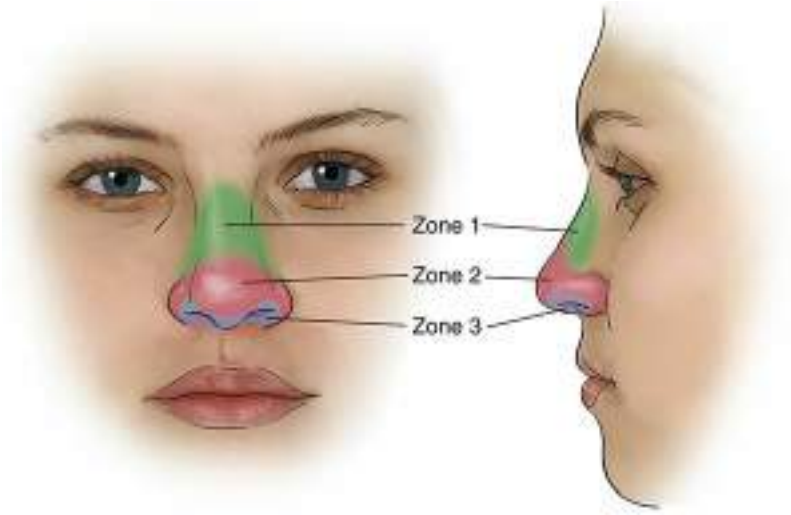

FIG. 163.5 Nasal skin zones.

Depiction of the three zones of nasal skin types. Reprinted from Burget GC: Modification of the subunit principle for reconstruction of nasal tip and dorsum defects. Arch Facial Plast Surg 1:16-18, 1999; with permission.

Key Anatomic Landmarks

1. Medial canthi to determine the midline and the position of the nasal subunits on the middle third of the face

2. Inferior extent of the frontal hairline to try to avoid raising a forehead flap with hair

Prerequisite Skills

1. Septoplasty

2. Open rhinoplasty

3. Harvest of conchal cartilage graft

Operative Risks

1. Necrosis of a skin flap. Any skin flap can become necrotic if the blood supply of the flap is exceeded (i.e., a base width-to-length ratio of 1:3 in the face should not be exceeded for a random skin flap), if the flap is handled traumatically, or if the patient has other risk factors, such as smoking, which can affect perfusion.

2. Septal perforation or flattening of the concha if cartilage grafts are harvested with suboptimal technique

Surgical Technique

Reconstruction of the nose begins with an analysis of the defect. With a diagnosis of the facial and nasal subunits involved and the nasal layers missing, one can evaluate the various reconstructive options and plan the surgical approach.

Nasal Lining Options

A thin, vascular, and supple nasal lining remains the goal of reconstruction. Thick bulky flaps, such as a nasolabial flap, will block the nasal airway. Cartilage grafts placed on poorly perfused flaps will necrose and extrude. Lining flaps that are highly vascular and thin can be taken from multiple donor sites within the nose (Fig. 163.6).[5,6] Menick's technique of using a folded forehead flap in three stages offers a new, refined method of replacing nasal lining, and the transfer of free fasciocutaneous flaps enables the reconstruction of the total or near-total defect.[7]

Turnover Flaps

Turnover flaps are small flaps of the skin surrounding a defect that are turned over like the pages of a book into the nasal airway. Because they are based on scar, their blood supply can be tenuous and their length will

be limited. If their blood supply appears inadequate at the time of reconstruction, cartilage grafting should be done secondarily.

Septal Mucoperichondrial Flaps: Ipsilateral and Contralateral

An ipsilateral septal flap, based anteriorly on the septal branch of the superior labial artery, has been described by Burget and Menick. The flap pivots on an anteroinferior point near the nasal spine and folds outward to provide lining for the nasal domes. The exposed septal cartilage is either harvested as a graft or left to remucosalize.

A contralateral septal flap can be harvested with or without septal cartilage. This technique involves harvesting the contralateral septal mucoperichondrium and swinging it like a trapdoor underneath the nasal dorsum through a dorsal perforation in the septum. The flap can reach the nasal sidewalls but not the alar margins.

Bipedicled Lining Flaps

The nasal lining of the alar margin can be successfully reconstructed with a bipedicled lining flap (Fig. 163.7). The flap is based medially on the septum and laterally on the vestibule and is pulled down to the alar margin. The secondary lining defect made above the alar margin can be covered with a contralateral (or ipsilateral) septal mucoperichondrial flap.

Menick´s Technique for Nasal Lining: The Folded Forehead Flap, Skin Grafts, and Three-Stage Nasal Reconstruction

To provide nasal lining, Menick has advocated folding the forehead flap on itself and setting it into the defect (Fig. 163.8). At a second operation, at 3 weeks, the covering portion of the flap is separated from its nasal lining portion and lifted entirely off the nose. The nasal lining flap is now thinned with removal of the frontalis muscle and excess subcutaneous tissue. Cartilage grafts are placed at this second stage. The covering portion of the forehead flap is also thinned and then reattached to the

nose. The pedicle is divided at a third stage 3 weeks after the second stage. For large nasal defects, a full-thickness skin graft can be sewn to the edges of the mucosal defect and to the frontalis muscle layer of the forehead flap in the first stage. Wound healing and contracture are not initiated until the subcutaneous and frontalis planes are surgically injured. Therefore the reconstructed lining of the folded flap or skin graft remains supple and soft until it is supported by the delayed placement of cartilage grafts during the second stage.

Microvascular Free Tissue

For total or subtotal loss of the nose, free tissue transfer of a fasciocutaneous flap, usually a radial forearm free flap, can be done to reconstruct the nasal lining vault (Fig. 163.9).[8] However, a bulky free flap will obstruct the nasal airway unless it is supported on the nasal septum. When the anterior nasal septum is present, Burget and Walton advocate rotating it forward as a septal pivot flap (Fig. 163.10).[8,9] This septal flap has the ability to support the length and projection of the nose without obstructing the airway. The raw external surface of the free flap is skin-grafted. At a second stage 5 to 6 weeks later, the skin graft and subcutaneous adipose tissue of the free flap are removed and formal nasal reconstruction with cartilage grafting and a paramedian flap is carried out.

Without a septal pivot flap, a single paddle free flap will collapse against the piriform aperture. For correction of this problem, a double-paddle radial forearm free flap can be used to create a double-vaulted nasal lining and a columellar lining.

Skeletal Support

As the local flaps used for nasal reconstruction heal, the collagen and myofibroblasts within the flap and wound contract, pulling the flap toward a center of centripetal contraction. Grafts of cartilage and bone support the skin flaps, preventing contraction, and after a few months show through the covering flap to give the reconstructed nose a normal shape. Cartilage and bone from the septum, concha of the ear, or cartilage from the ribs (sixth through ninth rib) are the best donor sites. Because the septum is a possible growth center, the ear and costal

cartilage are better options for sources of cartilage grafts in children. Grafts will survive only if placed on a well-vascularized bed, such as that provided by septal flaps. With the use of the folded forehead flap or microvascular free flaps, secondary placement of grafts is preferred.

To provide midline nasal support, there are several well-accepted options. A cantilevered bone graft can be harvested either from the outer calvarium of the skull or from rib as an osteochondral segment (Fig. 163.11). A sturdy longitudinal segment can then be crafted to extend from the nasion to the superior aspect of the nasal lobule as an onlay or cantilevered graft. This can be secured in place by suture to the underlying cartilaginous dorsum or plated/wired to the frontal bone and/or nasal bones as needed. Smaller segments of calvarial bone, rib, or septal cartilage can be carved into longitudinal struts for more limited reconstructions, as for the nasal sidewall.

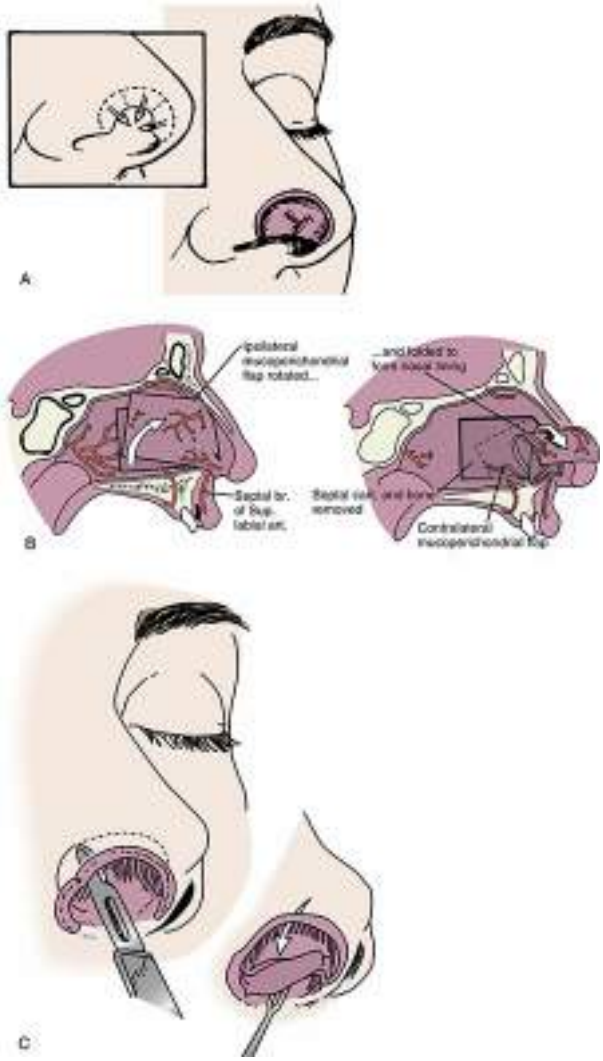

FIG. 163.6 Nasal Lining.

Options for nasal lining include **A,** turnover flaps, **B,** septal mucoperichondrial flaps, and **C,** bipedicled lining flaps. *art.*, artery; *br.*, branch; *cart.*, cartilage; *Sup.*, superior. From Barton FE: Aesthetic aspects of partial nasal reconstruction. Clin Plast Surg 8(2):177-191, 1981; Burget GC, Menick FJ: Nasal support and lining: the marriage of beauty and blood supply. Plast Recon Surg 84(2):189-202, 1989; and Burget GC: Aesthetic restoration of the nose. Clin Plast Surg 12:463-480, 1985; with permission.

FIG. 163.7 Superiorly based, two-stage nasolabial flap.

A, Defect of the soft tissue triangle, frontal view. **B,** Oblique view. **C,** First stage: Nasal lining reconstructed with a bipedicled lining flap, septal cartilage used to buttress the soft tissue triangle. **D,** Superiorly based nasolabial flap used for cutaneous coverage. **E,** Second stage: Nasolabial flap divided and inset, oblique view. **F,** Basal view. **G,** Appearance 1 week after second stage, frontal view.

FIG. 163.8 Three-stage nasal reconstruction with a forehead flap.

A, Alar defect, frontal view. **B,** Oblique view. **C,** First stage: Design of the folded forehead flap for nasal lining and cutaneous covering. **D,** Immediate postoperative appearance. **E,** Second stage: Flap divided along the alar margin; nasal and cutaneous flaps thinned of frontalis muscle and subcutaneous tissue. **F,** Conchal cartilage harvested. **G,** Conchal cartilage graft to the ala. **H,** Third stage: Division of the forehead pedicle and flap inset. **I,** Appearance 4 months after pedicle division, frontal view. **J,** Oblique view.

For alar cartilage reconstruction, strips of cartilage 4 to 5 mm in width and 1.5 to 2.0 cm in length are harvested from the concha of the ear, septum, or rib (Fig. 163.12). To make an arch, one weakens or scores the cartilage in the area destined to be the lateral genu, and the cartilage is bent into a curve using one or two spanning mattress sutures. The intrinsic curves of conchal cartilage make it ideal for alar batten grafts, but conchal cartilage may be too weak to support a scarred nasal skin

envelope. Septal and costal cartilage are stiffer than conchal cartilage and will better tolerate the compressive forces of a contracted skin envelope. A separate cartilage graft should be used to brace the soft tissue triangle.

FIG. 163.9 Radial forearm free flap (RFFF) for internal nasal lining.

A, Near-total nasal defect, frontal view. **B,** Lateral view. **C,** Basal view. **D,** Template for the design of an RFFF for internal nasal lining. **E,** Harvest site and RFFF design. **F,** RFFF inset; forearm skin used for internal lining. **G,** Skin graft applied to the raw (i.e., external) surface of the RFFF. **H,** Postoperative appearance, frontal view. **I,** Lateral view. The patient will undergo removal of the skin graft, flap thinning, placement of a rib graft, and coverage with a forehead flap.

Nasal Skin Coverage

The size of the defect and the zone of nasal skin thickness can serve as useful guides for selecting the appropriate skin cover. Because the skin of zone 1 is mobile, local rotation-advancement flaps or primary closure can successfully reconstruct small defects (less than 1.5 cm). Zone 2 contains thick, sebaceous, nonmobile skin. The only donor skin that matches zone 2 is the remaining skin of zone 2 (i.e., transposed with a bilobed flap) or forehead skin with its dense subcutaneous adipose tissue. Zone 3 skin is thin, nonsebaceous, and fixed to the underlying alar cartilage or fibrofatty structures. Composite grafts from the ear (<1.5 cm) and preauricular full-thickness skin grafts can blend well in zone 3.

For large defects (>1.5 cm) a paramedian forehead flap is the preferred coverage for all zones. Columellar defects present a reconstructive challenge. A distal extension of the forehead flap provides an optimal solution when the columellar defect is a missing element of a larger defect. Other options, in particular for isolated columellar defects, include superiorly or inferiorly based nasolabial flaps.

Full-Thickness Skin Grafts

Because the skin of the upper two-thirds of the nose (zone 1) is thin with few sebaceous units, full-thickness skin grafts blend well in this area. Possible sites of harvest include the preauricular area, postauricular area, nasolabial fold, and supraclavicular area. The forehead has also been found to be an excellent site of graft donor skin. Skin and a few millimeters of subcutaneous adipose tissue can be transferred from the forehead for superficial defects of the alae and tip (Fig. 163.13). A skin graft should not be harvested from an area that is a possible site for a forehead flap. Because of the temporary period of ischemia during wound healing, the melanocytes of a skin graft may be injured, causing the final graft to appear hypopigmented or hyperpigmented.

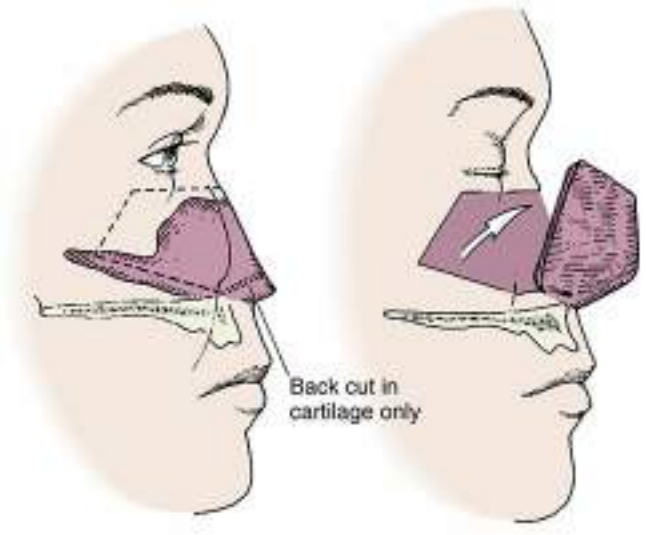

FIG. 163.10 Septal pivot flap.

To provide dorsal and caudal support, the central cartilaginous/bony septum can be pivoted or swung anteriorly. The blood supply of the septal pivot flap is centered over the septal branches of the superior labial arteries.

Composite Chondrocutaneous Grafts

A composite chondrocutaneous graft can be an option for reconstructing the nasal skeleton with defects also including nasal skin and/or inner nasal lining. Composite grafts can be harvested from the root of the helix or from the conchal bowl (Figs. 163.14 and 163.15). The survival of the composite graft depends mainly on the size of the graft and on the vascularity of the recipient bed. Diffusion from the recipient bed is the only source of nutrients to the composite graft in the early postoperative period. Several authors have reported the complete healing of composite grafts after partial necrosis. In general, to minimize the possibility of necrosis, graft size should not exceed 1.5 cm; if possible, composite grafts should be placed under or on well-vascularized tissue. Grafts may be harvested as two layers (skin, cartilage) or as three layers (skin, cartilage, skin). Composite grafts are mainly used for reconstructing the alae and columella.

Bilobed Flaps

The bilobed flap as described by Zitelli (Fig. 163.16)[10] is the most suitable method to repair small (<1.5 cm) superficial defects of zone 2 (tip or ala, Fig. 163.17). It moves the nasal defect from the zone of thick immobile skin (zone 2) to the zone of thin mobile skin (zone 1). The fundamentals of this transposition flap are as follows:

FIG. 163.11 Structural support of the nasal midline/dorsum.

A, Costochondral graft carved into an "L" strut with alar battens. **B,** Cantilevered cranial bone graft to be fixed to the frontal skull with a miniplate.

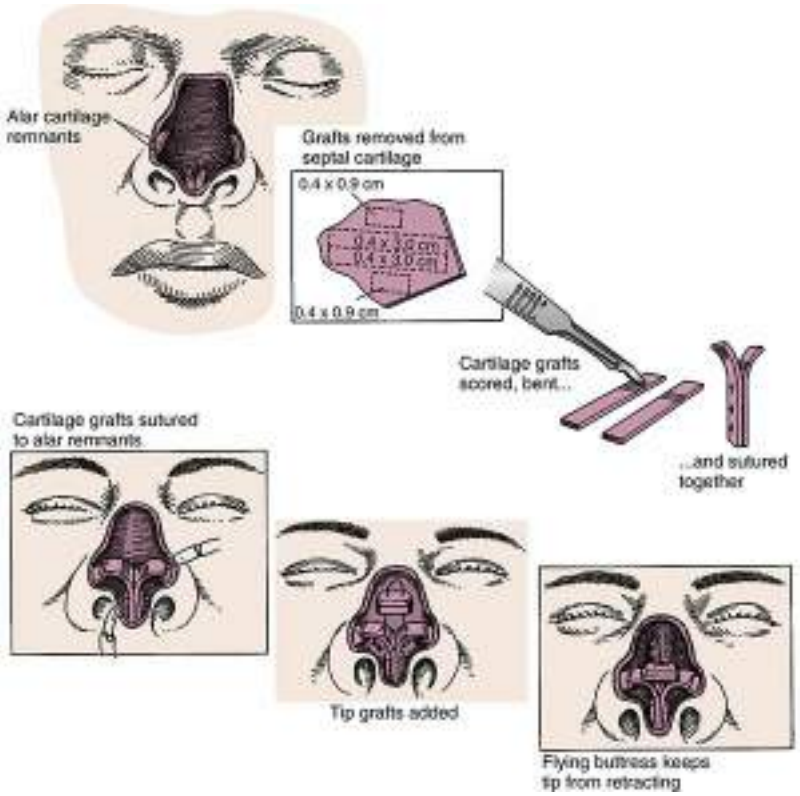

FIG. 163.12 Reconstruction of cartilage support.

If lining is created or preserved, cartilage from numerous sources (in this case the septum) can be tailored to restore the nasal contour and curvature. A cap graft or tip graft can be used to promote lobule projection. From Burget GC, Menick FJ: Aesthetic restoration of one-half the upper lip. Plast Reconstr Surg 78(5):583-593, 1986; with permission.

FIG. 163.13 Forehead full-thickness skin graft with adipose tissue.

A, Alar defect with skin graft harvested with 1 mm of adipose tissue on the dermis. **B,** Postoperative result at 1 year. Note the hypopigmentation. The contour has been well preserved without a depression.

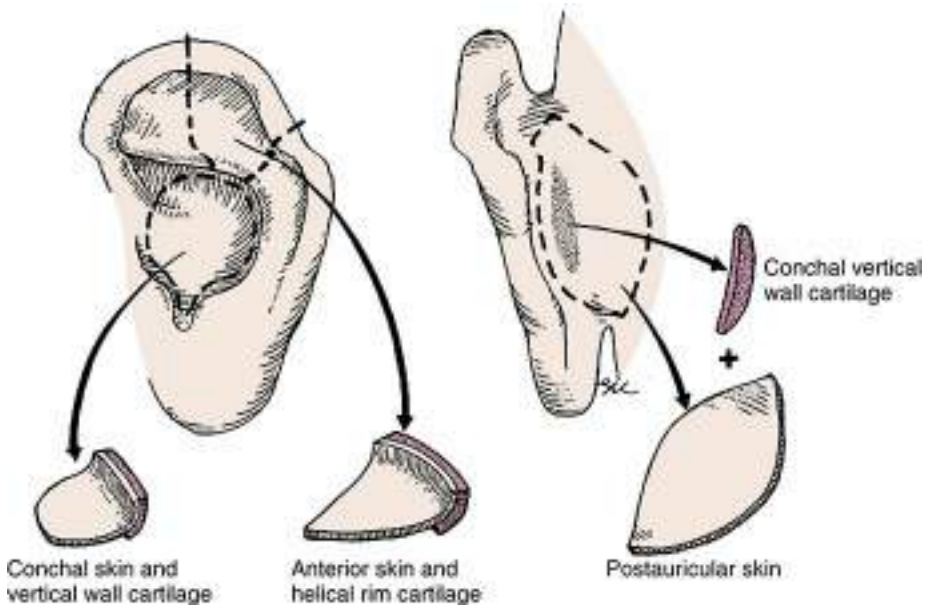

FIG. 163.14 Composite graft.

The ear is an ideal donor site for nasal reconstruction,

including full-thickness chondrocutaneous grafts. From Barton FE, Jr: Aesthetic aspects of partial nasal reconstruction. Clin Plast Surg 8(2):177-191, 1981; with permission.

FIG. 163.15 Composite chondrocutaneous graft for nasal stenosis.

A, Bilateral nasal stenosis after necrosis of the nasal tip. **B,** Defect of the ala and tip recreated. **C,** Harvest of a composite auricular graft. **D,** Inset of the composite graft. **E,** Immediate postoperative appearance.

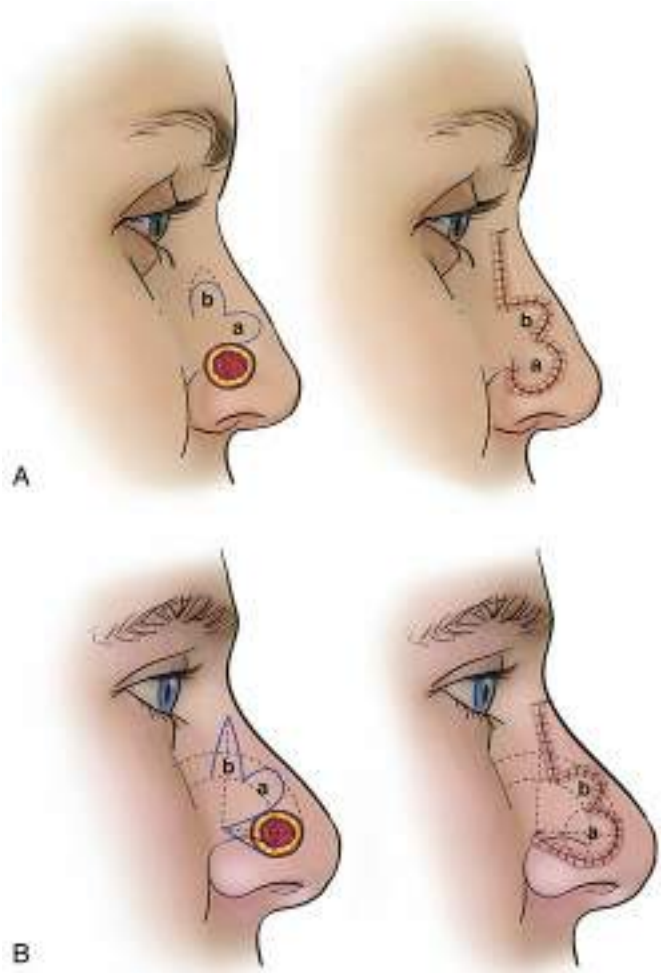

FIG. 163.16 Zitelli modification of the bilobed flap.

Compared with the original design of a 180-degree arc of rotation, which typically produces a dog-ear deformity at the rotational point, **A,** the modified transposition flap creates a smaller defect by using a 90-degree arc of rotation and minimizing dog-ear and trapdoor formation, **B.** Adapted from Bhatia A, Rohrer TE. Flaps and Grafts in Dermatologic Surgery. Chapter 7, Transposition Flaps. 79-90. ©2007, Elsevier Inc.

1. The arc of rotation can vary between 90 and 180 degrees but is generally designed to be between 90 and 100 degrees. The radius will usually approximate 1.5 diameters of the defect.

2. The first lobe should be the same size as the defect. The second lobe is smaller and just narrow enough to allow primary linear closure of the donor defect.

3. For medial defects, laterally based flaps can be designed.

4. Closure of the secondary defects should not distort normal landmarks, such as the lower eyelid.

Potential disadvantages of the bilobed flap are trapdooring (convex bulging) and obliteration of the alar groove.

Nasolabial Flaps

Based either superiorly or inferiorly, the nasolabial flap relies on a random blood supply derived from facial artery perforators and takes advantage of the abundance of mobile non-hair-bearing skin in the medial cheek. Primary closure of the defect within the nasolabial fold creates a minimal, postoperative deformity. Reconstruction involves first tracing an outline of the cutaneous defect on the donor site and then elevating the flap in a subcutaneous plane (Fig. 163.18; see also Fig. 163.7). The superiorly based nasolabial flap is good for reconstructing the entire alar subunit, the lower aspect of the nasal sidewall, and the nasal platform on which the alar base rests. The inferiorly based nasolabial flap is most useful for defects of the upper lip, floor of the nose, and columella. A nasolabial flap folded to create both internal and external lining creates a bulky alar rim that will require subsequent revision.

Forehead Flaps

A forehead flap transfers skin of ideal quality to reconstruct the nasal skin defect in patients of all ages. The forehead heals well with minimal scars even in donor sites left to heal secondarily. Midline or paramedian forehead flaps can be raised either on the supratrochlear or supraorbital vessels. Most surgeons elevate a paramedian flap based on an ipsilateral supratrochlear vascular pedicle that is located approximately 1.5 cm from the midline. A Doppler examination can be used to locate the pedicle, but even if no Doppler signal is found, a flap with a pedicle based almost anywhere along the midline of the forehead will likely survive. To avoid strangulation caused by the twisting of a wide pedicle, the pedicle width of a paramedian flap should be about 1.5 cm. To gain length for a paramedian flap, one can extend the flap into the hair-bearing scalp and/or extend the flap 1.5 cm below the orbital rim.

The pattern of the nasal defect should first be designed from the

contralateral normal side of the patient's face as a model. Local anesthesia with epinephrine should not be injected into the forehead flap so as to allow intraoperative evaluation of the blood supply. The forehead flap is then elevated from distal to proximal with all layers of the scalp (skin, subcutaneous tissue, and frontalis muscle) except periosteum. The forehead flap is then thinned only at the columellar inset and along the alar rim. Closure of the donor site should be done over the periosteum with subgaleal undermining of the forehead. Any gaps that cannot be closed should be kept moist with antibiotic ointment, covered with petroleum jelly gauze, and allowed to heal secondarily. The pedicle of the paramedian forehead flap in the glabellar region is typically covered with a split-thickness skin graft to decrease bleeding and oozing.

FIG. 163.17 Nasal tip defect reconstructed with a bilobed flap.

A, Bilobed flap design. **B,** Closure. **C,** Early postoperative appearance.

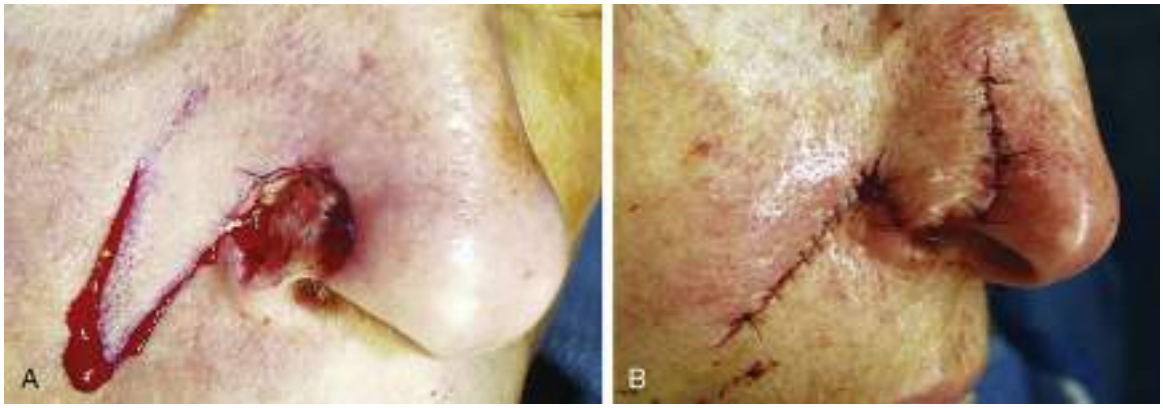

FIG. 163.18 Superiorly based, single-stage nasolabial flap.

A, Alar defect. **B,** Nasolabial flap inset.

Menick advises the transfer of only pristine, unexpanded forehead skin. An expanded forehead flap can contract after the completion of nasal reconstruction, producing inferior aesthetic results. If necessary, tissue expansion can be done secondarily after nasal reconstruction to close the forehead donor site or to perform forehead scar revision.

Common Errors in Technique

1. If the first step in a nasal reconstruction is not recreation of the defect (i.e., excising old scar and contractions), the final result will be a reconstruction and flap design that is too small.

2. If the lip, cheek, and nose all require reconstruction, the lip-cheek platform (i.e., nasal platform) should be reconstructed in a first stage prior to nasal reconstruction. If nasal reconstruction is done at the same time, subsequent wound settling can shift the lip-cheek platform, causing a reciprocal shift in the position of the reconstructed nose.

3. Reconstruction of missing nasal lining with bulky flaps, such as a nasolabial flap or free flap, can lead to nasal obstruction.

4. When more than 50% of a nasal convex subunit is missing, patching the nasal defect with a local flap without replacing the entire nasal subunit may worsen the aesthetic outcome.

Postoperative Period

Postoperative Management

1. Patients undergoing first-stage nasal reconstruction with a forehead flap should stay in the hospital overnight.

2. Any blanching of the flap or signs of venous congestion can potentially be reversed with removal of sutures or reinsertion of the flap.

3. Doyle splints or intranasal packs are generally not used unless there is a risk of synechiae formation.

4. Because they may compromise the flap's circulation, external dressings are not placed on a flap used for nasal reconstruction.

5. Skin sutures, as well as any external bolster placed on a skin graft, are removed 5 to 7 days after surgery.

6. Postoperative parenteral antibiotics are not routinely prescribed.

Complications

1. Skin flap necrosis

If a forehead flap is to be used in a patient who is a smoker, delay the forehead flap by 3 weeks prior to transfer. This can be done by incising the perimeter of the flap without elevating it.

2. Nasal obstructive breathing

3. Alar retraction

Although a normal alar lobule contains little cartilage, a reconstructed ala should contain a cartilage graft (i.e., in a nonanatomic position) that spans the entire lobule to prevent soft tissue contraction. Reconstruction of the soft tissue triangle also requires a separate cartilage graft to withstand the forces of contraction.

4. Nonaesthetic scars

Consideration of the subunit principle is mainly useful only for reconstruction of the convex subunits of the nose (i.e., the tip, dorsum, alae, and columella) with local flaps. This is because as a local flap heals, it contracts centripetally, pulling the flap into a convex shape.

Discussion

Evidence-Based Medicine Question

Should a pediatric nasal reconstruction be delayed until nasal growth is complete?

Psychosocial, functional, and aesthetic concerns should be addressed with early, definitive reconstruction. In children, reconstruction should be initiated and, if possible, completed before the child is of school age to avoid psychosocial repercussions. The reconstructed nose—with skin, lining, and support—will grow with the child. However, residual surgeries (to increase the nasal airway, to add cartilage grafts for the enhancement of projection or contour, and to revise scars) are expected.

Editorial Comment

Reconstruction in three stages with a folded forehead flap or forehead flap with a skin graft offers an excellent option for reconstructing the nasal defect with missing internal nasal lining.

Review Questions

1. The arc of rotation of a bilobed flap is generally designed with what angle?

   a. 45 degrees

   b. **90 degrees**

   c. 135 degrees

   d. 180 degrees

2. Consideration of the subunit principle is mainly useful for reconstruction of the following subunits except which one?

   a. Tip

b. Dorsum

c. Alae

d. **Sidewall**

3. The supratrochlear artery is located approximately how many centimeters from the midline?

a. 0.5

b. **1.5**

c. 2.0

d. 2.5

Scalp Reconstruction

Role of Tissue Expansion and Flap Reconstruction

Stephanie E. Dreifuss, Mario G. Solari, Ernest K. Manders, and Alex Senchenkov

Introduction

Scalp defects can occur secondary to trauma, tumor resection, infection, radiation, and congenital abnormalities. Strategies for scalp reconstruction must take into account the size of the defect, its characteristics, quality of surrounding tissue, donor site morbidity, timing of the adjuvant treatments, and patient-related variables. The reconstructive process may target skeletal and tissue defects. Staged revisional operations are commonly indicated in order to optimize aesthetic outcomes.

Key Operative Learning Points

1. The scalp is a unique hair-bearing tissue and is best reconstructed using tissue expansion.

2. Full-thickness, composite, radiated, and very large defects require microvascular reconstruction that offers predictable and reliable results.

3. Secondary procedures such as flap debulking, cranioplasty with patient-specific implants, and tissue expansion are very useful in enhancing cosmetic and functional outcomes of the scalp reconstructive process.

Preoperative Period

Preoperative Assessment

- Patient assessment is aimed to answer three questions:
    1. Is the tumor **resectable**?
    2. Is the resultant defect **reconstructible**?
    3. Is the patient **operable**, that is, able to withstand the proposed operation due to status of his or her general health?
- Resectability of the tumors is discussed in ablative chapters of the book.

History

- As in any preoperative assessment, it is critical to consider individual patient characteristics including **overall health** and **level of function** to establish their **operability.** Some patients may benefit from preoperative medical optimization to enable them to tolerate an operation and to optimize their healing potential.
- Patient **compliance** and **personal preference** should be taken into consideration prior to embarking on reconstruction that relies heavily on patient participation, such as frequent dressing changes or tissue expansions.
- Other specific patient and treatment characteristics, such as a plan for **adjuvant radiation** in oncologic patients or concomitant injuries in trauma or burn patients, must also be part of the patient assessment.

Physical Examination

- Characteristics of the defect:
    1. The most important factors that determine the reconstructive approach are defect **size**, **shape**, **location**, and **depth.**
    2. The condition of tissues surrounding the defect and the nature of **exposed structures** (soft tissue, periosteum, bone, or dura) may

significantly influence the reconstructive plan to involve microvascular tissue transfer or calvarial reconstruction.

- **Surrounding tissue:** As with any defect, control of the wound is an important initial step in the reconstructive process.
    1. The optimal **quality** of surrounding tissues must be attained by either serial débridements or one-stage excisional preparation of the reconstructive site, whereby poor quality tissues such as **scars**, **chronic wounds**, **radiated or damaged scalp** are excised, and new wound edges consisting of healthy tissues capable of effective healing are established (Fig. 164.1A and B).
    2. In the cases of malignancies, **negative margins of resection** must be obtained. This issue becomes particularly relevant in the cases of aggressive tumors such as angiosarcoma of the scalp or poorly differentiated carcinomas. In such cases, scouting biopsies are performed first, and often several operations are necessary in order to achieve negative margins on permanent pathologic studies.
    3. Other important considerations unique to the scalp include the shape and symmetry of the **hairline, direction of hair growth, pattern of hair-bearing, or baldness** and **eyebrows**, all of which might be distorted by tissue rearrangement.
- **Flap**, **graft**, and **recipient vessel availability** are determined by the review of previous surgical history, available imaging, and, most importantly, physical examination.

Imaging

- **Computed tomography (CT) scan** is indicated in:
    - Patients undergoing oncologic reconstruction to ascertain depth of invasion or lymph node involvement
    - Trauma patients to determine the pattern or extent of concomitant injuries
- **Magnetic resonance imaging (MRI)** useful in
    - Assessment of tumor involvement of the skull

- Intracranial invasion

- **Surgeon-performed duplex ultrasound** is the best in mapping out vasculature for free tissue transfer.

Indications

Primary indication for scalp reconstruction is a scalp defect with **exposed underlying structures** (galea, bone, dura, brain).

Reconstructive choices are largely dictated by the **size**, **condition,** and **extent of the defect**.

- Patients with radiation-related problems (i.e., osteoradionecrosis) or needing postoperative radiation, as well as the ones with large and composite defects, should be treated with microvascular tissue transfer if they can withstand surgical treatment.

FIG. 164.1 **A,** The patient with a remote history of a

radiated cranioplasty from combined treatment of the brain tumor, who developed infected osteoradionecrosis of the skull with an epidural abscess. **B,** Wide debridement and craniectomy, with immediate reconstruction using free latissimus dorsi muscle flap and temporary xenograft coverage were performed, which was followed by a staged full-thickness skin graft from the panniculectomy site and later a cranioplasty with the PEEK implant. Postoperative radiographic, **C,** and clinical, **D,** appearance of the patient-specific implant that was also designed to replace soft tissue deficit in the temporal fossa. Case of Giuseppe Lanzino, MD (Neurosurgery), and Alex Senchenkov, MD (Plastic Surgery), Mayo Clinic Foundation.

- Multiple reports support safety of microsurgery in the older but reasonably healthy patient, demonstrating that age should not be viewed as a contraindication to reconstruction and oncologically sound surgical care.
- In contrast, young and healthy individuals are the patients most likely to heal by secondary intention or with skin grafts. The healing area should be later revised with the help of serial excision and tissue expansion to minimize the sequelae of the scarring and loss of the hair-bearing scalp.

Contraindications

- Oncologic patients with **positive margins**, unless reconstruction is being performed for palliative purposes
- Defects that have been **inadequately débrided** and contain necrotic or nonviable tissue
- Wounds that contain **active infection**
- **Comorbidities** conferring an unacceptable surgical risk

Preoperative Preparations

- Consideration of patient preferences

- Preoperative evaluation may include cardiology evaluation or other assessment as indicated by the patient's past medical history.
  - **Cancer patients:** confirmation of negative margins and plan for adjuvant radiation
  - **Trauma patients:** management of concomitant injuries
  - **Infection:** Culture-specific antibiotic therapy is indicated if there is evidence osteomyelitis of the skull.
- **Imaging** as above
  - **Duplex ultrasound** to elucidate vasculature prior to free tissue transfer
- **Informed consent** should include discussion of risks, benefits, and alternatives of various reconstructive options. The patient needs to understand the need for various indicated procedures may arise intraoperatively.

Operative Period

Anesthesia: General

Positioning: Supine unless the defect is posterior or the latissimus dorsi (LD) flap is used, which will require lateral decubitus positioning. Care must be taken to avoid pressure injuries, and the prolonged lateral decubitus position should be used with caution.

Perioperative antibiotics are administered according to the Surgical Care Improvement Project (SCIP) protocol.

Monitoring: Intraoperative monitoring depends on the reconstructive approach selected. Most techniques require standard anesthesia equipment and intraoperative monitoring. However, free tissue transfer may require arterial line placement for close blood pressure monitoring and blood draws throughout the procedure.

Instruments and Equipment to Have Available

Microsurgical and craniofacial instrumentation as dictated by the planned extent of the case

Key Anatomic Landmarks

- Scalp layer mnemonic: S.C.A.L.P.
    1. **Skin:** The skin of the scalp is thick and well vascularized.
    2. **Subcutaneous tissue:** Vessels, nerves, lymphatics, and hair follicles reside in the subcutaneous tissue of the scalp. Multiple connective tissue septations are present, providing additional mechanical rigidity. They secondarily prevent collapse of the transected vessels, hence the need for closure of the scalp lacerations to achieve hemostasis. The scalp also has a rich lymphatic network, which explains the aggressive lymphatic spread of some tumors in this location (e.g., malignant melanoma).
    3. **Aponeurosis** *(galea aponeurotica):* The galea (Latin: Roman leather helmet) is the layer of dense connective tissue continuous with the temporoparietal fascia, superficial muscular aponeurotic system (SMAS), frontalis, and occipitalis muscles; hence the term *aponeurosis.* The galea provides the strength of the scalp. Closure of this layer is critical in order to offload tension from the skin.
    4. **Loose areolar tissue:** The subgaleal layer is the mobile layer of the scalp. It is relatively avascular and is considered a safe dissection plane. Undermining in this plane allows for increased mobilization of the overlying scalp tissue. Similarly, this layer serves as a route of spread for hematoma, purulence, or excess fluid into the periorbital fat.
    5. **Pericranium:** This layer is the periosteum of the skull.
- Vasculature
    1. Arterial supply of the scalp comes from four territories with extensive collateralization:
        a. **Anterior:** The **supraorbital and supratrochlear arteries** arise from the internal carotid system and supply the lateral and medial forehead, respectively. Their territory extends to the

anterior scalp.

b. **Lateral:** The **superficial temporal artery**, a terminal branch of the external carotid system, supplies the largest territory of the scalp. These vessels should be considered in designing of the local flaps.

c. **Posterior:** The **occipital arteries** supply the posterior scalp.

d. **Posterolateral:** The **posterior auricular artery** supplies the smallest scalp territory.

2. Vast anastomoses among arteries supplying these four territories allow for replantation of the scalp based on a single vessel.

3. Venous drainage accompanies named arteries, and venous outflow may prove to be more problematic in scalp replantations and flap designs.

- Sensory innervation

1. **Anterior:** The **supraorbital and supratrochlear nerves** arise from the ophthalmic branch of the trigeminal nerve and supply the anterior and anterolateral scalp.

2. **Lateral:** The **zygomaticotemporal nerve** supplies the skin lateral to the temporal crest. It is a branch of the maxillary division of the trigeminal nerve.

3. **Posterior:** The **greater and lesser occipital nerves** derive from spinal nerves and supply sensation to the posterior scalp.

4. **Posterolateral:** The **auriculotemporal nerve** arises from the mandibular branch of the trigeminal nerve and supplies the lateral scalp.

Prerequisite Skills

Experience with the full spectrum of reconstructive techniques including both microvascular and craniofacial surgery will enable the surgeon to select the most effective reconstructive strategy.

Operative Risks

1. Morbidity and mortality related to patient's general medical condition. American Society of Anesthesiologists **(ASA) classification** has been adopted for preoperative risk stratification.

2. Nonmicrovascular reconstructive complications, e.g., graft failure, skeletal exposure, dehiscence of the closures, and healing delays, are common.

3. Microvascular complication related to high prevalence of thrombophilia in oncologic scalp patients may necessitate perioperative anticoagulation. Technical difficulty of the procedure is related to small diameter and anatomic variability of the recipient vessels; however, free flap losses are exceedingly rare, and reconstructive success is very high.

Surgical Techniques

- **Secondary intention:** Closure by secondary intention occurs by means of the buildup of granulation tissue and wound contracture.
    1. This process is enhanced by negative pressure wound therapy.
    2. In order for contracture to occur, a well-vascularized wound bed must be present at the base of the defect. Therefore, this method is appropriate for small defects without skeletal exposure.
    3. Drawbacks to this technique include prolonged time to complete healing, the risk of displacing nearby structures secondary to wound contracture, and the resultant scar alopecia in the area of the wound.[1]
    4. Historically, drilling openings in the outer table in order to gain access to a more vascularized diploic space was employed to enhance the growth of granulation tissue or incorporation of biologic matrix (Integra, Life Sciences, Plainsboro, New Jersey) with the goal of eventual skin graft. These techniques play a distant secondary role in the modern reconstructive practice because of prolonged healing times and suboptimal functional and cosmetic results. Lastly, a recurrence of the tumor in the setting of violated outer table will require full-thickness craniectomy.
    5. Allograft, such as GammaGraft (Promethean LifeSciences, Inc.,

Pittsburgh, Pennsylvania), or xenograft material can be applied to scalp wounds or exposed skull for a temporary coverage in preparation for reconstruction. Following tangential excision of the burns, allograft is used to "test-drive" the wound to ensure the future skin graft take. After one to three weeks, the allograft adherence is confirmed and a split-thickness skin graft can be performed. In tumor patients, delays in coverage are often related to pending pathologic confirmation of negative oncologic margins or confirmation of adequacy of tangential excision of burns.

6. A dermal regeneration template such as Integra (a bilaminar construct composed of a collagen layer covered with a silastic sheet) has a different purpose. Its main goal is to serve as a template for vascular and tissue ingrowth into the collagen layer to build a recipient tissue bed for a skin graft. The split-thickness skin grafts applied to either Integra or granulating skull are usually thin and fragile. They often result in prolonged healing times and long-term morbidity (Fig. 164.2).

FIG. 164.2 Long-term result of a reconstruction of the full-thickness scalp defect from angiosarcoma excision. The defect was initially covered with Integra applied to the pericranium (the periphery of the defect) and diploic

matter of the skull in the central area, where the outer table was drilled out as a part of tumor resection. A split-thickness skin graft was used following incorporation of Integra. The patient has been suffering from dryness and continuous breakdowns of the fragile skin graft. Case of Ricky Cay, MD, Mayo Clinic Foundation.

- **Direct closure:** Given the mobility of the scalp in the subgaleal plane, primary closure of defects 3 cm or less may often be achieved with wide undermining of surrounding tissue, galeal scoring, and continuous external tissue expander application, e.g., DermaClose RC system (Wound Care Technologies, Inc., Chanhassen, Minnesota).[2]
    1. Attention must be paid to the resultant displacement of the hairline and eyebrows.
    2. To avoid scar widening and scar alopecia, layered closure with galeal approximation supports the overlying soft tissue closure.
    3. Primary closure of larger defects can be achieved in the parietal region where the tissue is more mobile; however, primary closure is more limited in the occipital region where less mobilization is possible.
    4. Additionally, a **coronal brow lift procedure** is useful in achieving direct closure of the small defects with a considerable secondary cosmetic benefit (Fig. 164.3A and B).
- **Skin graft:** Skin grafts require a healthy, granulating wound bed for optimal take and are usually inappropriate in radiated beds or wounds with skeletal exposure. Indications for skin grafting to the scalp are soft tissue wound with intact periosteum, well-excised burns, local flap donor site, and muscle free flap reconstruction.
    1. The drawbacks of the split-thickness skin graft to the scalp include contraction, color mismatch, alopecia, and long-term fragility (Fig. 164.2).
    2. Split-thickness skin grafts do not support hair transplantation or withstand adjuvant radiation well; hence they should generally be avoided in those settings.
    3. Full-thickness skin grafts fare better in either definitive

reconstruction or in combination with muscle free flap (Fig. 164.1D).

4. When coupled with tissue expansion, a split-thickness skin graft can later be excised to address these drawbacks (Fig. 164.4A and B).

- **Local flaps:** Local flaps, including transposition, advancement, and rotation flaps, are useful for reconstructing scalp defects.

1. General principles for local flap reconstruction are inclusion of a named vessel when possible, flap delay procedures to provide reliable blood supply, design of a wider flap to augment perfusion, planning the resultant defect in the least cosmetically sensitive area possible, wide undermining and galeal scoring to increase flap advancement, and planning incisions parallel to hair follicles to avoid scar alopecia.[3]

2. These flaps should be large in order to incorporate a sufficient number of vessels, accommodate the spherical shape of the skull, and allow for tension-free closure.

3. The most common reason for local flap failure is venous insufficiency.

4. Types of scalp flaps for small- and moderate-sized defects include advancement flaps, rotation advancement flaps, V-Y flaps, and bilobed flaps.[3]

5. To close the resultant defect after local flap advancement or rotation, surrounding tissues can be widely undermined. If donor site primary closure cannot be achieved after this maneuver, skin grafting can be performed. Later, the skin graft can be excised and closed with the scalp skin gained by staged tissue expansion (Fig. 164.4A and B).

6. For defects greater than 6 cm in diameter, multiple local flaps might be required.

7. Ultimately, approach to closure with local flaps depends on the anatomic region of the scalp.

   a. Anterior defects can be closed using the Juri flap or temporo-parieto-occipital flap. This operation may involve a flap delay

procedure, followed by elevation of a flap based on the parietal branch of the superficial temporal artery, and transposition of this flap to the anterior hairline with primary closure of the parietal donor site.[4]

b. Large anterior or occipital defects are amenable to the Orticochea flap technique, which can reportedly close as much as 30% of the scalp. It employs bilateral flaps based on the superficial temporal arteries and a large posterior flap based on the occipital vessels.[5] This strategy imposes a large amount of scar on the scalp and may prove inadequate for larger defects, only moving an area of alopecia from one area to another, perhaps less obvious, area.

c. Vertex defects can be closed using pinwheel flaps, which recreate the natural whorl hair-bearing pattern of the vertex of the scalp.

- **Tissue expansion:** Tissue expansion is an invaluable and preferred tool for scalp reconstruction as it successfully replaces like with like, without leaving a donor site defect. Furthermore, as much as 50% of the scalp can be reconstructed with tissue expansion. Tissue expansion preserves normal sensation and hair growth orientation and results in a delay phenomenon, thereby increasing the vascularity of the expanded flap.

1. Requirements for tissue expansion include the absence of infection, the presence of healthy and well-vascularized tissue, no prior history of radiation, and a compliant patient willing to undergo the lengthy expansion process and resultant, temporary disfigurement.

2. Other disadvantages of tissue expansion include the risk of exposure, extrusion, device compromise, flap necrosis, and infection.

a. A recent meta-analysis reported an overall 17.44% complication rate, with infection being the most common complication at a rate of 4.58%.

FIG. 164.3 **A,** Patient with full-thickness scalp loss from a burn that was reconstructed with a meshed split-thickness skin graft. **B,** A coronal browlift was performed for reconstruction of the defect from complete excision of the skin graft. Case of Alex Senchenkov, MD, Mayo Clinic Foundation.

FIG. 164.4 Staged reconstruction of the scalp defect from excision of the skin cancer: **A,** A rotational scalp flap and split-thickness skin graft of the donor site was performed, followed by the tissue expansion of the remaining scalp, and, **B,** complete excision of the skin graft. Case of Alex Senchenkov, MD.

b. Flap necrosis was found to occur at a rate of 3.65%, hematoma

or seroma at a rate of 2.85%, exposure in 1.68%, and device malfunction in 1.54%.[6]

c. For these reasons, direct contact of a tissue expander with patient-specific cranioplasty implants and ventriculoperitoneal shunts should be avoided due to the risk of contamination.

3. It is a common practice to plan an incision for tissue expander placement either perpendicular to the axis of expansion or within an area that can be excised in the subsequent staged procedures. If remote incision is chosen, one should avoid compromising blood supply of any potential future flaps that will be used in subsequent stages of the reconstruction. The author's preference is to place an incision at the edge of the future defect or lesion.

   a. The expander is placed in the subgaleal plane and minimally filled intraoperatively with concentrated methylene blue dye to ease the postoperative identification. Gentle expansion can be started in a week as healing proceeds. Expansions are performed 1 to 2 times weekly.

   b. The endpoint for injection is when the patient reports the expansion is just beginning to feel uncomfortably tight. The expander may be overfilled to yield maximal tissue gain considering the curvature of the skull and the expected contraction following removal of the expander.

   c. It is important to measure the arc over the expander and subtract the base width to get an estimate of the tissue advancement possible.

   d. Upon final advancement of the expanded tissue, the expander capsule may be incised to allow for increased flap advancement to offset the planning imperfections. However, this maneuver does compromise the blood supply.

- **Free flaps:** A free flap is indicated for complex and composite defects with damage to surrounding tissues by radiation, burns, infection, osteoradionecrosis, or other insults or when vital structures such as dura or critical hardware are exposed. It provides immediate coverage for complex and composite scalp and cranial defects by providing healthy tissue with superior blood supply.

1. Microvascular reconstruction plays a key role in oncologic cases that frequently require adjuvant radiation therapy that should be started within 6 weeks and completed within 100 days from the time of the resection for optimal oncologic outcome.
2. The superficial temporal vessels are the preferred recipient vessels due to their proximity but not due to their quality. In fact, these are the most technically challenging recipient vessels in microsurgical practice. Particularly in women, they are frequently very small, spastic, and disproportionately afflicted with atherosclerosis. The surgeon may split the bifurcation to increase the diameter of these often sub-millimeter vessels or dissect the vessels to the level of the tragus as it dives under the parotid gland where the vessel caliber increases.
3. Use of the facial, superior thyroid, and transverse cervical vessels as microvascular targets of free flap revascularization will require vein grafts to reach the defect (Fig. 164.5A) without compromising the aesthetic outcome of the operation (Fig. 164.5B).
4. The surgeon must decide between the following microvascular reconstructive plans:
    a. Free muscle flap with skin graft vs. cutaneous free flap: Muscle with skin graft will not tolerate radiation as well as a cutaneous flap but is larger in size, better fills dead space, and enhances clearance of infection.

FIG. 164.5 Immunocompromised patient with recurrently recurrent squamous cell carcinoma of the scalp undergoing microvascular reconstruction of the Mohs defect with the third free flap. The left superficial temporal vessels had been used for revascularization of the previous free latissimus dorsi muscle flap for occipital defect reconstruction. The right superficial temporal vessels were used for free anterolateral thigh flap for right parietal defect reconstruction in the past. In the present case, the reversed greater saphenus vein graft connected the radial artery of the radial forearm flap to the facial artery and nonreversed vein graft and established venous outflow into the facial and external jugular veins, **A,** with successful reconstructive outcome, **B.** Case of Alex Senchenkov, MD, Mayo Clinic Foundation.

b. Need and timing of staged cranioplasty

c. Available donor sites and their morbidity: The transverse rectus abdominis musculocutaneous (TRAM) or deep inferior epigastric artery perforator (DIEP) donor sites are favored by most patients due to their positive cosmetic impact, while LD, if not used as a split muscle, may decrease strength in manual laborers and patients whose pectoralis major muscle was damaged.

d. Defect size: small defects (radial forearm free flap or anterolateral flap [ALT]) versus large defects (TRAM or LD)

e. Desire for hair restoration: Cutaneous free flaps can support hair transplantation whereas skin grafted muscle flaps cannot.

f. Cosmetic expectations and willingness to undergo staged reconstructive procedures

5. An omental free flap with subsequent skin graft coverage was originally described for scalp reconstruction by Donald H. McLean and Harry J. Buncke in 1972, but its aesthetic outcome has been inferior.

6. In summary, microvascular tissue transfer effectively provides an immediate coverage solution in often desperate clinical situations.[7] Superb cosmetic and functional outcomes can be achieved by a combination of the reconstructive methods in the staged reconstructive process.

- **Calvarial reconstruction:** Indications for skeletal reconstruction associated with scalp defects include protection of underlying brain and restoration of normal contour.

1. Options for reconstruction include autologous and alloplastic methods.

a. Autologous techniques can involve banking and subsequent replacement of the original bone flap or split calvarial bone grafting from a remote area of the skull, ribs, or iliac crest. Parietal bone is preferred for split calvarial bone grafting due to its increased thickness.

b. Alloplastic materials such as titanium mesh, polymethylmethacrylate, and hydroxyapatite have been historically used to rebuild full-thickness calvarial defects. Presently, superior computer-assisted design/computer-assisted manufacture (CAD/CAM) patient-specific implants of MEDPOR (Stryker, Kalamazoo, Michigan), PEEK (poly-ether-ether-ketone, KLS, Martin Group, Jacksonville, Florida), PEKK (poly-ether-ketone-ketone, Biomet, Jacksonville, Florida), and titanium (KLS, Martin Group, Jacksonville, Florida) are available. The advances in three-dimensional technology permit exact anatomic reconstruction of the missing skeletal and sometimes soft tissue elements (Fig. 164.1C).

2. With any calvarial reconstruction, there is a risk of infection.

3. Contour deformities are common in non-patient-specific reconstructions (Fig. 164.6).

4. Autologous reconstructions carry the risk of graft resorption. One group reported infectious complications in 15.9% of cases.

5. Infections did not appear to differ significantly between groups reconstructed with autogenous and alloplastic materials. Instead, infections were found to be related to preoperative radiation and infection history.[8] This information would indicate that the primary reason for cranioplasty complication was *insufficient soft tissue coverage*, which can be overcome with liberal use of microvascular tissue transfer or prior tissue expansion.

- **Replantation:** With the scalp being a specialized, unique tissue, complete or near complete scalp avulsions (Fig. 164.7A) are best managed with replantation or revascularization of the avulsed part (Fig. 164.7C). This technique is the ideal means of achieving a near-normal postoperative appearance.

  1. Avulsions are most likely to occur in the subgaleal plane (Fig. 164.7B). Due to the avulsion mechanism of injury, it is critical to assess the quality of the vessels, resect damaged vessels, and plan for vein grafting if necessary.

FIG. 164.6 The patient with composite excision of the locally advanced squamous cell carcinoma of the scalp and calvarium underwent reconstruction with an immediate off-the-shelf (non-patient-specific) titanium mesh and free latissimus dorsi muscle flap. A noticeable cranial asymmetry was the resultant complication. Case of Michelle Clarke, MD (Neurosurgery), and Alex Senchenkov, MD (Plastic Surgery), Mayo Clinic Foundation.

2. The traditional teaching is that one arterial anastomosis is sufficient to sustain the entire scalp, but maximizing less-reliable venous outflow should also be emphasized.

3. The only contraindications to scalp replantation are life-threatening conditions of the patient or a severely traumatized, lost, or improperly preserved avulsed part.

Common Errors in Technique

1. Failure to widely excise radiated tissues of poor quality to the extent of reconstructive capability

2. Underestimating tissue requirements and regenerative potential, and choosing reconstruction with local tissues instead of microvascular tissue transfer

3. Selecting noncustomized titanium mesh for reconstruction of a large

calvarial defect that leads to poor symmetry and mesh show or exposure.

Postoperative Period

Postoperative Management

- **General principles:** Most scalp reconstructions that involve undermining or creation of dead space will require either drain placement or gentle head wrap to prevent postoperative seroma. Reston self-adhesive foam pads (3M, St. Paul, Minnesota) should be used carefully to avoid vascular compromise.
- **Specific considerations:** Other postoperative care is dependent upon the method of reconstruction.
    1. A patient undergoing closure by secondary intention should be educated in performing dressing changes, or there should be a compliant individual available to deliver wound care.

FIG. 164.7 **A,** Isolated traumatic avulsion of the scalp, **B,** with promptly delivered avulsed part, **C,** treated with scalp replantation. Case of Michael L. Gimbel, MD, and Alex Senchenkov, MD.

2. Skin grafts are best secured with a wound Vacuum-Assisted Closure (VAC) dressing (Kinetic Concents, Inc., San Antonio, TX). To optimize care of the skin graft, one layer of Xeroform is stapled or sutured to the skin and another layer to VAC sponge. The VAC dressing is applied for a period of 1 to 2 weeks. After its removal, the inner layer of Xeroform is left in place until the skin graft heals completely.

3. Free flaps and scalp replants require routine postoperative free flap monitoring. Flap color, capillary refill, temperature, and turgor should be assessed frequently, and arterial and venous signals should be monitored using handheld or implantable Doppler.

    a. For monitoring superficial temporal vessel-based free flaps, a Cook-Swartz monitor should be avoided because of the risk of the silicon cuff exposure due to the paucity of the overlying soft tissue.

    b. The ipsilateral temple also has to be removed from the patient's glasses for a period of 6 weeks to prevent pressure on the free flap pedicle.

    c. It is important to avoid pressure injuries to the fresh flaps. For occipital reconstructions the patient may need to be placed with his flap on a Clinitron portion of Rite Hite bed (**Hill-Rom, Inc.,** Batesville, Indiana) (upside down) or in a halo ring from PMT Halo Cervical Traction System (PMT Corporation, Chanhassen, Minnesota) to ensure protection of the flap.

4. In tissue expansion cases, expansions are initiated in approximately 1 to 6 weeks postoperatively and are continued 1 to 2 times weekly.

    a. Pain with expansions is an important consideration that often limits volume and frequency of expansion, and care should be taken to avoid pressure injuries to the fragile, expanding scalp.

Complications

- Unfavorable scarring, wound dehiscence, infection, and failure can

occur with any reconstructive operation.

- Complications specific to closure by secondary intention or skin grafting are unfavorable scarring, contraction distorting nearby structures, and graft failure.
- Tissue expansion might be complicated by infection and exposure or extrusion of the prosthesis. Infection can be managed by removal of the expander, irrigation of the pocket, and delayed expander replacement in 3 to 6 months. Exposure can be managed with removal of the implant or dressing changes until closure is accomplished.
- Local flaps can be complicated by seroma or hematoma, emphasizing the importance of meticulous surgical technique and proper drain placement. Flap necrosis is often the result of inadequate flap design resulting from vascular, usually venous, insufficiency. Subsequent management of flap necrosis is usually conservative unless there is an exposure of the critical structures. Readvancing the flap that already has compromised circulation is ill advised. If a reconstructive procedure is still needed, an alternative, frequently microvascular approach, should be taken.
- Free flap cases have prolonged operative times with inherent risks of hypothermia, venous thromboembolism, and pressure injuries. Care should be taken to prevent these perioperative problems. Underbody warmers, warming blankets, and fluid warmers are standard practice. A prophylactic dose of subcutaneous heparin is administered prior to induction and repeated intraoperatively every 8 hours. Padding (e.g., full body silicone mattress and silicone shoulder and axillary rolls) is important.
- "Anesthesia mumps," an acute transient parotid swelling, has been observed in the patient in prolonged lateral decubitus position that was required for LD muscle flap reconstruction of the scalp. Padding and minimizing time in lateral decubitus position are useful.
- Prolonged scleral corneal protector causes corneal abrasion symptoms that are probably ischemic in nature. If possible, corneal protectors should be avoided.
- Microvascular complications are dealt with by early aggressive microvascular and pharmacologic methods.[9]

Revisional Reconstructive Procedures

- Given the many unique characteristics of the scalp and the aesthetic importance of this region, staged revisions are common.
- Deformities that may be addressed include alopecia, widened scars, standing cone deformities, displacement of mobile structures such as eyebrows, eyelids, or the hairline, color and texture mismatch of skin grafts, and contour deformities.
  - Alopecia can be managed with secondary local flaps, tissue expansion, serial excision, or hair transplantation.
  - Wide scars can be revised with re-excision and layered closure. In these situations, it is critical to close the galea to provide a strength layer and offload tension from the overlying skin.
  - Standing cones should be excised only after allowing sufficient time for resolution to pass, at least 6 weeks.
  - Should eyebrows or eyelids be displaced, full-thickness skin grafts, balancing direct and hairline browlifts, tissue expansion, or secondary local flaps should be performed to achieve improved symmetry.
  - Similar techniques can be used to restore a normal hairline pattern.
  - Skin grafts that cause a color or texture mismatch can also be managed with serial excision or tissue expansion.
  - Contour deformities may require secondary cranioplasty.

Discussion

Evidence-Based Medicine Question

Controversy in reconstruction of the full-thickness scalp defects: to free flap or not to free flap and how "conservative" should we be?

Wide availability and superior outcomes of microsurgical reconstruction influenced the field of scalp reconstruction. Historically, scalp defects created a considerable problem in trauma and particularly in oncologic settings. The argument of what "conservative"

reconstructive strategy is in management of scalp defect has been around ever since microvascular reconstruction of these defects gained momentum.

On one hand, reconstructive advantages of microvascular tissue transfer are difficult to overstate. Free tissue transfer supplies healthy, well-vascularized tissue to an area where the native tissue was compromised by trauma, malignancy, radiation, poor healing, or other insults. On the other hand, however, patients who require oncologic scalp reconstruction comprise a very challenging group with their advanced age, multiple comorbidities, and high prevalence of thrombophilia. The healing potential of these individuals is very poor. While there are not enough elderly patients with scalp defects to generate large studies, favorable observations have been made of the general safety of microvascular reconstruction in elderly patients with head and neck tumors (Ref A), renal failure Ref C and peripheral vascular disease Ref B. These patient groups have similar performance levels to patients with oncologic scalp defects. These parallels may support the trend toward more aggressive use of microsurgical reconstruction in managing patients with full-thickness scalp defects.

The technical reconstructive argument clearly favors microsurgical approach as opposed to drilling out the outer table and embarking on prolonged wound care. In a study by Upton et al., in a series of patients undergoing free flap scalp reconstruction, over half had undergone prior skin grafts or local flaps. In 95% of these patients, definitive reconstruction was achieved with free flaps. Microsurgical reconstruction compared favorably with nonmicrovascular management of the scalp defects. Using the microsurgical approach decreased the risk of complications, length of wound healing, and, thereby, the need for subsequent operations. Furthermore, microvascular tissue transfer allowed for a better cosmetic result by enabling the use of hair transplantation, liposuction, or other modalities to match the contour and other characteristics of the surrounding soft tissue.

The authors support the argument that perhaps a free flap is the most “conservative” treatment for the full-thickness defects of the scalp in the hands of proficient microsurgical and effective perioperative care teams.

Editorial Comment

The three most commonly used free flaps for scalp reconstruction are an ALT, RFFF, and latissimus free flap. A latissimus free flap covered with a skin graft often has an excellent aesthetic outcome after the latissimus muscle has atrophied. If a subsequent cranioplasty (i.e., with a PEEK implant or titanium) is needed, elevation and re-inset of free flap with a cutaneous paddle (i.e., ALT or RFFF) is likely to have less risk of wound breakdown than a latissimus flap covered with a skin graft.

Review Questions

1. In reconstruction of hair-bearing scalp, what reconstructive option produces the most natural result?

   a. Microvascular reconstruction with cutaneous free flap

   b. Local scalp flap

   c. Full-thickness skin graft over incorporated Integra bilayer

   d. **Tissue expansion**

   e. Healing by secondary intention

2. What scalp reconstruction technique is most likely to cause alopecia?

   a. Limiting tissue expansion to 25%

   b. **Limiting tissue expansion to 50%**

   c. Avoiding use of electrocautery

   d. Closing with staples

   e. Beveling skin incision

3. Which reconstructive technique delivers the most predictable reconstructive outcome in treatment of full-thickness scalp defects with cranial exposure?

   a. Drilling out of the cranium outer table and negative pressure wound therapy followed by skin graft

   b. Immediate application of Integra bilayer followed by skin graft

c. Immediate or delayed scalp flap

d. **Microvascular tissue transfer**

e. Immediate placement of tissue expander and active expansion with temporarily covered wound

Paramedian Forehead Flaps

Nathan Cass, and Frederic W.B. Deleyiannis

Introduction

The origin of forehead flaps dates back thousands of years. Practitioners in ancient India were the first known to harvest skin from the forehead to repair facial defects, mainly of the nose. Due to nasal amputation as a common form of judicial and political punishment at the time, there was ample opportunity for the practice of reconstruction using forehead skin. Interestingly, the practitioners of the forehead flap surgical procedure belonged to the potter and tilemaker castes rather than that of the physicians. This method was kept as a closely guarded secret, passed down through oral tradition. The first written account of forehead flaps was a 1794 letter to the editor of the British periodical *Gentleman's Magazine*, likely written by Colly Lyon Lucas, the British chief surgeon of Madras, India. The first forehead flap performed in the West was in 1814 by Dr. Joseph Constantine Carpue of England. In the United States, John Mason Warren performed the first operation in 1834.

Further exploration and refinement of the forehead flap as a method of reconstruction followed throughout the 20th century. Forehead tissue is currently the gold standard for nasal reconstruction and is also used for many other facial defects. This chapter examines the use of the forehead flap in repairing defects of the head and neck.

Key Operative Learning Points

- The size, shape, and location of the defect dictate the surgical planning of the forehead flap.
- As it courses superiorly, the supratrochlear artery passes superficial to the corrugator supercilii muscle and deep to the orbicularis oculi and

frontalis muscles, piercing the frontalis to become subcutaneous 1 to 2.5 cm superior to the orbital rim.

- The base of an inferiorly based vertical forehead flap should be 1.0 to 1.5 cm wide, wide enough to allow for inclusion of the pedicle artery but narrow enough to permit easy rotation for preservation of length.
- The division and proximal inset of a forehead flap must be delayed until neovascularization of the flap has taken place.

Preoperative Period

History

1. History of present illness
   a. Forehead flaps are most commonly used to reconstruct defects of the nose.
   b. The mechanism of tissue loss may be excision of a cancer, trauma, infection, or congenital defects.
2. Past medical and surgical history
   a. Previous soft tissue trauma to the forehead (i.e., old lacerations, excision of cancer) can potentially disrupt the blood supply to a forehead flap.
   b. Age and comorbid conditions should be ascertained, as they dictate the patient's American Society of Anesthesiologists (ASA) classification and risk of general anesthesia.
   c. Patients must be psychiatrically stable and emotionally prepared if they are to undergo a multiple-stage flap reconstruction.
3. Medications
   a. If a patient is taking anticoagulation medication, the necessity of the anticoagulation and the potential health risks of temporary cessation or bridging should be weighed.
4. Social history
   a. Smoking is associated with a higher risk of complications (i.e.,

ischemia of the flap and delayed donor site healing).

Physical Examination

1. Characteristics of the defect to be reconstructed (Fig. 165.1)
   a. Size: Though the majority of defects are successfully reconstructed with a paramedian forehead flap, a median forehead flap may provide a larger surface area for a near-total nasal reconstruction.
   b. Shape: Dictates the design of the forehead flap. For example, the three-dimensional contour of a large nasal defect requires precise planning (i.e., a template of the nose is designed on the forehead) to reconstruct the different subunits of the nose (Fig. 165.2).
   c. Location: To reach inferior defects, such as a columellar defect, the forehead flap may occasionally need to be extended into the frontal hairline. To avoid the hairline, the flap can be lengthened by extending the incisions inferiorly into the brow or by designing it slightly obliquely.
   d. Tissue missing: The skin of the forehead flap is routinely used for reconstructing the cutaneous component of a nasal defect. Other options must be included to reconstruct composite nasal defects (i.e., defects involving cartilage and nasal lining).

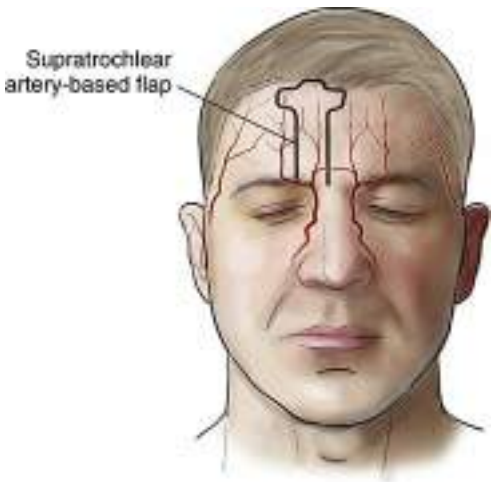

FIG. 165.1 Paramedian forehead flap based on right supratrochlear artery.

FIG. 165.2 Nasal tip, alae, and columella reconstruction with an expanded forehead flap.

A, Tissue expansion complete, template of the nasal defect outlined on the expanded forehead flap. **B,** Expander removed, flap about to be rotated. **C,** Nasal defect reconstructed, forehead closed primarily.

FIG. 165.3 Periorbital vessels and muscle relationships.

2. Forehead examination

   a. Examine the forehead skin for any abnormality (i.e., scar, actinic changes) that could affect blood supply, the quality of the skin, or the ability to close the defect created by raising the forehead flap.

   b. Note the position of the frontal hairline.

   c. The distance from the base of the forehead flap to the defect must be meticulously measured to ensure adequate length once the flap is rotated.

   d. Consider the possibility of using tissue expanders (see Fig. 165.2) for excessively wide defects.[1]

Imaging

- Imaging is not necessary in the surgical planning of a forehead flap.
- Intraoperative Doppler may be used to mark the course of the supratrochlear artery.

Indications

- Nasal cutaneous defects[2-4]
- Periorbital and cheek defects when other local options (i.e., cheek advancement flaps) are not available

Contraindications

- Not medically stable to undergo local anesthesia with sedation
- Psychiatrically or emotionally unstable (especially for multistage procedures)
- Significant scarring, previous radiation therapy to the forehead, or other previous surgery (i.e., bicoronal incision for access the frontal skull), which may disrupt adequate blood flow and preclude its use as

donor tissue

- Active smoking is not an absolute contraindication to surgery but should be approached with caution. Delayed procedures (e.g., incising the perimeter of the flap without initially raising it) may be advised.

Preoperative Preparation

- There are many options for the reconstruction of nasal defects. The surgeon and the patient should carefully decide which best fits the needs of the defect and the patient. Healing by secondary intention, primary closure, skin grafting, and other local flaps are alternative options (see Chapter 163).
- Timing of reconstruction
  - After creation of the defect (i.e., after Mohs surgery): The reconstruction may be more definitively planned preoperatively since the extent and location of the defect is known.
  - Concurrent with the creation of the defect (i.e., intraoperatively after tumor margins have been cleared with frozen sections): Preoperative counseling will likely include more reconstructive options since the extent of the defect is not precisely known before tumor excision. Delayed reconstruction pending final pathology margins is often desirable.
- Optimization
  - Medical conditions: Obtain medical clearance for general anesthesia if necessary.
  - Discontinuation of anticoagulation if possible
  - Cessation of smoking
- Photographs to document the defect, reconstructive options, and outcomes

Operative Period

Anesthesia

1. General anesthesia is preferable for most forehead flaps for patient comfort and intraoperative planning.

2. For patients unable to tolerate this, performing the operation under local anesthesia with IV sedation is acceptable.

   a. Either lidocaine or a mixture of lidocaine and bupivacaine will work well for local anesthetic infiltration, and benzodiazepines given intravenously may provide adequate relaxation and sedation.

Positioning

- Supine: The bed is turned 90 degrees, allowing access to both sides of the face, forehead, frontal scalp, nose, ears, and neck so that symmetry can be checked and cartilage grafts can be harvested if necessary.

Perioperative Antibiotic Prophylaxis

1. First-generation cephalosporin

2. Clindamycin for cephalosporin allergy

Monitoring

- Standard intraoperative monitoring should be used: EKG, pulse oximetry, end-tidal CO_2, and temperature probe.

Instruments and Equipment to Have Available

- Plastic surgery soft tissue tray containing #15 C blades, small double-pronged skin hooks, iris scissors, and 0.5 toothed forceps
- Needle tip cautery and bipolar cautery
- Sterile Doppler
- Rhinoplasty set to evaluate the nasal airway

Key Anatomic Landmarks

Forehead Blood Supply

1. Internal carotid artery (ICA) supply
    a. Ophthalmic artery is the first branch of the ICA
        1) Supraorbital artery: Courses superior to the center of the globe; exits the skull at the supraorbital foramen or notch to give blood supply to the forehead region superior to the midorbits
        2) Dorsal nasal artery: One of the two terminal branches; it courses anteroinferomedially along the medial canthal region and down to the superior nasal sidewall. At the anastomosis with the angular artery, there is often a central artery that courses superiorly to supply the glabella and the inferior portion of the central forehead.
        3) Supratrochlear artery: One of the two terminal branches; it exits the skull at the superomedial aspect of the orbit above the medial canthus and courses in a superior direction to supply the forehead tissue above its origin.
2. External carotid artery (ECA) supply
    a. Facial artery: Travels superomedially over the mandible, giving off the inferior and superior labial arteries. The terminal branch is the angular artery, which gives off the lateral nasal branch before continuing a superomedial course past the medial canthus to anastomose with the dorsal nasal artery and occasionally with the supratrochlear artery. After this anastomosis, the angular artery contributes to a central artery, which courses in a superior direction near the midline of the forehead.
    b. Superficial temporal artery: One of the two terminal branches (the other is the internal maxillary artery); it arises between the superficial and deep lobes of the parotid gland, gives off the transverse facial artery—which courses anteriorly to supply the lateral face—then terminates in two branches. The parietal branch supplies the posterosuperior scalp, and the frontal branch courses anteriorly to supply the lateral forehead where it anastomoses with

the supraorbital artery.

Prerequisite Skills

- Training and experience handling soft tissue, designing advancement–rotation cutaneous flaps, and raising pedicled flaps
- Training in functional rhinoplasty

Operative Risks

- Partial or complete flap loss
- Hematoma
- Infection
- Scalp numbness
- Brow and/or frontal hairline distortion or displacement
- Prolonged or poor wound healing at the forehead donor site

Surgical Technique

1. Flap design
   a. Inferiorly based: Most often used for nasal reconstruction
      1) Types (see Fig. 107.1)
         a) Paramedian[2-4]: Supratrochlear artery pedicle, skin flap centered over supratrochlear artery
         b) Midline[5]: Supratrochlear artery pedicle, skin flap centered in middle of forehead, nutrient artery on lateral edge of flap
            i) The central artery may also be used, which allows the flap to be based more inferomedially along the orbital rim and gives more length before reaching the hairline, which results in less hair-bearing skin transfer to the face.
         c) Median: Bilateral supratrochlear arteries; flap is more

broad-based but with a decreased arc of rotation given the width of the base.

2) Supratrochlear artery localization

a) Doppler ultrasonography. However, landmarks may reliably be used to locate the supratrochlear artery instead of a Doppler.

b) Multiple studies have confirmed that the supratrochlear artery is approximately 1.25 to 1.5 cm lateral to the midline at the orbital rim.

3) Supratrochlear artery course (Fig. 107.3)

a) Superficial to corrugator supercilii and deep to orbicularis oculi and frontalis muscles

b) Pierces the frontalis muscle to become subcutaneous 1 to 2.5 cm superior to the orbital rim

4) Technique

a) Outline the flap with a skin marker.

b) The flap should be based above the medial canthus with its center approximately 1.25 to 1.50 cm lateral to midline.

c) Design a flap width of 1.0 to 1.5 cm—wide enough to allow the supratrochlear artery to be encompassed within the flap with a margin on either side.

d) The skin paddle at the superior end may be widened if the defect to be reconstructed requires a larger area of skin.

e) Before making an incision, make a template of the flap (i.e., with a cut towel; see Fig. 107.2) and then rotate this template to the defect with the base of the flap (i.e., template) held in position. One can then check to see if the flap length and design are appropriate for the defect.

f) In multistage procedures (i.e., three-stage nasal reconstruction[3]) include full-thickness frontalis muscle in the distal end of the flap in order to minimize contraction; the flap may be thinned at subsequent procedures.

g) Try to design the forehead flap just below the hairline to

avoid transfer of hair-bearing skin to the nose or face.

h) The flap is inset into the nasal defect with 5.0 nylon sutures; a few deep dermal sutures may also be placed.

i) To decrease the bleeding on the undersurface of the forehead flap (i.e., the bridge over the intact nasal skin), one can skin graft this area with a split thickness graft or apply Alloderm.

b. Laterally based: Best for reconstruction of defects of the orbit or cheek if other local flaps (i.e., cervicofacial advancement flaps) and the midline blood supply of the forehead are not available.

1) Blood supply: Based on a superficial temporal artery (STA) or bilateral STAs. The donor site may be quite conspicuous when a large laterally based flap is used for midface defects.

2. Stages of reconstruction

a. Multistage procedures

1) First operation: Flap is initially sewn into the defect with the middle of the flap, forming a bridge over the intervening intact skin. Easy flap visualization allows ability to monitor for ischemia or venous congestion. If the pedicle is twisted, causing decreased perfusion, it may be detached from the defect and rotated back into its native position to reestablish blood flow. The flap would then be re-rotated back into the defect approximately 5 to 7 days after its initial harvest (i.e., increased perfusion based on the delay phenomenon).

2) Second operation (optional): The flap is raised from the defect and is thinned to match the defect site. Cartilage grafts may be placed or thinned.

3) Third operation: The flap pedicle is divided, and the proximal edge of the flap is inset into the defect for circumferential closure.

b. Single-stage procedure—island flap: The pedicle may be de-epithelialized and the flap tunneled through the subcutaneous tissue. The disadvantages of a single-stage forehead flap include the possibility of increased pressure on the artery and vein of the pedicle

from the tunneling, which could then result in ischemia or venous congestion.

3. Donor site closure

   a. Primary closure: Most preferable; may be accomplished if the flap is narrow or tissue expanders have been used (see Fig. 107.2)

   b. Secondary intention routinely yields a very acceptable scar. The donor site is kept moist with antibiotic ointment or Vaseline until it heals secondarily.

   c. Skin grafts are not routinely used.

Common Errors in Technique

- Insufficient flap length
  - Flap must be meticulously measured and re-measured to ensure adequate length.
  - Surgeon must account for loss of length that occurs with rotation of flap.
  - The inset of the forehead flap on the nasal defect must be tension-free.
- Inclusion of frontal hair in the forehead flap

Postoperative Period

Postoperative Management

1. Patients are often discharged the same day after a forehead flap. For patient comfort (i.e., oozing from the undersurface of the forehead flap or pain) or because of comorbid conditions, 23-hour or inpatient admission may be warranted.

2. If flap perfusion is in question or if the flap appears with excessive venous congestion, the patient should be brought back to the operating room and the flap rotated back into its native position.

3. Many forehead flaps will appear slightly congested (i.e., slightly blue)

once rotated into the defect. This slight congestion resolves within 2 to 3 days.

4. The division of the forehead pedicle must be delayed until neovascularization of the flap has taken place. This can usually safely be done after 3 weeks.

5. Minor interventions, such as dermabrasion and additional debulking, may be advised after final healing has taken place (6 to 12 months) to smooth the transition areas between the flap and native nasal skin.

Complications

- Partial flap loss due to arterial insufficiency or venous congestion
- Poor cosmetic outcome: Scarring, notching, poor color matching, eyebrow malposition, transfer of hair-bearing skin to a non-hair-bearing area

Discussion

Evidence-Based Medicine Question

During a multistage reconstruction of a nasal defect with a forehead flap, what is the most appropriate length of time to delay the second stage?

The currently accepted standard is to delay the final stage for at least 3 weeks for most patients and longer in smokers or patients with other small vessel disease (hypertension, diabetes.). The delay allows time for neovascularization to occur to the skin flap from the tissue surrounding the defect. Based on intra- and postoperative angiography using laser-assisted indocyanine green imaging, some studies assert that neovascularization of the flap occurs at 1 to 2 weeks and advocate for earlier pedicle division and inset of the flap in order to reduce facial deformity. Gentle manual compression of the pedicle can also be done in the clinic to ensure that the distal end of the flap has become vascularized (i.e., remains pink) from the recipient tissue. If the skin of distal forehead flap remains pink, the surgeon may then commence with the final stage of reconstruction. If the capillary refill is questionable, the division of the

pedicle should be delayed.

Editorial Comment

Tissue expansion may be used to expand the width and length of a forehead flap, but expanded tissue may contract as it heals. Tissue expansion of the forehead may also be used after a forehead flap has been raised to decrease any wide scars of the forehead that are a result of secondary healing at the donor site.

Pericranial Scalp Flap

Brian D. Thorp, Satyan B. Sreenath, and Adam Zanation

Introduction

Surgical extirpation and reconstruction represent the shared common core goals in both open and endoscopic anterior skull base surgery. Successful operative intervention requires thoughtful planning in the context of the patient's anatomy, pathology, and comorbidities.

It is important to realize that the goals for the treatment of benign processes differ from those of malignant processes. Although gross total resection is always favored, surgical decompression with attempts at complete surgical excision without undue morbidity should always be the default with benign pathologies. In contrast, the treatment of malignant processes requires clear surgical margins.

Reconstructive efforts of the skull focus on the watertight separation of the cranial cavity from the upper aerodigestive/sinonasal tract. This separation is required to minimize the risk of postoperative cerebrospinal fluid (CSF) leak and associated sequelae such as meningitis and/or pneumocephalus. Reconstruction should also provide the obliteration of dead space, preservation of function, and restoration of cosmesis.

An array of skull base reconstruction options exists ranging from acellular grafts to vascularized flaps. This chapter will focus on the pericranial flap (PCF), a vascularized pedicled flap based on the supraorbital and supratrochlear arteries. This versatile flap has been used in a multitude of applications throughout the skull base and head and neck, and often represents the primary reconstructive choice in open anterior skull base procedures and the primary extranasal reconstructive choice in endoscopic anterior skull base procedures. It should be noted that the galeopericranial flap is also a vascularized pedicled flap based on the supraorbital and supratrochlear arteries. In addition to including the

pericranium and immediately superficial loose areolar tissue, this flap includes the galea, thereby providing the reconstructive surgeon with a thicker pedicled flap.

Key Operative Learning Points

1. The PCF is a vascularized pedicle flap based on the supraorbital and supratrochlear arteries and can be used in open and endoscopic anterior skull base reconstruction.

2. The pericranium includes the calvarial periosteum and associated areolar tissue lying deep to the galea. The flap can be elevated and used without risk to the remaining scalp.

3. The endoscopic-assisted PCF can be accessed and elevated using an array of incisions. We favor a trichophytic incision at our institution. When used in the setting of an endoscopic skull base resection, only half of the pericranium should be used, thereby maintaining an additional PCF option for future potential usage.

4. Although an extended PCF can be elevated via open or endoscopic techniques, with a length adequate to reach clival defects, it is most frequently used for defects in the anterior cranial fossa and sella.

Preoperative Period

History

1. History of Present Illness

Patients who present to the skull base surgeon often require a multidisciplinary approach to ensure accurate diagnosis and evaluation for optimal therapy. A detailed description of this critical portion of the evaluation is outside the scope of this chapter, but should focus on identifying clinical features that afford insight into the clinical progression, involved primary and adjacent structures, and the potential for regional or distant disease. This information should guide further investigations and frame patient counseling.

2. Past Medical History

After identifying those patients who require anterior skull base surgery for which a PCF is considered, several factors must be taken into account.

a. Prior interventions that may affect the viability, presence, or healing capacity of the PCF and/or scalp.

1) Prior maxillofacial trauma that could have disrupted the vascular supply.

2) Prior transcranial or endoscopic surgery for which a PCF was used or transgressed. At our institution in the setting of a previously used PCF where a contralateral flap is not available, consideration of other reconstructive options such as a tunneled temporoparietal fascia flap or free tissue transfer is required.

3) Prior radiation therapy (including the scalp) that could affect wound healing or increase the difficulty of flap elevation must be considered. Of note, the report of a recent review indicated that there was no significant difference in the rates of CSF leak between those receiving radiation therapy (8.1%) and those not receiving radiation therapy (2.6%).[1]

b. Medical Comorbidities

1) Diabetes mellitus, hypercortisolism, poor nutritional status, and cigarette smoking are risk factors for delayed wound healing and should be taken into account by the surgical team.

c. Medications

1) All efforts should be made to hold antiplatelet and anticoagulants prior to surgical intervention to minimize the risk of excessive bleeding or the development of a hematoma in the donor site or surgical site.

Physical Examination

A comprehensive physical examination is of upmost importance when evaluating patients for skull base surgery. The physical examination should consider findings that indicate the degree of tumor extension

including local mass effect and cranial nerve neuropathies. A thorough review of these features is outside the scope of this chapter, but a specific notation should be made regarding evaluation of the scalp for potential development of a PCF.

1. Evaluation of the scalp
    a. Prior incisions or scars should prompt directed questioning to ascertain the likelihood of a viable PCF. Suspected damage to the vascular supply or prior usage essentially eliminates its use in reconstruction of the skull base.
    b. Evaluation of the hair and hairline should also be noted, because this will help the reconstructive surgeon plan the incisions for flap access. Additionally, the facial skeleton and position of the calvarial convexity should be noted, because an incision placed anterior to or posterior to the convexity may make complete elevation of the flap challenging when using an endoscopic-assisted approach.
2. Nasal endoscopy
    a. Bilateral sinonasal endoscopy provides the reconstructive surgeon with critical information regarding the location of the tumor and helps to determine the availability of intranasal vascularized flap options (i.e., nasoseptal flap [NSF]), which are often unavailable in revision surgery or when malignant tumors involve the nasal septum.

Imaging

1. Anatomic imaging
    a. The evaluation of the primary site requires at least a computed tomography (CT) maxillofacial scan with image guidance protocol and a complementary contrasted magnetic resonance imaging (MRI) scan of the brain with image guidance protocol. These studies are critical in allowing the skull base team to assess the burden of disease, surrounding critical neurovascular structures, candidacy for resection, and the projected surgical defect.
    b. Such studies can also provide clues to the availability of intranasal vascularized flaps that may not be obvious on sinonasal endoscopy.

2. Imaging studies for staging should be sought in patients with malignant tumors to ensure appropriate treatment goals and treatment planning.

Indications

1. In open transcranial anterior skull base surgery, the PCF remains the most frequently used flap with its passage inferior to the supraorbital bone segment into the surgical defect with suturing and/or apposition to the resection margin.

2. Endoscopic anterior skull base surgery

- Vascularized reconstruction produces lower rates of postoperative CSF leaks compared with free grafts in the presence of large dural defects.[2] It is preferable in repair of defects localized to the clivus and in patients with high-flow intraoperative CSF leaks.[3]
- The PCF is the primary extranasal vascularized pedicle flap used at our institution when intranasal options are not available in the presence of large dural defects and/or high-flow CSF leaks localized to the anterior fossa/ethmoid roof and sella.[4]
- Using radiological studies, the distance of the defect, locations, and size estimates of the PCF needed to fill defects were performed. Using a 3-cm correction factor accounting for flap transposition through the nasionectomy and retraction, the following flap length estimates were needed to reach the following defects: 11.31 to 12.44 cm for anterior fossa defects, 14.31 to 15.57 cm for sellar defects, and 18.3 to 20.42 for clival defects.[5]

Contraindications

1. Prior compromise of the vascular supply.

2. Prior flap usage without a contralateral option or flap transgression.

3. Defects localized to the posterior fossa/clivus; the defect generally lies at the distal-most aspect of an extended flap with the possibility of poor or inadequate coverage of the defect.

Preoperative Preparation

Prior incisions of the face/scalp should be evaluated to determine whether the blood supply (supratrochlear, supraorbital vessels) to the PCF is intact. Alternative flaps or materials should also be considered in reconstructing the skull base in the event of injury to the PCF's blood supply during harvest. The size of the expected defect/s will determine the length and design of the PCF.

Operative Period

Anesthesia

General anesthesia is used, given the need for skull base dissection and/or reconstruction. Paralysis may or may not be used and is dictated by the need for neurophysiological monitoring during the resection portion of the operation.

Positioning

At the discretion of the surgeon, the patient may be placed in a supine position or in a modified "beach chair" position, with the head of the bed elevated and feet lowered. Occasionally, a mild degree of reverse Trendelenburg can also be used to optimize positioning and assist in visualization.[6] Mayfield pin immobilization may be used for open or combined approaches. For endoscopic procedures, pin immobilization is not required, and the head should be turned slightly toward the operating surgeon.

Perioperative Antibiotic Prophylaxis

1. Ceftriaxone, a third-general cephalosporin with good CSF penetrance, is used in patients without a documented allergy to penicillin.

2. Clindamycin is used in patients with a documented allergy to penicillin.

Monitoring

Intraoperative monitoring other than that for general anesthesia is generally not indicated in the harvest and inset of the PCF.

Instruments and Equipment to Have Available

1. Open/Combined
   a. Rainey clips with appropriate clip appliers.
   b. Transcranial instruments including a pneumatic drill with burs.
   c. High-speed drill with 3- and 4-mm course diamond burs.
   d. Microdissection instruments.
   e. Monopolar and bipolar cautery, hemostatic agents, and an array of pledgets.
   f. Commercially available dural substitutes for grafting.
2. Endoscopic
   a. Basic endoscopic sinus surgery set.
   b. High-speed drill with 3- and 4-mm course diamond burs.
   c. Endoscopic monopolar and bipolar cautery, endoscopic clip appliers with an array of hemostatic clips, hemostatic agents, and an array of pledgets.
   d. Commercially available dural substitutes for grafting needs.
   e. Absorbable and nonabsorbable packing materials.
3. Image guidance
   a. Line-of-sight image guidance is often favored in open procedures or those using pin immobilization.
   b. Electromagnetic image guidance may also be used when pin immobilization is not used. The choice between line-of-sight and electromagnetic image guidance is that of the operating surgeon, because both modalities provide comparable information.

Key Anatomic Landmarks

1. Thorough knowledge of the anatomy of the scalp is required to successfully elevate the PCF. The pericranium is the calvarial periosteum extending about the cranial convexity in the midline with the lateral boundaries delineated by the superior-most aspect of the temporalis muscles and their overlying fascia. Immediately superficial to the pericranium lies loose areolar tissue followed by the galea. At the discretion of the reconstructive surgeon, both of these layers can be incorporated into the flap to provide a thicker flap depending upon the reconstructive needs.

2. The supraorbital and supratrochlear arteries provide axial vascular supply to the flap. A unipedicled or bipedicled PCF flap can be designed based on the plan for reconstruction. We favor an unipedicled design for endoscopic-assisted PCF, because this leaves the contralateral flap for a later date if necessary. The position of the vascular supply can be identified using a Doppler probe or the supraorbital notch can be palpated and a flap pedicle width of 3 cm (1.5 cm on either side of the notch) can be designed.

3. The nasion is the most depressed portion of the nose on profile view and is generally at the intersection of the frontal process of the nasal bones and nasal process of the frontal bones. A surgical window created at this site, termed a nasionectomy, affords intranasal access just anterior to the anterior aspect of the frontal sinus outflow tract.

Prerequisite Skills

Head and neck oncologic and skull base training. Endoscopic skull base training is highly recommended due to the specific requirements of this procedure.

Operative Risks

1. Neurovascular structures

   a. A detailed understanding of the anatomy of the scalp and skull base, including the relative locations of neurovascular structures, is critical

in the harvest and inset of the PCF. The prime neurovascular structures at risk are the supraorbital and supratrochlear vessels and the supraorbital nerve. With a thorough understanding of the trajectory of these structures, they may be successfully avoided and the sensory and motor functions of the scalp can be preserved.

2. Coronal approach versus endoscopic-assisted

   a. Depending on the harvest technique employed by the surgeon (standard open coronal incision versus minimally invasive endoscopic-assisted approach), there are distinct operative risks due to the length and location of the incision, the need for a craniotomy, and the effect on the frontal sinus outflow tract. Historically, the standard approach for the harvest of a PCF involved a coronal incision.[7] However, operative risks in this approach are higher with increased morbidity and involvement of other neurovascular structures including the superficial temporal artery and frontal and temporal branches of the facial nerve.[7]

      The standard open harvest of the PCF is largely reserved for combined or large open craniofacial resections. The minimally invasive endoscopic-assisted approach has become the primary approach that we employ at our institution in the harvest of the PCF, which will be discussed in detail later.[6,8]

Surgical Technique

1. Coronal approach

   a. A standard coronal incision is made beginning in the preauricular region and traversing to the contralateral preauricular region. Once the incision is made, the plane between the subgaleal fascia and overlying galea is identified and the coronal flap is elevated anteriorly in this plane. Given the lateral extensions of the incision, the frontal branches of the facial nerve are identified and are elevated with the galea.[7]

   b. Next, the PCF is elevated off of the calvarium and brought anteriorly toward the supraorbital rims, taking care not to disrupt the supraorbital or supratrochlear vessels. If needed for tumor extirpation, a bifrontal craniotomy with removal of segments of the

supraorbital rim is performed that allows for easy rotation and inset of the PCF, after which supraorbital bone is replaced superiorly over the flap for complete reconstruction.[7]

2. Endoscopic-assisted approach

   a. Once the tumor extirpation or other pathology has been addressed, attention is turned to the reconstruction portion of the procedure. Depending on the level of dural involvement and dissection, some form of synthetic dural substitute is often used for initial dural repair and placed in an underlay fashion to cover the defect.

   b. The scalp incision is planned as an ipsilateral hemicoronal incision, which is placed in a trichophytic fashion at the hairline near the midline and continued to the temporal hair tuft in standard hemicoronal fashion. The true skin incision is generally only approximately 3 to 4 cm in length and is often limited to the most superior aspect of the hemicoronal incision, but may be lengthened in either direction as necessary for flap exposure. Prior to the incision, a Doppler ultrasound probe can be used to identify the supraorbital and supratrochlear vessels, at which point a 3-cm-wide flap pedicle is outlined with the pedicle marked in the midline at the supraorbital rim.

   c. Following the incision, the dissection is carried out posteriorly in the subgaleal plane and then carried anteriorly to the orbital rims (Fig. 166.1). Subgaleal dissection may be aided with the use of 0- and 45-degree rigid endoscopes, which provide high-definition and magnified images of the dissection. Once an adequate posterior length is achieved, often approximately 15 cm posterior from the brow, a horizontal incision is made down to the pericranium at the posterior aspect of the flap with the use of extended needle tip cautery under direct endoscopic visualization.[6,8] Next, bilateral vertical incisions are made at the edge of the flap and carried forward from posterior to anterior, tapering toward the pedicle and ensuring both adequate flap and pedicle width (see Fig. 166.1). The PCF is then meticulously elevated from the cranium and mobilized to the superior orbital rim under direct endoscopic visualization (Fig. 166.2).

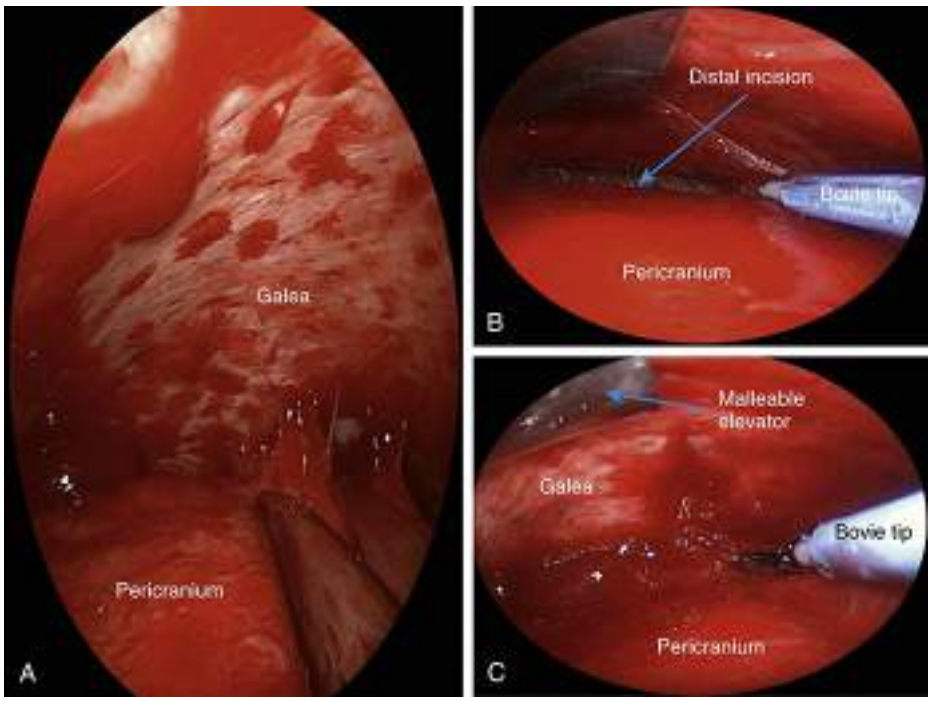

FIG. 166.1 **A,** Progressive elevation of the scalp within the subgaleal plane allowing for the isolation of the underlying pericranium. **B and C,** Following isolation of the pericranium, monopolar cautery is used to perform circumferential incisions about the pericranium with care taken to preserve a 3-cm-wide pedicle at the proximal aspect of the flap in the region of the superior orbital rim (arrow).

d. Attention is then turned to the glabella, where an approximately 1-cm, horizontal skin incision is made in a natural skin crease and carried down to the periosteum at the level of the nasion. The subperiosteal plane at the level of the nasion is then dissected superiorly until it communicates with the subperiosteal plane of the PCF over the frontal bone.[8] Subsequently, a 3-mm coarse diamond burr is used to drill a 4 mm × 1.5 cm through-and-thorough bony defect, or ostectomy, at the level of the nasion (Fig. 166.3). Direct visualization of the ostectomy using the endoscope allows for safe drilling and minimizes potential injury to surrounding structures.

e. The PCF is then transposed in the subperiosteal plane into the region of the glabellar incision under endoscopic visualization to prevent torsion of the flap pedicle. Next, the PCF is passed and rotated through the nasionectomy and into the sinonasal cavity under direct

visualization.[8]

f. In the sinonasal cavity, the PCF is extended to cover the skull base defect including the inlay graft, dural edges, and surrounding bony edges, where it acts as an extradural onlay.[8] During this interval, the flap is placed in a redundant position anteriorly to ensure that any potential space in this region is obliterated (Fig. 166.4). The edges of the flap are generally bolstered with a bioresorbable nasal dressing that assists in minimizing the formation of adhesions and provides mechanical compression. A layer of an absorbable hemostatic agent is then applied, followed by intranasal, expandable packing sponges, which help to support the reconstruction. Lastly, a 7-mm suction drain is placed under the scalp. The scalp and nasion incisions are then closed primarily in a multilayered fashion.

Common Errors in Technique

1. Flap length

   a. A common error in PCF reconstruction is underestimating the necessary length of the flap. According to Patel et al.,[5] who studied clinical outcomes and preoperative radiographic analysis in PCF reconstruction, preoperative analysis of CT scans can anticipate the necessary length of a PCF for an expected skull base defect. Additionally, it is important to be aware that some length will be lost with rotation and contracture of the flap. In an effort to overcome this, it was found that adding an additional 3 cm to the calculated length of the flap based on preoperative CT scans provided adequate length for closure.[5]

2. Flap inset

   a. Another critical element in the inset of the PCF is the location of the flap pedicle as it traverses the frontal sinus through the nasionectomy. Because there is potential risk for obstruction of the frontal sinus outflow tract, a large confluent frontal sinusotomy (Draf III) is performed and the flap is positioned to traverse this sinusotomy in the midline.[5] By doing so, the outflow tracts of the frontal sinus are maintained on each side of the pedicle, which minimizes the risk of mucocele formation.[5,9]

3. Sinonasal packing

a. Flap failure secondary to its migration from the reconstruction site can sometimes be linked to inadequate sinonasal packing or removing the packing too early. It has been demonstrated that nasal packing left in place for 5 to 7 days postoperatively provides support for the repair and maximizes apposition of the flap to native nasal and skull base tissue.[1,5,8,9] With maximum apposition, rapid mucosalization of the tissue is facilitated in addition to minimizing the risk of a CSF leak postoperatively.

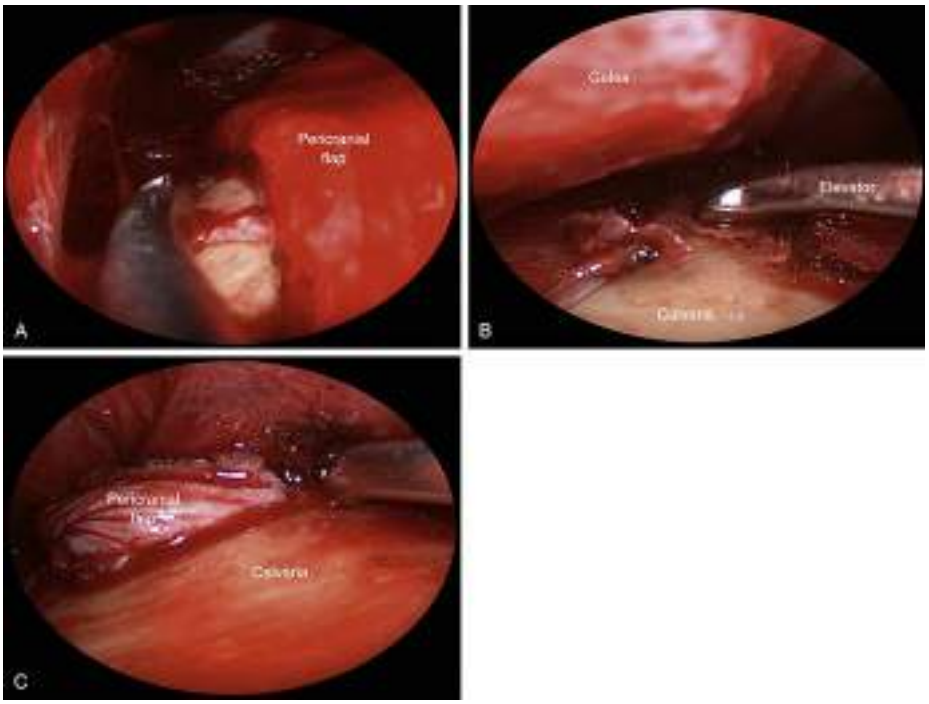

FIG. 166.2 **A and B,** Following circumferential incisions, a periosteal elevator is used to elevate the flap circumferentially. This is usually carried from the vertex/distal aspect of the flap toward the superior orbital rim. **C,** Care is taken to maintain the width of the pedicle while ensuring adequate elevation, thereby providing the appropriate degree of flexibility to allow the introduction of the flap into the nose.

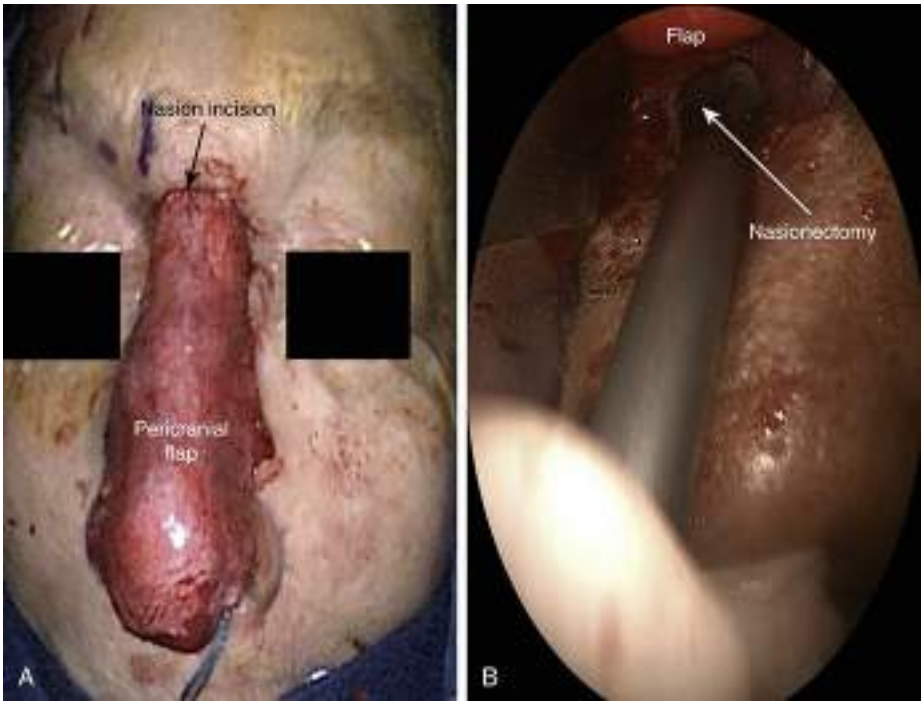

FIG. 166.3 **A,** After subperiosteal elevation, the flap is transposed through the incision in the nasion and temporarily reflected onto the nose. **B,** With the flap reflected inferiorly, a nasionectomy is performed with a high-speed drill via the nasion incision allowing access to the nasal cavity.

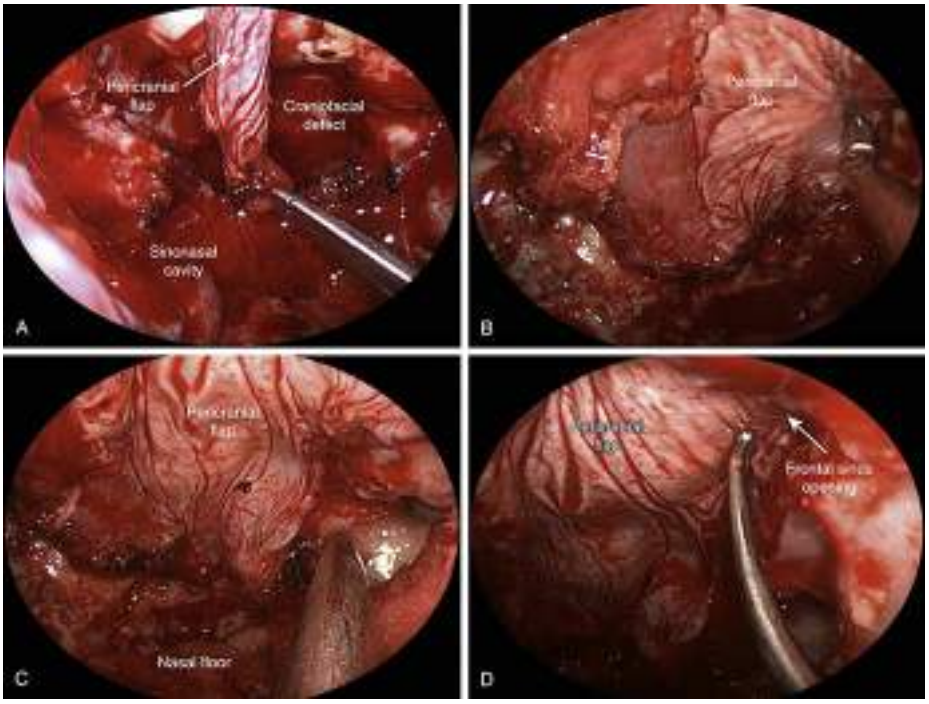

FIG. 166.4 **A,** Following nasionectomy, the flap is introduced through this bone window from an extranasal position to an intranasal position (arrow). **B and C,** The flap is then fully extended allowing complete coverage of the defect. **D,** Care is taken to ensure that the flap is placed into the confluent frontal sinus opening to ensure obliteration of any potential space in this region as the flap is spread across this portion of the skull base (arrow).

Postoperative Period

Postoperative Management

1. Given the intra- and extracranial components of the operative procedure, it is often recommended that patients undergoing PCF reconstruction be monitored in an intensive care unit (ICU), preferably a neurosurgical ICU.

2. In selected patients, including those with elevated intracranial pressure, morbid obesity, and/or those in whom significant dural defects with resulting high-flow CSF leaks are anticipated, consideration of

preoperative placement of a lumbar drain is undertaken. It should be noted that the use of lumbar drains for CSF diversion is becoming less common and is often restricted to specific patient populations and/or surgical sites.

3. Nonabsorbable sinonasal packing is generally left in place for 5 to 7 days postoperatively, after which time it is removed. Absorbable packing material is usually left in position and allowed to be slowly washed away with postoperative sinonasal irrigations.

4. The patient is usually kept on antibiotics with coverage for staphylococcus while nonabsorbable packing material is in place. The antibiotics are often continued until the first postoperative outpatient visit.

5. In the postoperative period, the patient is kept on strict CSF leak precautions, which include: no nose blowing, no use of straws, no heavy straining, no use of continuous positive airway pressure (CPAP) machines, and keeping the head of the bed elevated at least 30 degrees.

6. Close postoperative follow-up is recommended for wound inspections, sinonasal debridement as indicated, and monitoring of the PCF via sinonasal endoscopy.

7. No smoking.

Complications

1. CSF leak

   a. The predominant postoperative complication with the use of the PCF for skull base reconstruction is CSF leak. Importantly, the most common cause of CSF leak following vascularized skull base reconstruction repair is due to flap defect or displacement, and rarely flap death.[1,2,9] The diagnosis of a CSF leak after skull base repair should be primarily clinical with the main signs being clear rhinorrhea, increasing headache, and possibly meningitis. Beta-2 transferrin is specific for CSF and can be tested for in the rhinorrhea fluid; however, we usually make the diagnosis of a postoperative CSF leak by clinical examinations. If a leak is suspected, a fine-cut head CT is obtained to evaluate for pneumocephalus and allows for

revision surgical planning if needed. The management of a postoperative CSF leak depends on the quality of leakage. A low-flow CSF leak can be managed with conservative therapy with bed rest, stool softeners, and lumbar drainage. IV antibiotics with CSF penetration are continued if a leak is suspected. If the leak is a high-flow CSF leak, then revision surgery with bolstering of the defect with additional material (adipose tissue, dermal adipose tissue, acellular dermis, or collagen matrix) is needed. The bolstering can be done with an endoscopic endonasal approach from below or through revision craniotomy if necessary. Prevention of a CSF leak is mostly dependent on proper placement and bolstering of the vascular flap at the time of primary surgery.

2. Other major perioperative and postoperative complications

a. Intracranial infection

b. Pneumocephalus

Intracranial infection and pneumocephalus are additional complications that are concomitant with a CSF leak. These usually present in the early postoperative period (less than 3 weeks). Management is similar to CSF leak listed above. Pneumocephalus also requires 100% rebreather O_2 and elevation of the head of the bed, especially if any tension component is noted. At times, revision craniotomy is required for tension pneumocephalus or intracranial infections. Airway diversion with a tracheostomy may be required for persistent pneumocephalus in rare cases.

c. Mucocele formation and prolonged skull base crusting

Both mucocele formation and prolonged crusting are due to disruption of the normal sinonasal mucosa. Radiation also has an impact on the risks of these complications. These are late complications usually occurring 6 months to 20 years after the primary surgery. The diagnosis of prolonged crusting is usually due to quality-of-life complaints from the patient and crusting noted on endoscopy. Treatment of crusting is through serial debridement, good nasal hygiene, and culture-directed antibiotics if an infection is noted. Mucoceles are usually incidentally found on serial imaging and are usually asymptomatic. Rarely, they can present with pain or infection. Treatment is usually endoscopic

drainage.

d. Donor site complications such as hematoma, superficial wound infections and scar hypertrophy are rare.

Alternative Management Plan

1. In situations that preclude the use of the PCF for reconstruction of skull base defects, other choices for vascularized skull base reconstruction include the NSF, tunneled temporoparietal fascial flap, palatal flap, and rarely, microvascular free flaps.[4,5]

2. Skull base defects may also be repaired with free-tissue grafts including mucoperichondrium, mucoperiosteum, and/or fascia. Noncellular grafting materials such as Alloderm may also be used for repair.[10]

Discussion

Evidence-Based Medicine Question

Is the endoscopic-assisted PCF an option comparable to other vascularized flaps used in skull base reconstructions?

In the modern era of endoscopic endonasal skull base surgery, vascularized, reconstructive techniques have become a mainstay in the repair of large skull base defects.[2] Although the NSF remains the primary choice for vascularized skull base reconstruction, clinical and operative situations exist in which the viability of the NSF may be compromised or the defect may require a repair with a larger vascularized flap. Should the need arise, the endoscopic-assisted PCF serves as an excellent option in the repair of skull base defects.[2,5,8]

The PCF is very useful in reconstructing defects extending from the anterior skull base to the sella turcica. Minimal donor site morbidity considering the inherent size variability, lengthy flap pedicle, and reliable vascular supply provided multiple advantages to the reconstructive surgeon. Clinical outcomes in which the PCF was used for reconstruction of the skull base have revealed comparable outcomes to

other types of vascularized skull base reconstruction.[9] In summary, the endoscopic-assisted PCF is a versatile option for the repair of a wide range of skull base defects.

Editorial Comment

Although the PCF is the most frequently used flap in the reconstruction of skull base defects, it is also used to reconstruct local defects in the head and face including the scalp and nose/nasal lining. It can be designed as a unilateral, bilateral, laterally based, or anteriorly based flap. It is easy to harvest, safe, and cost-effective.

Review Questions

1. What is the vascular supply for the pericranial flap?

   a. Superficial temporal artery

   b. Supraorbital artery

   c. Supratrochlear artery

   d. **b and c**

2. What is the average length of the pericranial flap needed for repair of a sellar defect?

   a. 10 cm

   b. 12 cm

   c. **15 cm**

   d. 20 cm

3. What is the average width of the pericranial flap pedicle?

   a. 2 cm

   b. 2.5 cm

   c. 3 cm

d. **3.5 cm**

Temporoparietal Fascial Flap

Peter D. Costantino, Margherita Bruni, and Amir R. Dehdashti

Introduction

In general, the temporoparietal fascia is a poorly recognized, but highly useful, layer of tissue that invests the lateral scalp overlying and extending beyond the surface area of the underlying temporalis muscle. Skill in recognizing and elevating the temporoparietal fascia is important in both skull base exposures such as the infratemporal fossa approach and in reconstructive procedures that use the temporoparietal fascia as a pedicled flap based upon the superficial temporal artery and vein. Its successful preservation helps to ensure the continuity of the frontal branches of the facial nerve, and its elevation as a pedicled flap is valuable in the reconstruction of a wide array of defects. With a rich vascular supply, large area, thinness, pliability, and mobility, it allows for reconstruction of soft tissue, orbital, anterior or middle cranial fossa, nasopharyngeal, oropharyngeal, oral, maxillary, and palatal defects with ease.[1] The ability to accept a skin graft makes it an excellent choice for facial, auricular, scalp, or orbital defects.[2] In the oral cavity or pharynx, rapid mucosalization of the graft eliminates the need for further grafting over it. As a hardy graft it has utility in buttressing cranial defects with cerebrospinal fluid (CSF) leaks, permitting watertight exclusion of the intracranial contents from the upper aerodigestive tract. Bilateral flaps that remain connected across the sagittal suture may be harvested to reconstruct larger midline defects, that is, a "visor" flap. We have found temporoparietal fascial (TPF) flaps to be particularly useful in the management of palate defects, obviating the need for an obturator or free flap reconstruction in some cases. In pituitary or extended pituitary approaches, a flap can be tunneled through the maxillary sinus into the sphenoid sinus and draped along the dural defect. This permits vascularized closure in situations where a nasoseptal flap is unavailable

or inadequate for closure.[3]

Key Operative Learning Points

- The TPF flap is a robust vascularized tissue flap with myriad utility used in cranial base, facial, oral and pharyngeal reconstruction.
- The pedicle must be meticulously protected during the tedious dissection.

Preoperative Period

History

- A thorough history is important to identify inappropriate candidates for this flap. Examples include patients who have had embolization or ligation of the external carotid artery and those in which previous surgery or trauma has transected the flap or its vascular supply.
- Previous parotidectomy is not necessarily a contraindication unless the superficial temporal vessels were sacrificed.

Physical Examination

- Thorough examination of the head and neck should be completed to gauge the extent of the tumor and anticipate the size of the defect.
- Examine the neck and scalp for evidence of previous surgery that could have compromised blood supply to the flap.
- The superficial temporal artery is generally 2 mm at the pretragal region and can be identified by Doppler to confirm adequate blood supply prior to deciding upon its use.

Imaging

- Careful preoperative review of computed tomography (CT) and magnetic resonance (MR) imaging is necessary to ensure that

vasculature to the flap will not be compromised during the resection of the tumor.

Indications

- The TPF flap's area, thinness, pliability, and mobility make it a good choice for reconstruction of soft tissue, orbital, anterior or middle cranial fossa, nasopharyngeal, oropharyngeal, oral, maxillary, and palatal defects.

Contraindications

- The flap cannot be used if there has been previous disruption to its blood supply or when anticipated resection would disrupt the blood supply.
- Previous radiation therapy is a relative contraindication as it may result in poor wound healing and increased risk of flap necrosis.

Preoperative Preparation

- Patients should be counseled that there is a hemi-coronal incision with increased risk of alopecia along the donor area.
- A particular advantage to this flap is that there is no significant donor site defect since the flap is so thin.

Operative Period

Anesthesia

- General

Positioning

- Supine
- Turn the bed 180 degrees.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin
- If penicillin (PCN) allergic, give clindamycin

Monitoring

- No nerve monitoring is necessary.

Instruments and Equipment to Have Available

- Basic head and neck surgery set
- Double-hook retractors
- Bipolar cautery
- Hemostatic slurries or Gelfoam

Key Anatomic Landmarks

- Moving from superficial to deep, the layers of the scalp consist of skin, subcutaneous adipose tissue, the superficial temporoparietal fascia, loose areolar tissue, the temporalis fascia of the temporalis muscle, temporalis muscle itself, the pericranium, and then the calvarium.
- The temporoparietal fascia consists of a 2- to 4-mm thick layer of connective tissue that is continuous with the galea aponeurotica superiorly and the superficial musculoaponeurotic system (SMAS) inferiorly. Between the temporoparietal fascia and the deep temporalis fascia is a loose areolar tissue layer that permits the scalp to glide over the fixed temporalis fascia of the temporalis muscle. This avascular areolar layer facilitates dissection between these two fascial layers, that is, the temporoparietal fascia superficially and the more deeply located temporalis muscle fascia.
- The temporoparietal fascia is supplied by the superficial temporal artery, a terminal branch of the external carotid artery. The superficial

temporal artery originates from the external carotid system and becomes superficial immediately behind the posterior limit of the parotid gland at the level of the tragus. It proceeds cephalad along this course, over the root of the zygoma, and into the tissues of the scalp within the temporoparietal fascia.

- The vessels typically divide into frontal and parietal branches approximately 3 cm above the zygomatic arch, with the frontal vessels arborizing with branches of the vessels that feed the frontal pericranium; that is, the temporoparietal fascia is contiguous with the same pericranium that is employed to create a pericranial flap. Hence, the temporoparietal blood supply anastomoses with the supraorbital and supratrochlear vessels in a rich axial pattern. Concurrently, the superficial temporal vessels also anastomose with the occipital vascular system posteriorly. The system is drained by typically paired veins that run superficial to the artery.
- From a surgical standpoint, it is important to recognize that the frontotemporal branches of the facial nerve run within the superficial temporalis fascia. Their course can be approximated by using the line of Pitanguy, described as a line drawn from 0.5 cm inferior to the tragus to a point 1.5 cm lateral to the brow. The branches control forehead mobility on that side; injury to these nerves results in inability to raise the ipsilateral brow or blepharoptosis.[4]

Prerequisite Skills

- Knowledge of head and neck anatomy, particularly the scalp
- Proficient in soft tissue techniques
- Head and neck or reconstructive fellowship

Operative Risks

- Injury to the vascular pedicle during harvest
- Flap necrosis if the pedicle is kinked during rotation
- Injury to the frontal branch of the facial nerve

- Secondary alopecia

Surgical Technique

- An incision is designed within the preauricular crease extending superiorly to create a hemi-coronal incision. The hair is not shaved but rather parted and braided with rubber bands to expose the incision site.
- A #15 blade is used to make the scalp incision at the midpoint of the temporal fossa, and this is carried down through the dermis and subcutaneous adipose tissue of the scalp, but not any deeper. The temporoparietal fascia is located immediately below the subcutaneous adipose tissue of the scalp, as are the superficial temporal vessels. Carrying the incision deeper than the subcutaneous scalp adipose tissue runs the risk of damaging the temporoparietal fascia and, more importantly, the superficial temporal vessels, thereby rendering the flap useless.
- Care must be taken in identifying the temporoparietal fascia as it can be densely adherent to the subcutaneous tissues of the scalp. In this regard, dissection of the superficial surface of the temporoparietal fascia is facilitated by staying immediately deep to the hair follicles while applying traction to the hair-bearing scalp with a double-hook retractor.
- Sharp dissection with tenotomy scissors is carried both anteriorly and posteriorly allowing a large flap to be exposed as defined by the reconstructive requirements of the defect.
- The superficial temporal system also supplies a rich subdermal plexus to the overlying scalp. As the hair-bearing scalp and subcutaneous adipose tissue are lifted off of the superficial surface of the temporoparietal tissues, these feeding vessels are transected, and bleeding should be controlled with bipolar cautery. Monopolar cautery can damage the underlying superficial temporal vessels or the flap itself and can contribute to postoperative alopecia of the overlying scalp.
- This dissection can be tedious but should be carried out meticulously so as to not disrupt the superficial temporal vessels. These vessels often

can be seen within the superficial temporal fascia and should be protected.

- Limiting the dissection anteriorly at the temporal hairline protects the branches of the facial nerve; however, if the nerve is identified and carefully protected, further dissection can proceed. The flap can be extended to include galea superiorly and posteriorly if necessary (Fig. 167.1).
- Once the scalp flap has been elevated adequately, the superficial temporalis fascia is sharply incised and then dissected from the underlying deep temporal fascia. Between these is a layer of loose areolar fascia that is avascular and makes for an easy sharp or even blunt dissection. As the fascia is elevated inferiorly, care is taken to not disrupt the superficial temporal vessels, which should be kept under direct vision to reduce the possibility of injury.
- The flap is then rotated into position. Usually removing the zygomatic arch is not necessary with this thin flap, but it may increase length and decrease vascular congestion of the flap. Due to its rich blood supply the flap readily accepts a skin graft.
- When the flap is intended for repair of the anterior or middle cranial fossa, it is typically tunneled over the zygoma and through the maxillary sinus, which is opened to permit access. The flap then emerges through a large maxillary antrostomy into the nasal cavity and can be draped into position (Figs. 167.2 and 167.3).
- When used for palate repair, the flap is similarly tunneled through the maxillary sinus, then inferiorly to the palate defect. It is tacked into position transorally with absorbable sutures and allowed to mucosalize as it heals.

Common Errors in Technique

- Failure to identify the correct plane of dissection
- Disrupting the blood flow to the flap during dissection
- Not taking care to meticulously avoid hair follicles during dissection, which increases risk of alopecia

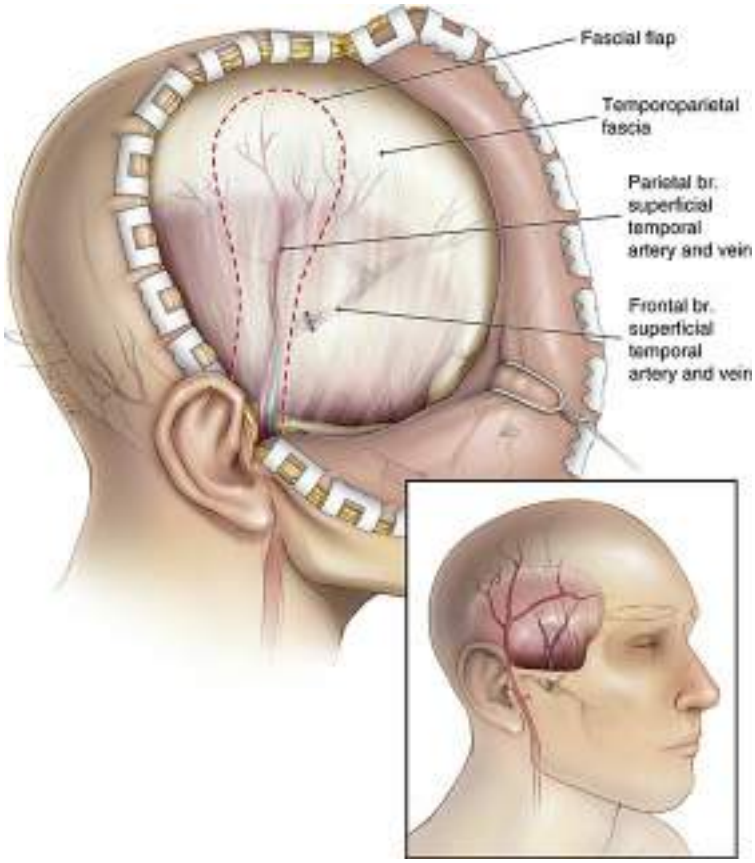

FIG. 167.1 The temporalis fascia is exposed, and the planned fascial flap with associated parietal branch of the superficial temporal artery is outlined with the dotted line. Note the frontal branches of the superficial temporal artery and vein have been clipped.

Postoperative Period

Postoperative Management

- Intraoperative steroids should be given and continued as a taper for several days after to prevent edema and venous congestion of the flap.
- Harvesting of a large TPF flap can compromise the scalp and lead to breakdown of the incision; therefore pressure dressings should not be placed postoperatively.
- A suction drain can be placed and removed when output is minimal.
- Routine postoperative antibiotics are used.

Complications

- The scalp receives its blood supply from the superficial temporal system, and necrosis of the flap or breakdown of the incision can be an issue, especially when harvesting large flaps. To reduce this risk, local anesthetic with vasoconstrictive agents is not injected, Raney hemostatic clips are not used, and pressure dressings are avoided.
- Alopecia can develop, although these areas can be excised in the future if desired.
- Donor site morbidity increases in the setting of previous radiation, and these patients should be counseled regarding these risks preoperatively.
- Injury to the frontal branches of the facial nerve is a potential risk, which can be avoided by not taking the flap anterior to the temporal hairline.
- Necrosis of the flap is a risk, in the event the pedicle is compromised during dissection or kinked during rotation. Because of the thin nature of this flap, there is no donor defect on the side of harvest.
- Alternatives to this flap include a pericranial flap or free tissue transfer.

Discussion

Evidence-Based Question

In a literature review detailing major TPF flap uses as a tool in head and neck reconstruction, what were the distinct application categories that were defined?[1]

Answer: The TPF flap was found to be versatile and demonstrated utility in orbital reconstruction, auricular reconstruction, combined skin/tissue transfer, facial reconstruction, skin and mucosal defect repair, pharyngeal reconstruction after salvage laryngectomy, and skull base reconstruction including CSF repair.

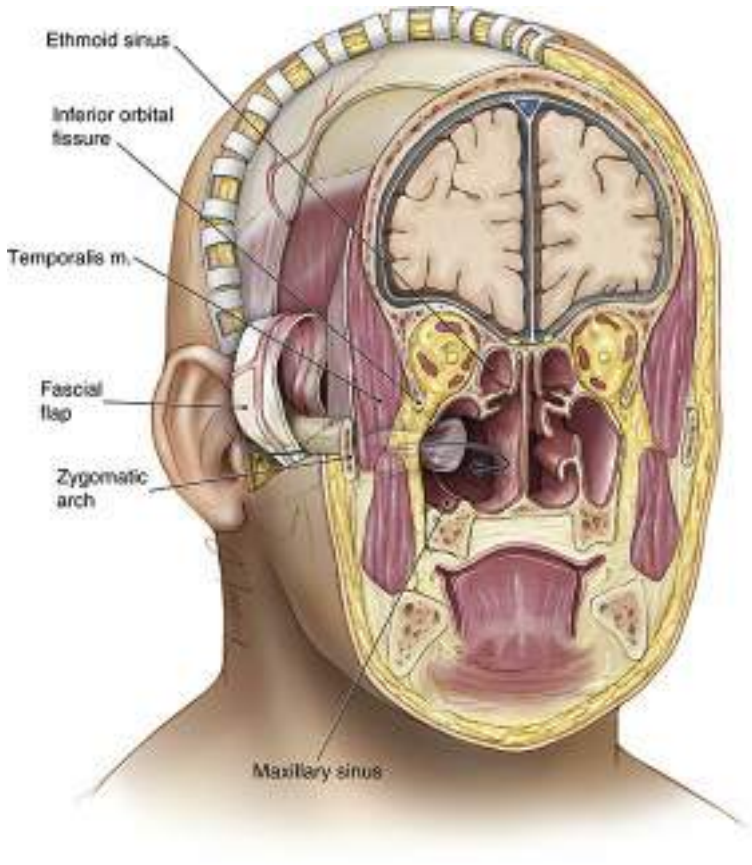

FIG. 167.2 The flap has been raised and is then tunneled anterior to the zygomatic arch and through the maxillary sinus in order to reach the sphenoidotomy.

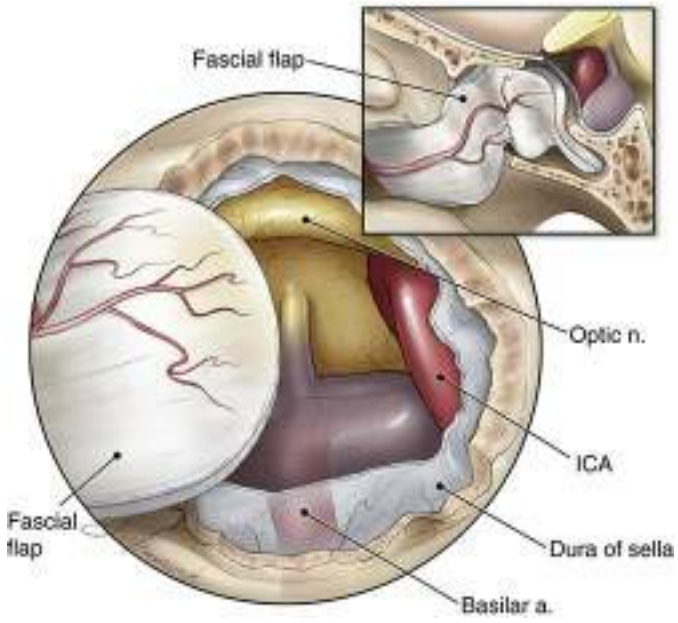

FIG. 167.3 The flap is brought into the sphenoid and used to repair the dural defect of the sella. *ICA*, Internal carotid artery.

Editorial Comment

The TPF flap is a very versatile flap. It can be harvested as a pedicled flap, free flap, or composite flap with hair-bearing skin or parietal bone. Care must be taken during resection of the cancer in this area so as not to injure the superficial temporal vessels for immediate or future use.

Temporalis Muscle Transposition

Peter D. Costantino, Margherita Bruni, and Amir R. Dehdashti

Introduction

The pedicled temporalis muscle flap is a very versatile, local, axial flap with many uses in craniofacial reconstruction (e.g., orbital cavity augmentation following exenteration, coverage of a temporal/subtemporal calvarial defect, maxillectomy augmentation, hemipalatectomy reconstruction, and mastoid/temporal defect reconstruction). As a moderately bulky flap with a good range of rotation, it allows for the reliable reconstruction of a variety of sites. In particular, it is the only local flap adequate in bulk and surface area for reconstruction following maxillectomy or unilateral palatomaxillectomy. It can be used to reconstruct the cranial base or to cover mesh or plates used to repair at the cranial base, temporal bone, or orbital rim. The flap has a sufficiently robust blood supply that it can be split into anterior and posterior paddles by bisecting the muscle along its fibers from its origin to the level of the zygomatic insertion. In this way, the muscle can actually be used as two separate flaps, connected to a common blood supply from the deep temporal artery. Bilateral flaps can be harvested to permit larger reconstructions that cross the midline.

Key Operative Learning Points

- Vascularized flaps are the reconstruction modality of choice. Compared with free flaps, pedicled local flaps require less time, involve less morbidity of the donor site, and do not require microvascular expertise.
- Preoperative embolization or intraoperative oncologic resection can disrupt the blood supply to this flap and render it nonviable.

- Injury to the frontotemporal branch of the facial nerve is avoided by careful dissection at the level of the adipose tissue pad, taking care to leave the superficial layer of the deep temporalis fascia up with the skin flap.
- A superficial temporalis fascia flap may be raised along with the muscle for extended defects; if this is done, care should be taken to preserve the separate blood supply to the temporoparietal fascial flap.

Preoperative Period

History

- Proper patient selection is imperative in deciding to use this flap. Although it is robust and applicable to many regional defects, this flap should not be used in cases where its internal maxillary or deep temporal blood supply has been compromised.
- A thorough history will often reveal patients who may not be appropriate candidates for the use of this flap. Examples include patients who have had embolization of the ipsilateral internal maxillary artery, those who have had extensive dissection along the medial surface of the muscle, cases where excision of the muscle was required, or those where the external carotid artery had to be sacrificed.

Physical Examination

- Thorough examination of the head and neck to gauge extent of tumor and size of anticipated defect
- Examine the neck and scalp for evidence of previous surgery that could compromise the blood supply to the flap.
- Examine the temporal region to evaluate the bulk of temporalis muscle.

Imaging

- Careful preoperative review of computed tomography (CT) and

magnetic resonance imaging (MRI) is necessary to make sure that the vasculature to the flap will not be compromised during tumor resection.

- Special care must be taken with patients who have malignancies of the maxillary sinus, where the tumor may have penetrated the posterior confines of the maxillary sinus cavity. Tumor contamination of the infratemporal fossa in such cases can result in compromise of the deep temporal artery, precluding the use of this muscle as the reconstructive flap. This situation must be recognized preoperatively, as there are no local "backup" flaps for palatomaxillary repair when the deep temporal is resected and the temporal artery is not usable; that is, a free tissue transfer is the only other reconstructive option in such situations.

Indications

- For craniofacial reconstruction—that is, augmentation of the orbital cavity following exenteration, coverage of a temporal/subtemporal calvarial defect, maxillectomy augmentation, hemipalatectomy reconstruction, and reconstruction of a mastoid/temporal defect
- Secondary to its bulk and surface areas, this flap has particular utility for reconstruction following maxillectomy or unilateral palatomaxillectomy.
- It may be used to reconstruct the cranial base or to cover mesh or plates used for repair at the cranial base, temporal bone, or orbital rim.

Contraindications

- The temporalis muscle flap cannot be used if there has been previous disruption of its blood supply (e.g., preoperative embolization) or when anticipated resection would disrupt the blood supply.
- It should not be used if the patient is unwilling to accept a temporary cosmetic deformity due to repositioning of the muscle and subsequent temporal hollowing (patients are counseled that this defect can be repaired at a later stage).

Preoperative Preparation

- Patients should be counseled that the harvesting of this flap will result in a potentially significant concave deformity over the temporal fossa. This deformity can be augmented in a secondary procedure whereby adipose tissue, hydroxyapatite cement, or silicone/polymeric implants are used to fill this potentially substantial deformity. Following augmentation, the aesthetic results are usually excellent.

Operative Period

Anesthesia

- General

Positioning

- Supine

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin
- If the patient is allergic to penicillin, clindamycin can be used.

Monitoring

- No neurologic monitoring is necessary.

Instruments and Equipment to Have Available

1. Basic head and neck surgery set
2. Bipolar cautery for control of bleeding
3. Raney hemostatic clips for control of scalp bleeding

4. Hemostatic slurries or Gelfoam for control of venous oozing

5. Sagittal saw and midface plating set

Key Anatomic Landmarks

- The temporalis muscle is a fan-shaped structure lying within the temporal fossa of the skull; it originates from the lateral surface of the calvarium anterior to the coronal suture and inserts onto the coronoid process of the mandible. During its course from origin to insertion it passes underneath the zygomatic process, becoming infratemporal where it meets the mandible. The temporalis muscle is 12 to 16 cm long; its thickness varies from 0.5 to 1 cm. It becomes functionally much thicker following elevation (~2.0 cm), and the muscle pedicle can tolerate up to a 130-degree arc of rotation, which can be expanded to 180 degrees if the zygoma is resected or temporarily transposed.[1,2]
- The superficial surface of the muscle is covered with a smooth, shiny layer of temporalis fascia, which should not be confused with the temporoparietal fascia. The latter is superficial to the temporalis fascia and represents an entirely separate tissue layer. The temporalis fascia is part of the muscle itself and derives its blood supply from the muscle tissue, whereas the temporoparietal fascia envelops the superficial temporal vascular system and is continuous with the galea aponeurotica superiorly and the superficial musculoaponeurotic system (SMAS) inferiorly. Within the temporoparietal fascia are the frontotemporal branches of the facial nerve as well as the superficial temporal vessels. In contrast, there are no nerves or named vessels within the temporalis fascia.[1,2]
- As one proceeds anteroinferiorly from the origin of the muscle on the side of the skull toward the zygoma, the temporalis fascia splits into superficial and deep layers to envelop the temporal adipose tissue pad. Again, these superficial and deep layers of the temporalis fascia should not be confused with the superficial temporoparietal fascia, which is separate and distinct from the temporalis fascia in all of its layers. The superficial and deep layers of the temporalis fascia come back together below the temporal adipose tissue pad and commonly insert onto the deep surface of the zygomatic arch along its superior border.

- The blood supply to the temporalis muscle is from the anterior and posterior branches of the deep temporal artery, which arises from the second portion of the internal maxillary artery. These vessels enter the muscle at its deep (medial) surface superior to the coronoid process within the infratemporal fossa. There is also an accessory blood supply from the middle temporal artery arising from the superficial temporal artery. It is critical from a surgical standpoint to realize that only the deep temporal artery provides a sufficient blood supply to maintain muscle viability. The middle temporal artery alone is inadequate to maintain the muscle as a reconstructive flap.
- Last, the motor supply to the temporalis muscle is from the temporal branches of the mandibular nerve, a division of the trigeminal nerve. It enters the muscle along its anteromedial surface deep in the infratemporal fossa.

Prerequisite Skills

- Understanding of the complex anatomy of this region
- Standard dissection techniques and familiarity with bone work (osteotomies and replating at the conclusion of a procedure)

Operative Risks

1. Injury to the vascular pedicle
2. Flap necrosis/dehiscence
3. Injury to frontal branch of the facial nerve

Surgical Technique

- A hemicoronal incision is made down to the layer of the temporalis fascia. This fascia is thick and glistening white, distinguishing it from the wispier appearance of the superficial temporoparietal fascia. Between the superficial temporoparietal fascia and the temporalis fascia is a layer of very loose areolar tissue, creating a natural plane that facilitates separation of the two fascial layers with blunt dissection

(e.g., using a periosteal elevator). If these layers do not separate easily, most likely the correct interfascial plane has not been identified and the dissection is either too superficial or unnecessarily deep to the desired plane of dissection. It is within this plane that the anterior scalp flap is elevated off the temporalis fascia to the level of the temporal adipose tissue pad.

- When the first signs of this yellow adipose tissue pad are identified as the scalp flap is elevated from posterior to anterior, the dissection plane must change to lift the adipose tissue pad with the scalp to protect the frontal branches of the facial nerve reliably. Hence the temporal adipose tissue pad is elevated with the scalp flap. This maneuver also serves to minimize temporal hollowing, which can result from damage to the adipose tissue pad.
- When the posterosuperior limit of the adipose tissue pad is identified, the temporalis fascia is incised with electrocautery. The adipose tissue pad is then lifted with its overlying superficial temporal fascia as well as the superficial temporoparietal fascia (the layer containing the frontal branches of the facial nerve). The adipose tissue pad is lifted off the deep temporal fascia down to the level of the zygoma. At this point the fascial layers converge and insert onto the zygomatic periosteum. This confluence of fascia and periosteum can then be lifted off the zygomatic arch bone with a periosteal elevator.
- A subzygomatic dissection is then performed, fully freeing the temporalis muscle fibers from the deep surface of the zygoma. The muscle is dissected to its insertion at the coronoid process. At this point the muscle is elevated from the temporal fossa using cautery, staying close to the bone as the muscle is elevated. Venous bleeding can be encountered as the muscle becomes infratemporal near the insertion of the deep temporal artery into the muscle itself. This venous bleeding is best controlled by hemostatic slurries or Gelfoam, as aggressive electrocautery can potentially compromise the blood supply to the muscle.
- With most skull base defects, zygomatic osteotomies are required to achieve the arc of rotation required for reconstruction. With a thin muscle and particularly for isolated orbital exenteration defects, a zygomatic osteotomy may not be needed. In contrast, all maxillary, palatal, and temporal bone defects are best served by including a

zygomatic osteotomy. For maxillary and palatal defects, the zygoma is plated back into anatomic position after muscle transposition. In contrast, an osteotomy of the zygomatic root is usually required for tension-free reconstruction of the temporal bone defect. Additionally, the transfer of bulky temporalis muscles should routinely include osteotomies of the zygomatic arch and even the coronoid to maximize flap rotation and minimize the risk of strangulation of the blood supply.

- From a technical standpoint, zygomatic arch transposition is best achieved following temporalis flap elevation by freeing the masseter attachment to the zygoma inferiorly, thereby skeletonizing the zygoma with electrocautery. This is followed by osteotomy using a reciprocating saw. Holes can be predrilled in the zygoma; then anterior and posterior osteotomies are performed. The transposed bone is kept in moist saline gauze until it is replaced at the conclusion of the flap inset.
- The coronoid process is addressed with careful dissection of the muscle attachments, taking care not to disrupt the blood supply to the muscle. It can be removed by performing an osteotomy or by fracturing it off with a rongeur. Removal of the coronoid allows for increased length and mobility in positioning the flap.
- The flap is then inset and sewn into place with absorbable sutures. Any muscle exposed in the oral cavity is left bare (ungrafted), as it will reliably mucosalize within several weeks. Note that although initially bulky, the muscle flap will atrophy, fibrose, and thin with time.
- If removed, the zygomatic arch is then replaced with screws or plates. A suction drain is placed in the temporal fossa and the scalp is closed in the usual fashion.
- Figs. 168.1 to 168.6 show one of the author's cases demonstrating a maxillary defect after tumor resection followed by reconstruction with a temporalis muscle flap. The bulky muscle permits obliteration of the defect and functionally re-creates the palate. The facial contour is restored with titanium mesh.

Common Errors in Technique

- Failure to identify the correct plane of dissection
- Disruption of blood flow to the flap

Postoperative Period

Postoperative Management

- A drain is usually placed over the temporalis fossa and removed once output is minimal.
- A light pressure dressing is placed around the head.
- Intraoperative steroids should be given to decrease muscle swelling. These should be continued postoperatively for several days as a taper.
- The standard postoperative antibiotic regimen is implemented.

Complications

- Pedicled flaps have a robust vascular supply; however, previous radiation therapy can impair healing. Flap dehiscence can be managed conservatively, as these flaps frequently close by secondary intention/fibrosis without a requirement for further surgery.
- Flap necrosis should be suspected in nonhealing defects or when the muscle appears to be nonviable. It is common to have ecchymosis and a dark appearance to the muscle in the immediate postoperative period and lasting for several days to a week; however, a bedside needle prick can be used to confirm blood flow. If a necrotic flap is noted, it should be débrided to healthy bleeding muscle.
- An ipsilateral deformity with a temporal concavity is a known outcome with this procedure. We prefer not to reconstruct immediately owing to the risk of infection but to wait for healing and, if necessary, until after postoperative radiation. The defect can be corrected via a temporal incision and filled with hydroxyapatite cement or autologous adipose tissue graft at a later time.
- Injury to the frontal branch of the facial nerve can result in temporary or permanent ipsilateral paresis.

Alternative Management Plan

- Palatal defects can be allowed to heal and can be managed with an obturator.
- A temporoparietal fascial flap may be an option if less bulk is adequate for repair.
- Free tissue transfer if more bulk is needed

Discussion

Evidence-Based Medicine Question

What kinds of outcomes have been reported when temporalis muscle is used as a primary reconstruction modality for palatomaxillary defects?

- Wang et al., in a retrospective chart review of their single-institution 15-year experience, concluded that the temporalis flap was a reliable reconstructive option with acceptable outcomes.[3]
  - Of a total of 69 flaps harvested, no flap was lost in its entirety, and there were only four cases of marginal or partial loss.
  - Transient paralysis of the temporal branch of the facial nerve was noted in five patients; this resolved without treatment within 3 months of surgery.
  - Based on self-evaluation of temporal aesthetic outcomes, 70.1% of patients judged their outcome as "good."
  - The size of the primary defect was significantly associated with diet status, mouth opening, and intelligibility of speech, while postoperative radiation correlated with restricted mouth opening and diet.

Editorial Comment

Golovine first reported the use of the temporalis flap for orbital reconstruction in 1898. Since that time the flap has been used to reconstruct multiple maxillofacial and skull base defects because of its

wide range of mobility, arc of rotation, and robust blood supply. The versatility of this flap, relative ease of its harvesting, and minor associated cosmetic defect make it invaluable in head and neck reconstruction.

FIG. 168.1 Coronal computed tomography (CT) image of a recurrent ameloblastoma in the right maxillary sinus.

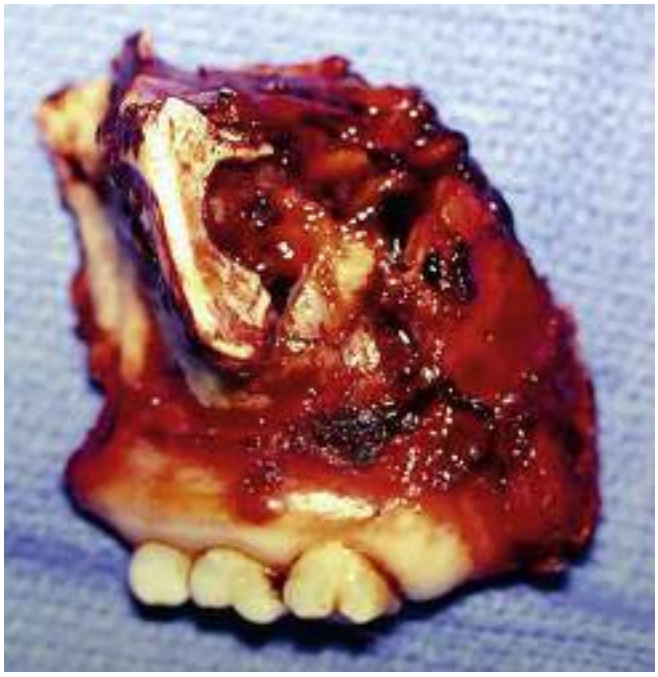

FIG. 168.2 The surgical specimen after total right maxillectomy.

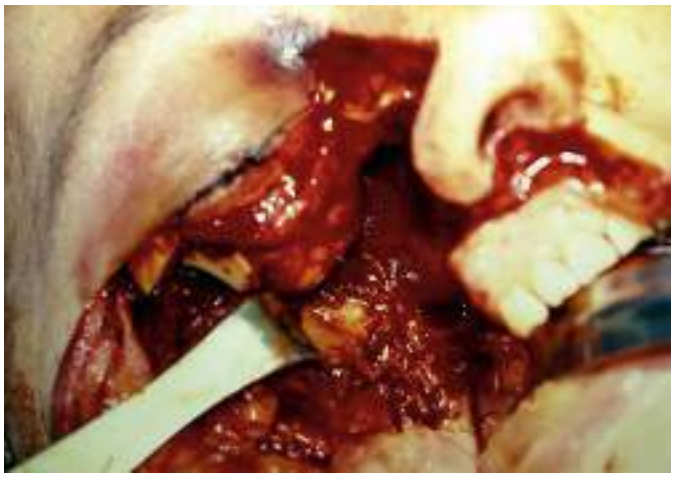

FIG. 168.3 The maxillary defect after resection.

FIG. 168.4 Harvesting the right temporalis muscle flap. The muscle has been elevated off the cranium.

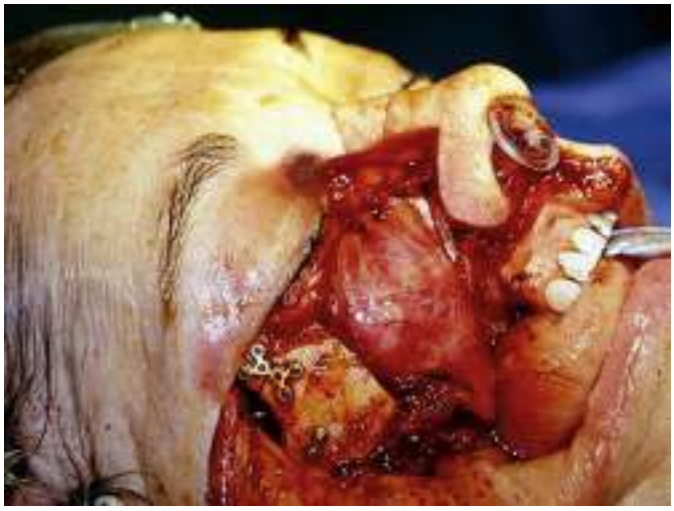

FIG. 168.5 The muscle has been rotated and set into the defect. Note that the zygomatic arch had been temporarily removed for tunneling of the muscle and now has been replaced with titanium miniplates.

FIG. 168.6 Titanium mesh is placed to reconstruct the cheek contour. Note that inferiorly the flap re-creates the palate, obviating the need for an obturator.

Review Questions

1. The frontal branches of the facial nerve run within which tissue layer?

   a. Subcutaneous adipose tissue

   b. Deep temporal fascia

   c. **Superficial temporal fascia**

   d. Within the temporal adipose tissue pad

2. What is the maximum arc of rotation of a temporalis muscle flap?

   a. 90 degrees

   b. 120 degrees

   c. 130 degrees

   d. **180 degrees**

3. All of the following are potential complications of a temporalis muscle flap except

   a. **Lower-lip weakness on ipsilateral side**

b. Inability to raise the forehead on ipsilateral side

c. Temporal hollowing

d. Flap necrosis

4. All of the following are true except

a. The temporal adipose tissue pad is elevated with the scalp flap during the process of exposing a temporalis muscle flap.

b. The blood supply to the temporalis muscle can be at risk during the elevation of the flap in the infratemporal fossa.

c. **The middle temporal artery is sufficient to support the viability of a temporalis muscle flap.**

d. Coronoid resection and zygomatic arc transposition can be used in patients with thick muscle or defects requiring a large arc of rotation to minimize tension upon closure.

Deltopectoral Flap

Jason I. Kass, and Eugene N. Myers

Introduction

The deltopectoral flap (DP), introduced by Bakamjian in 1965,[1] dramatically changed how defects in the head and neck were reconstructed. For instance, reconstruction following total laryngopharyngectomy was accomplished using a combination of local skin flaps (Wookey procedure); delayed pedicle flaps from the back, chest, or abdomen; or split-thickness skin grafts fashioned over a stent.[2,3] These procedures frequently failed as a result of poor skin graft survival, severe strictures, fistulas, and infection. The delayed flaps took many months until inset, by which time the cancer had often recurred. The DP provides healthy, reliable, nonradiated skin to rebuild various defects and quickly became the most popular flap until the pectoralis major myocutaneous flap was introduced by Ariyan in 1979.[4]

The DP is a cutaneous flap based on the first four skin perforators from the internal mammary artery (IMA); (Fig. 169.1). These perforators vascularize a skin paddle that extends from the IMA, just lateral to the sternum, to the deltopectoral groove. Skin beyond the deltopectoral groove, overlying the deltoid, can be harvested, but the vascularity of this distal portion is supplied from deltoid perforators from the thoracoacromial trunk and the anterior circumflex artery and vein and is not completely reliable as a nondelayed flap. A flap 20 cm in length and 10 cm in width can reliably be raised and used with a high likelihood of success.[5]

Despite the evolution of regional and free-tissue options for reconstruction of defects in the head and neck over the last 50 years, the DP remains an important and versatile option for oral and pharyngeal reconstruction and for resurfacing the neck.

Key Operative Learning Points

- The DP flap is based on the first to fourth perforators from the IMA.
- The DP flap is a fasciocutaneous rotational flap that can be used for external skin coverage, carotid coverage, reconstruction of the pharynx, and repair of pharyngocutaneous fistulas.
- The skin paddle is reliable when it is medial to the deltopectoral groove. The vascular supply beyond that point is based on a variable blood supply. For longer flaps, the distal portion should be raised in a delayed fashion.
- Although classically a two-stage reconstruction, an island DP flap can be completed in a single stage with primary closure of the skin of the chest wall.

Preoperative Period

History

1. History of present illness
   a. Pharyngoesophageal defects following total laryngectomy
   b. Exposed skin defects of the neck requiring coverage with vascularized tissue
   c. Exposed vessels, particularly the carotid artery following surgical resection
   d. Coverage of a chronic wound
   e. Intraoral defects requiring reconstruction with a skin paddle
   f. Lack of recipient vessels in the neck for free tissue transfer
2. Past medical history
   a. Prior head and neck treatment:
      1) Prior history of radiation to the chest or neck
   b. Comorbid medical illnesses—cardiac, renal, pulmonary or neurologic (e.g., stroke)—that would significantly elevate

perioperative risks

c. Surgical history:

1) Prior surgery of the upper chest

2) Scars that suggest the IMA perforators may have been injured

3) Prior cardiac surgery that may have sacrificed the IMA

4) Prior pectoralis myocutaneous flap where the incision transected the IMA perforators

d. Family history: Bleeding disorders are important to identify prior to operative intervention.

3. Medications

a. Antiplatelet drugs

b. Herbal products (increased risk of bleeding)

c. Alcohol (consider risk of withdrawal)

d. Allergies to antibiotics

4. Mental and social status

a. Ability to give consent

b. Social support structure

c. Willingness and ability to undergo a two-stage operation should secondary division of the pedicle be required (staged DP)

Physical Examination

- Examination of the proposed donor site
  - Signs of prior surgery or injury to the IMA
  - Pacemaker/defibrillator
  - Central venous catheter port for chemotherapy
  - Radiation changes of the skin
  - Identify any cutaneous precancerous/malignant lesions on the planned skin paddle.
- Identification of potential alternative reconstructive donor sites using a

cutaneous flap

- Similar evaluation as above for pectoralis major myocutaneous flap
- Allen test of both forearms for possible radial forearm free flap
- Examination of thigh skin for possible anterolateral thigh free flap

Imaging

- No specific imaging is required prior to elevation of this flap.

Indications[6,7]

- Typical
  - Repair of cutaneous defects of the neck

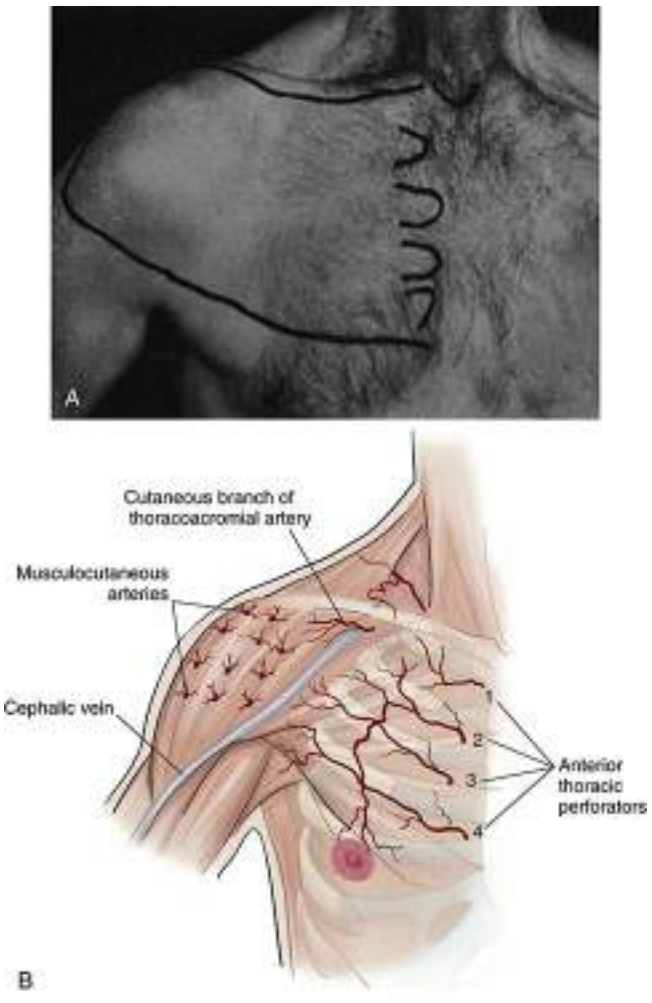

FIG. 169.1 **A,** Outline of incisions for the DP. IMAs are represented by semicircles. **B,** Drawing of the blood supply of the DP.

  - Coverage of exposed carotid artery or chronic wound infection
  - Coverage of other rotational or free tissue flaps[8]
  - Pharyngocutaneous fistula (prevention or treatment)
- Less common
  - Reconstruction of the soft palate
  - Reconstruction of the buccal mucosa
  - Closure of defects in the hard palate[9]
  - Reconstruction of the nasopharynx
  - Reconstruction of the pharynx (1 or 2 stages)

Contraindications

- Defects that are unable to be reached by the flap (anything rostral to the zygoma is generally very difficult to reach)[9]
- Patients with prior incisions that violate the IMA perforators
- History of cardiac surgery with ipsilateral harvest of the IMA

Preoperative Preparation

- No specific preoperative preparation is required beyond that used for surgical ablation.
- If the reconstruction is being performed secondarily, then the patient should have a routine preoperative evaluation to ensure that their condition is optimized for surgical intervention. This includes a cardiopulmonary examination and a complete blood count (CBC).

Operative Period

Anesthesia

- This flap is typically used for anterior neck skin defects and pharyngeal or intraoral reconstruction, immediately following resection of a tumor of the head and neck, during which the patient is under general anesthesia. The DP flap can, in some situations, be elevated under local anesthesia. If the distal portion of the flap was raised and replaced as part of a delay procedure, it could also be performed under local anesthesia.

Positioning

- The patient is supine with the chest wall, neck, and upper arm in view. The arm can be tucked in at the patient's side.

Perioperative Antibiotic Prophylaxis

- Prophylaxis is dictated by the planned reconstruction. For clean cases, no antibiotic prophylaxis is required. For clean-contaminated intraoral reconstruction, cefazolin and metronidazole are recommended. Cefuroxime or clindamycin can be used if the patient is allergic to penicillins.

Monitoring

- There is no nerve monitoring required during flap elevation and inset.

Instruments and Equipment to Have Available

- Standard head and neck set
- For the classical DP flap, a dermatome is used to harvest a split-thickness skin graft to resurface the pectoralis muscle.

Key Anatomic Landmarks

- There are usually four perforators from the IMA that vascularize the skin lateral to the sternum.
- The deltopectoral groove is the typical lateral extent of the reliable portion of the skin paddle. Beyond this groove, the skin is vascularized by deltoid perforators. If this skin is included, the flap is less reliable because it relies on random subcutaneous vessels.
- The cephalic vein runs in the deltopectoral groove beneath the skin.

Prerequisite Skills

- Experience in reconstructive surgery is required. A comfort level with elevating pectoralis major, supraclavicular, or other rotational flaps is recommended.

Operative Risks

- Related to the duration of the procedure
  - Intraoperative cardiac events
- Related to flap elevation
  - Aspiration: Ensure that there is no significant air leak in the cuff and that the endotracheal tube is sufficiently inflated to protect the airway.
  - Airway fire: If the flap is being elevated near a tracheostomy or tracheostoma, maintain oxygen saturation below 30% when using electrocautery near the airway. Maintain good communication with the anesthesia team regarding fire risks.

Surgical Technique

- Classical medially based deltopectoral rotational flap (Fig.169.2)
  - The superior skin incision is placed along the superior edge of the clavicle.
  - The width of the base includes the first four interspaces between the clavicle and the fourth rib.

- The lateral edge of the flap can reliably extend to the deltopectoral groove without concern for major tip necrosis. Beyond that, the flap can be extended to the lateral aspect of the upper arm. In those cases we recommend delaying elevation of the complete flap. When reconstructing the tongue, floor of the mouth, or pharynx, the flap has a typical width-to-length ratio of 2:1.

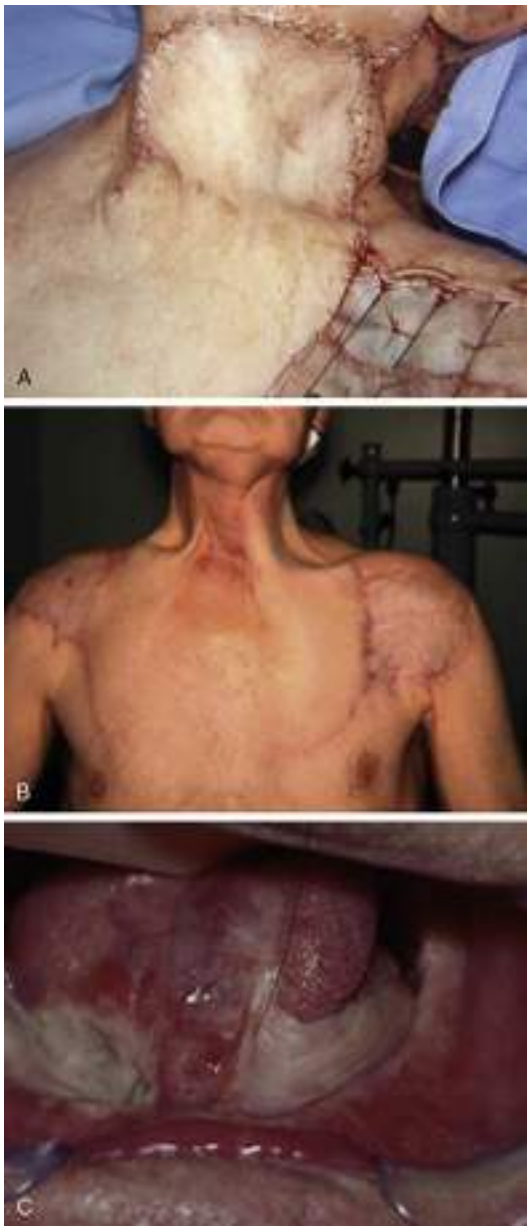

FIG. 169.2 **A,** DP inset into a defect produced by excision of the skin of the left neck. Also demonstrated are the tacking sutures in the skin graft and the catheters used to protect the skin from pressure necrosis from the black silk sutures used to

reduce the size of the chest defect. **B,** A DP was used to resurface the left neck. **C,** A DP was used to resurface a defect in the left floor of the mouth. A skin graft was used to resurface a defect in the right floor of the mouth following excision of a squamous cell carcinoma 20 years following the resection of the lesion on the left.

- When delaying the flap, incise the skin margin and undermine only the portion of the skin supplied by the thoracoacromial artery perforators. Once these vessels have been ligated, the flap can be sutured back in place. We recommend delaying the final flap elevation for 2 to 3 weeks.
- The skin paddle is elevated deep to the fascia of the pectoralis muscle in a lateral-to-medial direction. Elevation should stop about 2 cm lateral to the sternum to prevent injury to the IMA perforators.
- The elevated skin paddle is then rotated into place and inset with care taken to ensure that there is no tension on the suture line. The flap may be passed over an intact bridge of skin or designed as an island flap (see below).
- If additional length is needed, an incision can be made through the skin and subcutaneous tissue overlying the sternum, inferior and medial to the most inferior perforator.
- The chest wall defect is typically covered with a split-thickness skin graft and a Penrose drain or suction drain is placed in the wound.
- Split-thickness skin grafts are harvested from the lateral aspect of the thigh. The skin grafts are sewn to the edges of the chest wall defect. Tacking sutures of 3-0 plain gut are used liberally to decrease the possibility of any shearing effect or large collection of blood or serum between the skin graft and the muscle (see Fig. 169.2A).
- Sutures of 0-silk on a Keith needle are placed with the first bite through the skin bordering the superior aspect of the donor site (Fig. 169.2A) and the second bite through the skin of the inferior border of the donor site. The needle is passed through a 1-cm piece of red rubber catheter to protect the skin from pressure necrosis from the suture. Then the suture is placed through the inferior edge of the donor site and back superior and placed through the skin of the superior edge of the donor site, then through another piece of red

rubber catheter, and then tied with a surgeon's knot. Several such mattress sutures are usually required.

- Using a rolled up 4 × 4 gauze pad, any blood is pressed out from between the skin graft and the pectoralis muscle.
- Pieces of Xeroform gauze are tucked under the mattress sutures and spread out to cover the skin grafts.
- The flap is then left in place for 3 to 4 weeks. At that point, although not necessary, the pedicle can be divided with inset of the base of the flap into the donor site or the redundant flap may simply be excised.

- Island DP flap (see Fig. 169.3)[10]
  - A skin paddle is drawn at the lateral edge of the flap to ensure that, following elevation, the flap will reach the defect without tension. The pivot point for the base of the flap is generally 3 to 4 cm from the sternum.
  - A skin incision is made over the midportion of the pedicle and the skin is elevated, sharply, just deep to the dermis. This leaves all the subcutaneous adipose tissue undisturbed. Small vessels that bleed are cauterized using focal bipolar or needle-tip monopolar electrocautery.
  - With the skin overlying the flap pedicle elevated, the pedicle is elevated from the chest wall. An incision is made superiorly and inferiorly deep to the fascia of the pectoralis muscle.
  - A tunnel is created deep to the superior chest skin into the neck. It should also be large enough to allow the skin paddle to pass with minimal restriction.
  - The flap is elevated laterally off the chest wall and passed through the tunnel into the neck. Care should be taken not to shear the skin island off of the pedicle.
    - If the chest wall has considerable subcutaneous bulk, four tacking sutures can be placed in the corners of the skin paddle so that it will resist shearing forces during rotation.
  - Depending on the size of the island skin paddle, the skin can typically be closed primarily. A Penrose or suction drain is placed beneath the skin.

- If the skin defect cannot be closed primarily, a split-thickness skin graft is used.

Common Errors in Technique

- The skin will become congested if the rotation at the base of the pedicle compresses the venous drainage (internal mammary vein [IMV]) vein. The flap should be elevated such that the skin paddle can be inset without twisting the proximal portion of the pedicle.
- For the island DP flap, the skin incision and elevation over the pedicle should be done sharply, just deep to the hair follicles. Elevating the flap within the subcutaneous adipose tissue will injure small superficial vessels that travel in the subdermal plexus.

Postoperative Period

Postoperative Management

The DP flap does not require any unique postoperative monitoring. A suction drain or Penrose drain is helpful to allow for routine drainage. Care must be taken to ensure that a hematoma does not accumulate beneath the flap. Primary focus should be on tip ischemia and necrosis. This will inevitably lead to wound dehiscence, fistula with pharyngeal/intraoral flaps, and infection. The Xeroform gauze and bolster sutures are removed from the chest wound in 2 weeks and any excess split-thickness skin graft is removed.

Complications[6]

The largest series of DP flaps (n = 678)[6] reported the following complications:

- Intraoperative loss (1%): rare and secondary to injury to the proximal main pedicle
- Tip necrosis (major, 17%; minor, 14%)
- Fistula (16%)

- Infection (11%)
- Flap separation (6%)
- Stricture (2%)
- Hematoma (1%)

Alternative Management Plan

Depending on the defect, there is a wide variety cutaneous, fasciocutaneous, and musculocutaneous flaps that can substitute for the DP flap. These include both regional and free tissue transfer. When time is of the essence, harvesting and insetting of the DP flap and resurfacing the donor site are much faster.

Discussion

Evidence-Based Medicine Question

Where should the modern-day reconstructive surgeon place the DP among the many choices for pharyngoesophageal reconstruction?

There are no studies that directly compare outcomes between the DP and the varied regional and free tissue options. The reconstructive surgeon is left to make decisions based on expert opinion, experience, and comfort level between the many options. Of the recently published reports, all written by experienced microsurgeons, the DP flap has been used for vascularized skin coverage of the neck, carotid protection, creation of a controlled fistula, closure of a pharyngocutaneous fistula, and pharyngoesophageal reconstruction.[5] It continues to be useful when recipient vessel options are few or as a buttress to microvascular reconstruction for massive defects.[6]

FIG. 169.3 Closure of a pharyngeal defect using an island deltopectoral flap.

A, Design of the skin paddle. The *solid line* represents the planned incision. The *dotted line* demonstrates the width of the subcutaneous pedicle. **B,** Following elevation of the flap. **C,** A subcutaneous tunnel was created and the skin paddle was used to close the pharyngocutaneous fistula. **D,** Primary closure of the skin defect is shown.

Editorial Comment

Prior to 1965, when Dr. Bakamjian introduced the DP, reconstruction of defects in the head and neck region were primitive at best. Radiation using orthovoltage machines was given in large doses to attempt to cure

advanced stage cancers. When the cancer recurred, as it often did, radical surgery resulted in the formation of tissue necrosis, bone exposure with osteoradionecrosis, and oropharyngocutaneous fistulas. To prevent exposure and blow out of the carotid artery, the wounds were closed incorporating an orostome or pharyngostome to prevent saliva from undermining the cervical flaps and exposing the carotid artery, which regularly led to rupture of the wall of the vessel, exsanguination, and death.

The introduction of the DP flap was a game changer because it allowed immediate reconstruction with a nondelayed regional flap from outside of the radiated field. This eliminated the stomas and promoted accelerated healing. As imaginative head and neck surgeons adapted this flap, they quickly found additional uses for it such as reconstruction of defects of the middle and lower thirds of the face, the oral cavity, the neck, and the esophagus. Dr. John Conley used an epithelial shave of the proximal portion of the tubed pedicle flap to do a one-stage reconstruction of a total laryngopharyngeal defect.

As often happens, the introduction of a new technique stimulated the imagination of the new generation of surgeons to find ways of improving closure of these challenging defects. In 1979 Dr. Steven Ariyan proved this point when he introduced the pectoralis major myocutaneous flap, which has become the most frequently used regional pedicle flap in head and neck reconstruction. For more than 30 years imaginative surgeons have introduced a wide variety of free flap transfer, often using a combination of tissues (e.g., osseocutaneous free flaps) and free flaps in conjunction with regional pedicle flaps. With intense research being carried out with 3-D imaging and stem cells, we can be sure that in the future immediate reconstruction of defects in the head and neck will change for the better yet again.

Review Questions

1. What is the blood supply to the medially based DP?

a. Pectoral branch to the thoracoacromial artery

b. Thoracoacromial artery directly

c. Perforators from the subclavian artery

d. **Perforators from the IMA**

2. What is the most common contraindication to elevating and using a DP?

a. Prior neck irradiation

b. History of cardiac bypass surgery

c. **Prior pectoralis major reconstruction with a scar perpendicular to the DP pedicle**

d. Prior radical neck dissection on the ipsilateral neck

3. When designing a medially based DP, at what length does tip necrosis become likely and delayed elevation a prudent operative plan?

a. Any distance lateral to the deltoid muscle

b. Any distance lateral to the nipple

c. **Any distance lateral to deltopectoral groove**

d. All flaps should be delayed

Pectoralis Major Musculocutaneous Flaps in Head and Neck Surgery

Zoe M. Macisaac, Mario G. Solari, Ernest K. Manders, and Alex Senchenkov

Introduction

Regional flaps play an important role in reconstructive surgery of the head and neck. Introduced in 1979,[1] the pectoralis major musculocutaneous flap was an important improvement over the deltopectoral flap and multistage tissue transfers that had dominated the reconstruction attempts previously. This flap allowed effective and more reliable single-stage tissue transfer for reconstruction of complex defects of the neck and face, upper aerodigestive tract, and skull base. This development enhanced resection capability and enabled patients with cancer of the head and neck to receive timely adjuvant radiation therapy, facilitating surgical treatment combined with curative intent. However, with advances in microvascular tissue transfer, the pectoralis major flap has been relegated to a secondary role in reconstruction.[2-4] Nevertheless, the pectoralis major flap remains an important reconstructive option for certain indications.

Key Operative Learning Points

1. The role of the pectoralis major musculocutaneous flap in contemporary head and neck reconstruction lies in the salvage of patients who are not candidates for free flaps or for coverage of the neck when a free flap is deemed unwarranted.

2. The flap is based on the pectoral branch of the thoracoacromial trunk. The trunk originates from the subclavian vessels and emerges at the point projected on the skin just medial to the deltopectoral triangle bordered by the deltoid, pectoralis major, and clavicle (also known as the

Mohrenheim fossa). The pectoral branch runs along a line drawn from that projected point to the xiphoid process (Fig. 170.1A). The pedicle runs on the undersurface of the pectoralis major muscle (Fig. 170.2B) in the clavipectoral fascia and must be visualized and protected during dissection.

3. Dissection of the flap should be performed with minimal muscle bulk (Fig. 170.3) and, when necessary, comprising the entire muscle. Complete denervation of the muscle included in the flap is important to prevent subsequent animation of the flap and to promote atrophy.

4. The skin paddle is often designed on the inferior border of the muscle or inframammary fold in women (see Fig. 170.3); its perimeter can be used as the exposure for flap dissection (see Fig. 170.1A). Distal location of the skin paddle improves the arc of rotation.

5. A minimal-access dissection of the flap through the perimeter of the skin paddle is best performed with the use of lighted retractors. Complete hemostasis and secure ligation of the deltoid and acromial branches of the thoracoacromial trunk are the key. A laparoscopic harmonic scalpel is an excellent adjunct in this dissection (see Fig. 170.1C).

Preoperative Period

History

1. Previous procedures that may have compromised the anatomic integrity of the pectoralis major flap (subpectoral pacemaker placement or any operation in the area of the pedicle) and congenital absence of the pectoralis major muscle (e.g., Poland syndrome) will preclude its use as a reconstructive option.

2. Paralysis of the ipsilateral latissimus dorsi muscle will result in shoulder impairment.

3. All medical comorbidities—including those that relate to mortality risk (e.g., respiratory and cardiac disease, alcoholism) and those related to wound healing (e.g., diabetes, nutritional status, smoking, thyroid dysfunction)—should be assessed and mitigated preoperatively if

possible.

Physical Examination

1. The functional and anatomic integrity of the pectoralis major flap and the ipsilateral latissimus dorsi muscle must be evaluated.

2. The amount of subcutaneous adipose/breast tissue overlying the muscle should be examined in order to determine whether the flap should be harvested as a myocutaneous or myofascial flap.

Imaging

1. Imaging is typically unwarranted for flap evaluation but if necessary the authors favor a surgeon-performed duplex ultrasound evaluation as the most versatile form of imaging.

Indications

1. Infection or radiation-related carotid artery exposure or blowout

2. Complications of carotid endarterectomy or stenting

3. Cervical skin defects with vascular exposure following neck dissection, pharyngeal or esophageal fistula, and/or failed free flaps

4. Reconstruction of the upper aerodigestive tract in patients with vessel-depleted, multiply operated necks

5. Medical comorbidities or poor physical status, precluding microvascular tissue transfer

Contraindications

1. Anatomic compromise of the pectoralis major muscle and/or its blood supply is an absolute contraindication.

2. In the case of the nonfunctional latissimus dorsi muscle, shoulder dysfunction should be balanced against a critical defect.

FIG. 170.1 A 68-year-old man with a history of carcinoma of the tonsil treated with chemoradiation developed exposure of the cervical spinal hardware through the posterior pharyngeal and cervical esophageal wall.

A, The flap is harvested through the perimeter of the skin paddle and inset. A meshed 1.5:1 and stretched split-thickness skin graft is used to offset the tension of radiated skin on the flap. The flange of the tracheostomy tube is trimmed and sutured to prevent application of the tracheostomy ties postoperatively. **B,** Postoperatively, secondary contracture of the skin graft minimizes the deformity, the denervated muscle atrophies, and the skin paddle of the flap is excised in the office under local anesthetic. Case of Mark S. Allen, MD [thoracic surgery], and Alex Senchenkov, MD [plastic surgery], Mayo Clinic Foundation.

3. Cosmetic concerns in women and deformity in men should be taken into consideration and discussed preoperatively.

4. Insufficient arc of rotation and/or size of flap to cover defect. This can be determined at the time of flap design if not before.

Preoperative Preparation

1. Negative margins after excision of the tumor

2. Uninfected wound

Operative Period

Anesthesia

1. General

Position

1. Supine

2. The bed is turned 90 or 180 degrees from the anesthesiologist.

Perioperative Antibiotic Prophylaxis

1. **Preoperative:** A first-generation cephalosporin may be administered; if the procedure is done in conjunction with cancer extirpation, no additional antibiotics are needed for harvesting of the flap.

Monitoring

1. Continuous monitoring of blood pressure, pulse, and oxygen content per anesthesia

2. Arterial blood gases when indicated

3. Hemoglobin and hematocrit when indicated

Instruments and Equipment to Have Available

1. Routine head and neck set with retractor set

2. Monopolar and bipolar electrocautery

3. Lighted retractors if minimal exposure is preferred

Key Anatomic Landmarks

1. The pectoralis major muscle is related superiorly to the clavicle and deltoid muscle and inferiorly to the rectus abdominis and external

oblique.

2. Origin from the medial half of the clavicle, anterior surface of the sternum, cartilaginous portion of the upper seven ribs, and the aponeurosis of the external oblique muscle; insertion to the lateral lip of the bicipital groove of the humerus

3. Dominant pedicle: Pectoral branch of the thoracoacromial artery and venae comitantes (from the subclavian artery and veins: emerges through the clavipectoral [coracoclavicular] fascial bridge between the subclavius and pectoralis major muscles and runs on the deep surface of the muscle)

4. Care must be taken to ligate the acromial and deltoid branches during flap dissection. Failure to do so may result in unwanted postoperative bleeding.

5. Minor pedicle: Pectoral branch of the lateral thoracic artery and vein that emerges below the clavicle and enters the deep surface of the upper border of the muscle 3 to 4 cm lateral to the thoracoacromial branches; in a few patients this is the main blood supply to the flap

6. Minor segmental pedicle: Internal mammary perforating arterial branches through first to sixth intercostal spaces and venae passing through the intercostal spaces to enter the deep surface of the muscle within 1.5 to 2 cm of the sternal margin

7. Minor segmental pedicle: Perforating branches of the fifth, sixth, and seventh intercostal arteries, passing through the intercostal spaces to enter the deep surface of the muscle 4 to 6 cm from the sternal origin

8. Motor nerve supply: Lateral pectoral nerve (from the lateral cord of the brachial plexus, entering the muscle on its deep surface approximately at its midpoint)

9. Motor nerve supply: Medial pectoral nerve (from the medial cord of the brachial plexus, entering the muscle on its deep surface laterally after passing through the pectoralis minor)

10. Sensory nerve supply: Segmental innervation from the second through seventh intercostal nerves

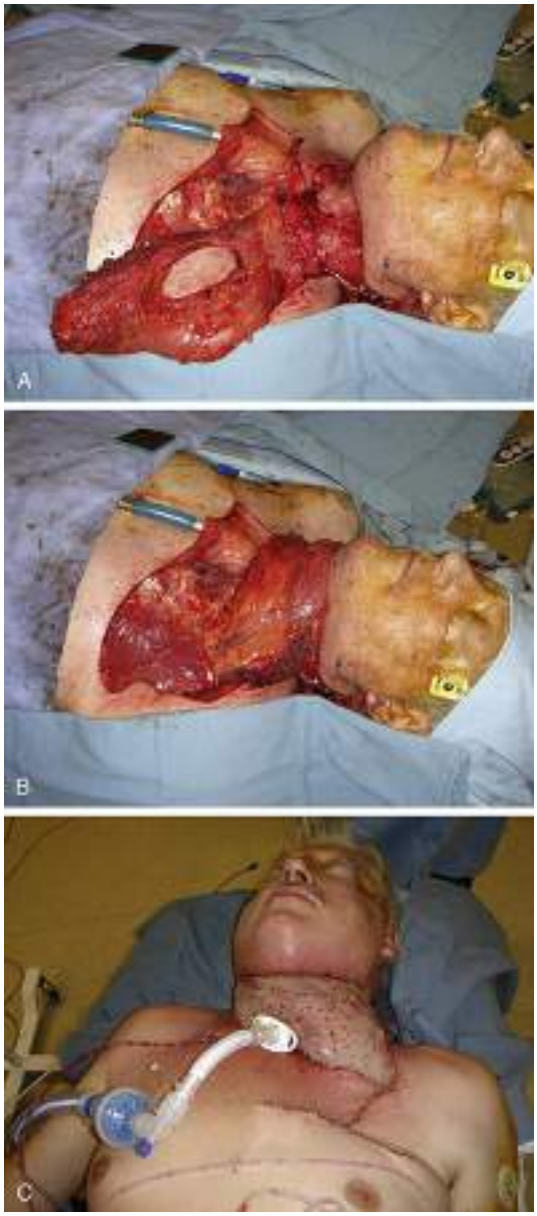

FIG. 170.2 Salvage laryngectomy with neck dissection for chemoradiation failure of squamous cell carcinoma of the larynx. Postoperatively the patient developed a pharyngeal leak. A pectoralis major musculocutaneous flap is used for reconstructive salvage. **A,** Beveling out dissection of the small paddle maximizes its viability. **B,** The entire muscle is used to ensure coverage of both the pharynx and neck. **C,** The radiated neck and skin of the upper chest are completely divided to prevent compression of the flap pedicle and exposed muscle surface if grafted with a sheet split-thickness skin graft. Case of Ernest K. Manders, MD, and Alex Senchenkov, MD.

FIG. 170.3 A pectoralis major musculocutaneous flap dissection in a female patient in the setting of surgical salvage. The skin paddle is harvested from the inframammary fold on the narrow denervated strip of muscle. Case of Alex Senchenkov, MD.

Prerequisite Skills

1. Knowledge of the anatomy of the chest wall
2. Proficiency in soft tissue surgery
3. Understanding of the defects amenable to this reconstruction

Operative Risks

1. Bleeding
2. Damage to the pedicle
3. Shearing of the cutaneous portion of the flap from the underlying muscle
4. Hemopneumothorax

5. Poor flap design

Surgical Technique: (Include Narrated Videos Online)

- Pectoralis major musculocutaneous flap:
  - Design the skin paddle adjacent to the inferior border of the muscle and outline the territory of the deltopectoral flap as well as the thoracoacromial vessels (see Fig. 170.1A). Duplex ultrasound is a useful adjunct study that confirms the vascular anatomy of the flap.
  - Dissection is started with the skin paddle, and the perimeter of this incision is often sufficient for the entire exposure. If the skin paddle has a random component (i.e., not directly overlying the muscle), care must be taken to recruit a deep fascial plane just above the intercostal muscles to preserve the blood supply of this random portion of the skin paddle.
  - A narrow central slip of muscle containing the vascular pedicle is dissected in the cephalad direction. This is best accomplished using lighted breast augmentation retractors or a head light. A laparoscopic harmonic scalpel is particularly useful to achieve secure hemostasis. The preserved lateral remnant of the muscle will provide an anterior axillary fold postoperatively. In many cases the entire muscle is harvested, using the flap to cover vessels, a pharyngeal suture line, or other areas of defect.
  - Careful visualization of the vascular pedicle on the deep surface of the muscle and palpation of the pulse are important to the safety of the dissection.
  - Complete the dissection up to the clavicle and divide and ligate the deltoid and acromial branches of the thoracoacromial trunk, which will enhance the arc of rotation of the flap (see Fig. 170.2B).
  - The pectoral nerves must be identified (see Fig. 170.2B) and divided to induce muscle atrophy and prevent animation of the flap.
  - A tunnel is made between the chest and the neck in a subcutaneous plane to allow passage of the flap into the neck/defect. The tunnel should easily allow passage of four fingers. Detached from its

clavicle insertion, the clavipectoral fascia forms a fascial band, which must be released to avoid compression of the pedicle.

- Radiated neck skin lacks compliance; therefore such tunnels should be released with skin grafting of the muscle if necessary (see Figs. 170.1B and 170.2C).
- Flap inset is done without twisting the pedicle. Deep aspects of the flap are secured to prevertebral fascia or other structures such as the mandible to avoid down pulling due to gravity, thus preventing dehiscence and leaks.
- Internal mammary perforators 2, 3, and 4 are preserved in order to maintain the blood supply for a future deltopectoral or internal mammary artery perforator (IMAP) flap.
- Most donor sites can be closed directly. For larger skin defects, vacuum-assisted closure (VAC) and DermaClose with staged closure have been employed. Skin grafts are rarely needed.
- Ties around the neck should not be used postoperatively. The authors' practice for patients with both free and pectoralis major flaps is to cut off the tie opening on the flange of the tracheotomy tube and suture it to the neck skin (see Fig. 170.1B). A sign saying *Nothing Around Neck* is posted over the patient's bed.

Common Errors in Technique

1. Excessive tissue bulk resulting in difficulty closing the neck or defect
2. Tight tunnel causing pedicle compression
3. Compression of the flap pedicle with the tracheostomy cannula tie
4. Limited pedicle length and arc of rotation

- Preoperative flap design and measurements are critical. It should be recognized that body habitus may limit the reach of the flap.

5. Excessive traction on the thoracoacromial pedicle

- Careful design, dissection, inset of the skin paddle, and suture stabilization of the muscle portion of the flap are preventive measures.

6. Skin paddle loss

- The skin paddle should be designed to lie at least in part over the muscle territory (see Fig. 170.1B).

7. Dehiscence

Postoperative Management

1. Adequate pain control, warm room, and adequate hydration to avoid vasospasm

2. Tracheostomy care to prevent pedicle compression (see Fig. 170.1B)

3. Perioperative antibiotics

4. Referral to physical therapy

Complications

1. Dehiscence of flap and postoperative fistula due to its bulk and pedicle attachment. Immediate care for salivary leak is required (drainage of saliva, débridement). Additional flaps may be necessary and urgent if there is exposure of the carotid artery.

2. Partial flap necrosis typically due to inadequate blood supply to random portion of flap

3. Reduced shoulder and neck function

Alternative Management Plan

1. Free flap reconstruction

2. Other regional flap reconstruction

Discussion

Evidence-Based Medicine Question

What are the benefits and disadvantages of using a pectoralis major flap for head and neck reconstruction compared with free flap

reconstruction?

Introduced by Ariyan in 1979,[1] the pectoralis major regional flap became the standard and reliable method of reconstruction of large defects in the head and neck until microsurgical reconstructions became widely available.[2-4]

Despite its reliability and shorter operative time, the pectoralis major flap is associated with *longer hospital stays*[2-4] and *higher hospital costs* ($28,460 for free flap reconstruction compared with $40,992 for pectoralis major reconstruction).[2] Longer hospital stays associated with pectoralis major flap reconstruction may be related to the *increased rate of adverse events* (partial flap necrosis, salivary fistula, wound infection, and delays in healing). Flap physiology, flap bulk, pedicle tethering, and wound morbidity of the donor site—which communicates directly with the site of the reconstruction—may play deleterious roles.[2-4] Healing delays in patients treated with pectoralis flaps are not trivial: in the setting of multimodality oncologic treatment, these patients require adjuvant radiation therapy within 6 weeks and completion of all treatments within 100 days for the best oncologic outcomes.

There are important physiologic differences in the blood supply of pedicled flaps and free flaps that may pertain to the superiority of microvascular reconstructions. Frequently skin paddles lie at least one angiosome away from the pedicle vessel's vascular territory.[4] In the case of a pectoralis flap, the skin paddle is primarily supplied by the internal mammary perforators rather than the branches of thoracoacromial vessels, as demonstrated by the classic work of Taylor and Palmer.[5] In contrast, the blood supply of the free flap skin paddle corresponds to the very angiosome of its vascular pedicle. The reliability of such microvascular flaps and the power of their blood supply are truly superior to traditional regional flap reconstructive surgery.

Editorial Comment

As microsurgical techniques have become widely adopted and refined, free flap reconstruction has supplanted reconstruction with the pectoralis major flap. However, for patients who are not candidates for free flap reconstruction, the pectoralis major flap remains a viable option.

Alex Senchenkov

Review Questions

1. Which of the following is a relative contraindication to using a pectoralis major flap?

   a. Infection-related carotid artery exposure

   b. Neck defect with esophageal leaks

   c. Pharyngeal reconstruction in the patients with vessel-depleted multiply operated necks

   d. Severe thrombophilia

   e. **A nonfunctional latissimus dorsi muscle**

2. A 78-year-old moribund patient underwent a composite resection for treatment of locally advanced squamous cell carcinoma of the oral cavity; previous palliative radiation had failed. Because the patient could not tolerate the length of the microvascular reconstruction procedure owing to severe cardiovascular comorbidities, a pectoralis major musculocutaneous flap was used in the surgery. The entire procedure was performed on the basis of a weight-based heparin nomogram and aspirin in view of recently placed cardiac stents and symptomatic cerebrovascular disease. Four hours after arrival in the intensive care unit (ICU), the patient was hemodynamically labile and a small hematoma of the chest wall was noted at the flap donor site. The patient is returned to the operating room for re-exploration of the site. General "nonsurgical" oozing is noted in the lateral aspect of the most cephalad part of the dissection pocket. The next step should be which of the following?

   a. Decrease heparin drip to 500 U/h and return the patient to the ICU

   b. Transfuse single-donor platelets and, if improvement is noted, return the patient to the ICU

   c. Pack the site with a clotting agent (e.g., Surgicel) and return the patient to the ICU

   d. **Extend the skin incision for close evaluation of the pedicle site**

e. Apply wound VAC to allow sponge compression to small bleeding sites

3. A 69-year-old edentulous man with squamous cell carcinoma of the oral cavity invading left mandibular parasymphysis (T4 N0) underwent composite resection with bilateral neck dissection and reconstruction with an osteocutaneous free fibula flap. On postoperative day 1, the patient was taken back to the operating room for venous congestion and underwent venous thrombectomy. Despite postoperative anticoagulation, necrosis of the intraoral skin paddle developed and salivary leak into freshly dissected neck ensued. The patient was again returned to the operating room where the free fibula was found to be completely necrotic. Following débridement, what will be the most appropriate course of action?

   a. Placement of radial forearm fasciocutaneous free flap over the existent mandibular plate

   b. Placement of pectoralis major/rib osteomusculocutaneous flap

   c. Use of iliac crest bone graft with pectoralis major musculocutaneous flap

   d. Placement of pectoralis major musculocutaneous flap to cover the existent reconstruction plate

   e. **Removal of the plate and pectoralis major musculocutaneous flap (mandibular swing)**

Cervicofacial Transposition Flaps

Brittany Howard, and Trevor Hackman

Keywords

cervicofacial flaps; submental island flap; supraclavicular flap

Introduction

Historically, regional flaps from the cervicofacial region have played a key role in the reconstruction of defects in the head and neck. A regional flap is a vascularized tissue flap that is pedicled on an axial blood supply and is not immediately adjacent to the defect area that requires reconstruction. Since the introduction of this technique in the 1960s, the possibility of reliably transposing large volumes of vascularized tissue for reconstruction has revolutionized our ability to resect disease and safely reconstruct defects in the head and neck. Although significant focus was placed on the role of free flaps for reconstruction during the 1980s and 1990s, recent years have brought a rebirth of interest and enthusiasm for the use of regional flaps.

The advantage of regional flaps is that they can provide diverse tissue options for reconstruction (fasciocutaneous, myofascial, musculocutaneous, and osseomusculocutaneous) with low donor-site morbidity. Additionally, operative times are typically lower than with free flap reconstructions because most regional flaps are adjacent to the primary surgical field, do not require repositioning, can be harvested rapidly, and do not require microvascular techniques. In today's age of increasing concern over health care costs, the association of regional flap reconstruction with decreased operative time and a shorter length of hospitalization as compared with free tissue transfer is an added benefit.

Key Operative Learning Points

1. An ideal reconstruction provides a patient with the best outcome (in both function and form) with the lowest donor-site and overall morbidity.

2. Flaps can be characterized by their pattern of vascularity. Flaps from the cervicofacial region include both random-pattern vascular flaps (cervicofacial flaps) and axial vascular pattern flaps (cervicopectoral, supraclavicular, deltopectoral, and submental flaps).

3. A comprehensive understanding of regional anatomy allows for the use of multiple regional flaps to reconstruct defects in the head and neck.

4. Planning for the vascular pedicle and its final geometry are of key importance for flap viability and success in reconstruction.

Preoperative Period

History

1. History of present illness

   a. The extent and complexity of the defect requiring reconstruction must be determined.

      1) Ideally defects should be reconstructed with like tissue. If a defect involves a loss of cutaneous tissue, it is ideally reconstructed with cutaneous tissue of similar color, thickness, and texture.

      2) Similarly, if the defect includes multiple tissue types such as epithelium and muscle, a flap including tissue of similar thickness and tissue type is ideally used for reconstruction.

   b. Current function and future functional needs should be elicited.

      1) Preoperative swallowing and breathing should be evaluated.

      2) Possible need for postoperative airway protection (tracheostomy) and nutritional support (nasogastric feeding tube) should be considered.

2. Past medical history

a. Prior treatment in the head and neck region

1) Prior head or neck surgery may affect the viability of regional reconstructive options.

2) Prior radiation may affect postoperative healing and flap viability.

b. Medical illnesses that may affect flap viability and reconstructive outcomes

1) Diabetes, especially if poorly controlled, can affect healing outcomes and flap viability.

2) Peripheral vascular disease may affect flap viability.

3) Coagulopathies may affect postoperative bleeding or coagulation.

4) Tobacco abuse/nicotine exposure is associated with arterial constriction and vascular insufficiency. It should be avoided in the perioperative period.

c. Family medical history

1) Coagulopathies can promote postoperative bleeding or coagulation and thus flap viability.

d. Medications

1) Consideration of risks/benefits to discontinuing any drugs that would increase the risk of bleeding. Development of a hematoma can threaten flap viability.

Physical Examination

1. Examination of the face

a. The face should be carefully evaluated for any scars or evidence of prior surgical intervention, as this could disrupt blood flow for a cervicofacial advancement flap. The size of the defect should be measured to make sure that the planned flap is large enough to cover the defect.

2. Examination of the neck

a. The neck should be carefully evaluated for any scars or evidence of prior surgical intervention that may affect blood flow.

b. In planning a submental island flap, the amount of submental skin redundancy must be measured via the "pinch test," with the patient in mild neck extension to ensure adequate flap volume while sparing enough tissue for closure of the primary donor site without restricting head elevation.

3. Doppler examination

a. A preoperative Doppler exam ination is required for the supraclavicular artery flap to identify and trace the vascular pedicle from the supraclavicular fossa over the clavicle and onto the deltoid region of the shoulder. This can be done either in the office or on the day of surgery.

b. The site of Doppler signals should be marked with a marking pen to facilitate future identification.

Imaging

1. Computed tomography (CT) scan with contrast: Although not required for flap planning, this may be useful to evaluate the vascular system within the neck if prior surgery has been performed. It can help in surgical planning to establish that the vessels of the flap pedicle are intact.

2. CT angiography (CTA) or formal angiography: Although rarely needed, an angiogram may be useful if there is concern regarding the presence of the flap's pedicle vessels.

Operative Period

Anesthesia

1. General anesthesia

a. This is the most commonly used anesthetic approach because the flap is often harvested concurrently with tumor resection.

b. General anesthesia is helpful in procedures that require dissection of the vascular pedicle, since this calls for meticulous care.

c. Use of a paralytic is at the discretion of the surgeon depending on the nerves at risk.

Positioning

1. The patient is positioned supine.

2. Placement of a shoulder roll or extension of the neck away from the side of operation may be beneficial during early flap elevation.

a. At the end of the surgery, if the closure is under tension, consider removing all rolls and rotating the patient back to neutral position to reduce tension and aid in primary closure.

Antibiotics

1. Their use depends on the defect to be reconstructed and the associated risk factors.

Monitoring

1. Monitoring of the facial nerve is recommended when its branches are at risk.

Instruments and Equipment to Have Available

1. Standard head and neck set

2. Bipolar cautery

3. Sterile Doppler

4. Spy fluorescent angiography—allows for the prediction of flap viability after harvesting

Operative Risks

1. Flap viability: Because of the random pattern of the flap, it is at increased risk for vascular insufficiency, especially at its distal and peripheral edges.

2. Bleeding: The development of a hematoma in the wound can compromise the flap's viability owing to compression of the pedicle.

   a. Meticulous hemostasis should be established at the time of closure.

   b. Suction drains should be placed whenever possible owing to the significant dead space created during flap elevation and risk of hematoma formation.

3. Injury to the cranial nerves

   a. Branches of the facial nerve are at risk most noticeably in raising of the cervicofacial and submental island flaps. Nerves should be identified and protected during primary flap elevation.

   b. The accessory nerve is at risk during elevation and rotation of the sternocleidomastoid muscle flap. It should be identified, dissected free of the muscle, and preserved during flap elevation/rotation.

Cervicofacial Flap

The cervicofacial flap is unique among the flaps discussed in this chapter as it is the only flap with a random blood supply; as such it is better categorized as a local flap rather than a regional one. However, given its importance in cervicofacial reconstruction, it is included in this discussion. The cervicofacial flap is a fasciocutaneous flap based off of a random blood supply; it encompasses tissue from the facial and cervical regions. Although it is commonly referred to as an advancement flap, it is more correctly classified as an arc rotation flap, as its movement for closure of the defect includes both advancement and rotation vectors.

Preoperative Period

Indications

1. Defects of the cheek and lateral face

   a. Unmatched in its ease of harvest, ability to resurface large defects, good color match, and esthetic result with minimal donor-site morbidity

   b. Ideal for thin superficial defects

Contraindications

1. Vascular insufficiency of the flap owing to its size, base, or other factors

   a. The primary limitation of the flap is that, because of its random blood supply, it requires a large base for maximal vessel recruitment and vascularity may be compromised at its distal edges.

   b. Patients with prior radiation therapy, surgery, or significant peripheral vascular disease are more vulnerable to ischemic loss of the flap.

   c. Given the dependence of the flap on a microcirculatory network, it is strongly recommended to have the patient forego nicotine for a minimum of 2 weeks prior to surgery.

2. A patient who is unable to tolerate revision procedures

   a. Advancement and rotation of the flap can result in a temporary standing-cone deformity.

   b. If there is concern regarding the vascularity of the distal flap, the standing cone should be left and a revision surgery planned to remove the deformity once neovascularization from the wound edges into the flap has occurred.

Operative Period

Surgical Technique

Flap Design

- The flap is designed beginning from the posterior edge of the facial

defect requiring reconstruction.

- The superior limb of the flap extends posteriorly from the facial defect to the area of the mastoid tip. The incision is then dropped down the neck approximately 2 cm posterior to the anterior edge of the trapezius muscle; it then turns anteriorly in a natural skin crease in the neck at the level of the clavicle (Fig. 171.1).

FIG. 171.1 Cervicofacial flap design (A to D): Patient with a defect in the anterior right cheek after resection of a skin cancer.

A, The posterior limb is carried horizontally to the preauricular region and then continued around the lobule in the postauricular tissue to increase the potential arc of rotation. The incision is then carried inferiorly to the clavicle. Horizontal skin creases in the lower neck are marked and the level of horizontal transition depends on

the arc of rotation needed. **B,** Skin incisions are made along the preplanned lines, including a postauricular limb to increase the arc of rotation. **C,** The flap is elevated in a subcutaneous plane to allow for rotation and to avoid risk to the facial nerve. **D,** Final operative result: Drain is in place. The postauricular limb is excised, as is the "dog ear" deformity that arose anteroinferiorly.

- The size of the flap to be elevated is based on the size of defect to be resurfaced, calling for ongoing intraoperative assessment of the flap size and freedom of rotation needed to achieve a tension-free closure.

Flap Elevation (see Fig. 171.1)

- The flap is elevated in a subplatysmal plane in the cervical region.
- Elevation occurs in a supra-*Superficial muscular aponeurotic system* (SMAS) plane in the facial region.

Rotation and Advancement of the Flap Into the Defect (see Fig. 171.1)

- During rotation a standing-cone deformity is created at the base of the flap. If there is any concern for flap viability, this standing cone is left intact, to be addressed at a future staged procedure, as its removal can compromise the vascular supply to the distal portion of the flap.

Drain Placement

- Drains should almost always be placed, as development of a hematoma under the flap can impair its viability and the surgical outcome.
- Placement of a light compressive dressing should be considered to maintain good contact between the flap and the underlying wound bed (especially if no drain is placed).
- Appropriate design, inset, and drain placement allow for very acceptable long-term results (Fig. 171.2).

Supraclavicular Flap

A regional flap that has received significant attention in recent years for its applicability to head and neck reconstruction is the supraclavicular flap. It is an attractive option for reconstruction of defects in the head and neck, given its excellent color and texture match, favorable arc of rotation, ease of harvesting, and minimal donor-site morbidity.

Preoperative Period

Indications

1. The supraclavicular flap is a thin fasciocutaneous flap whose skin color closely matches that of the head and neck.

2. The supraclavicular flap is ideally suited to resurfacing soft tissue defects of the neck, lateral skull base, floor of mouth, and lower face.

3. Reconstructive surgeons have recently expanded the applications of the supraclavicular flap and have compared it to the regional equivalent of the radial forearm free flap.

   a. Both the supraclavicular and radial forearm free flap provide thin, pliable fasciocutaneous vascularized flaps for reconstruction.

   b. The supraclavicular flap has been described for reconstruction of pharyngectomy defects,[1] as with the radial forearm free flap.

   c. In terms of viability, this flap has been directly compared with free flaps for the reconstruction of hemiglossectomies[2] and lateral skull base defects.[3]

Contraindications

1. Caution must be exercised when the flap is being considered as a reconstruction option in patients who have previously undergone neck surgery, particularly level 4, and supraclavicular fossa neck dissection, as the supraclavicular perforator off the transverse cervical artery may be absent, resulting in a nonviable random flap.

Operative Period

Key Anatomic Landmarks

- Supraclavicular triangle
  - The cutaneous perforator of the supraclavicular artery is identified within the supraclavicular triangle.
  - The supraclavicular triangle is defined posteriorly by the anterior border of the trapezius, the posterior border of the sternocleidomastoid muscle, and inferiorly by the clavicle.

FIG. 171.2 Final aesthetic outcome after reconstruction of a facial defect with a cervicofacial rotation advancement flap. Note excellent match of skin color and texture.

Surgical Technique

1. The supraclavicular flap is designed as an elongated ellipse over the supraclavicular region extending inferiorly to the deltoid tip. A flap width of 6 to 8 cm typically allows for primary closure of the donor site.

   a. Wider flaps (10 to 16 cm) can be harvested with reliable viability if needed for defect reconstruction, but primary closure cannot typically be achieved for these donor sites, so that secondary skin

grafting will be necessary.

2. From its base at the supraclavicular triangle, the flap can be extended laterally over the shoulder for lengths up to 26 cm; when the flap is extended onto and beyond the deltoid tip, the vascular supply will have a random pattern.

   a. As a rule, the flap should not be extended more than 5 cm beyond the last audible Doppler signal (Fig. 171.3).

3. The cutaneous perforator of the supraclavicular artery is identified within the supraclavicular triangle and is the fulcrum around which the flap can be rotated.

4. The flap is elevated working distal to proximal along the flap in the subfascial plane. The flap can be designed so that it is maintained with a cutaneous base or as an island perforator flap to maximize the arc of rotation.

   a. Care should be taken to avoid injuring the cephalic vein on the flap's ventral surface.

   b. While cautery may be used to elevate the distal aspect of the flap, sharp dissection is recommended to release the flap off the fibrous attachments to the clavicle and trapezius muscle.

5. For the majority of supraclavicular flaps, the donor site can be closed primarily after appropriate undermining of the surrounding soft tissue.

6. Placement of a drain is recommended.

Submental Island Flap

The submental flap is a versatile regional flap that can be designed as a fasciocutaneous, musculocutaneous, myofascial, or osseomusculocutaneous flap. Its utility for reconstructing defects in the head and neck has drawn significant interest in recent years. The submental island flap is a central perforator flap that can be based on either or both of the submental vessels.

Preoperative Period

Indications

1. Because of its unparalleled color and texture match to facial skin, the submental island flap provides an excellent option for the reconstruction of facial defects.

    a. The ability to include a muscular component with the flap makes it superior to the cervicofacial flap in reconstructing facial defects where additional bulk is desired to correct potential deficiencies of contour.

2. Oral cavity, oropharynx and laryngectomy defects

3. Lateral skull base defects

4. Anterior skull base and orbital defects

5. This is a bipedicled flap that has a maximally robust vascular supply and may be appropriate for the reconstruction of midline defects (anterior floor of mouth, larynx, pharynx).

    a. However, its lateral reach is limited by the bilateral nature of its pedicle.

6. A unilateral pedicle is ideal for the reconstruction of lateral defects; the pedicle's average length is 8 cm, reliably allowing reach from the level of the zygoma superiorly to the level of the clavicle inferiorly.

    a. Based upon a unilateral vascular pedicle, a large flap paddle can be raised with reliable viability of the entire cutaneous component.

    b. The cutaneous component of the flap can extend from the ipsilateral angle of the mandible to the opposite mandibular angle and from the mandible superiorly to below the level of the hyoid (as large as 17 cm × 9 cm).

Contraindications

1. Prior neck surgery may have damaged the vascular supply to the flap and thus have impaired its viability. Submental artery and vein perforators to the overlying cutaneous component are typically divided in a standard neck dissection exposure.

2. Patients with bulky level 1b cervical metastasis and/or potential extracapsular extension as the submental vessels transverse this location

FIG. 171.3 Supraclavicular artery flap (A and B): Right supraclavicular flap raised to reconstruct a defect in the floor of the mouth.

A, The vascular pedicle has been mapped with Doppler ultrasonography from the triangle created by the posterior edge of the sternocleidomastoid muscle (SCM), the clavicle, and the anterior edge of the trapezius muscle over the shoudler to the deltoid tip. The flap incisions are planned around this axial pedicle with the distal aspect of the flap overlying the deltoid tip. **B,** The flap has been raised fully and the remnant lateral skin edges of the arm have been approximated with piercing towel clamps in anticipation of primary closure.

Operative Period

Key Anatomic Landmarks

1. The submental artery originates from the facial artery deep to or within the submandibular gland. It courses over the superior aspect of the submandibular gland anteriorly on the superficial surface of the mylohyoid muscle and sends up cutaneous perforator branches that traverse both medially and laterally to the anterior belly of the digastric muscle.

2. The submental vein or veins provide the venous drainage for the flap but have a notably more variable course. The submental vein may be a terminal branch of the facial vein or, less commonly, may originate from the external jugular system. This variable venous anatomy becomes highly important during flap harvesting and elevation, as the accidental loss of veins during initial exposure can compromise the vascular integrity of the final flap.

Surgical Technique

1. Surgery begins with planning of the flap design (Fig. 171.4).
   a. The size and complexity of the defect requiring reconstruction are then considered, as is the extent of inclusion of muscle within the flap.
   b. Although the flap can be raised as a fasciocutaneous flap, inclusion of the ipsilateral mylohyoid and the anterior belly of the digastric muscle simplifies the dissection and provides added protection of the vascular pedicle coursing along the superficial surface of the mylohyoid.
   c. If additional bulk is advantageous, the contralateral mylohyoid and anterior belly of the digastric muscle can also be included. An osseomusculocutaneous flap can be designed with inclusion of the inferior aspect of the mandibular mentum with the flap.
      1) This is based upon bony perforators near the midline of the flap and can be especially useful in the reconstruction of the maxilla where small bony defects exist.

2. The dominant cutaneous perforators are first identified with a Doppler near the insertion of the anterior digastric muscles on the mandible.

3. The superior incision is planned so that it overlies the inferior edge of the body of the mandible; placing this incision too far below the level of the mandible will put the perforating vessels at risk.

4. The superior incision is drawn laterally just below the level of the mandible to the desired lateral limit (can extend angle to angle).

5. A pinch test is used to determine the vertical height of the skin paddle that can be harvested and still allow primary closure; this inferior extent

is then marked.

6. The medial superior incision is opened first, carrying the incision onto the mandible at the midline.

7. The flap is dissected away from the mandible with a Cottle elevator in a subperiosteal plane and the anterior belly (or both anterior bellies depending upon the defect) of the digastric muscle is/are released from the mandible.

8. The skin incision is then opened on the ipsilateral side of the vascular pedicle to the lateral extent of dissection and to the depth of the platysma muscle.

9. The posterior platysma muscle is then carefully divided to expose the submandibular gland.

10. The marginal mandibular nerve is identified overlying the facial vessels and the submandibular gland. With the operator maintaining a view of the marginal mandibular nerve at all times, the intervening platysma muscle is divided superiorly to connect the anterior and posterior portions of the dissection, protecting and preserving the underlying marginal mandibular nerve.

11. With the superior incision complete on the ipsilateral side, the marginal mandibular nerve is then mobilized off the underlying fascia of the submandibular gland and swept upward out of the field of dissection for the remainder of the procedure.

12. The vascular pedicle is next identified at the deep posterior aspect of the submandibular gland.

a. The venous system is always superficial and lateral to the arterial supply, and venous drainage can be rapidly identified to be either coursing into a common facial vein or less commonly into the external jugular vein.

13. The venous and arterial pedicles are then traced through the gland, dividing the perforators going to the gland. Care is taken to preserve a broad fascial cuff from the pedicle to the skin, through which the skin perforators travel.

14. The submandibular gland may be preserved or removed. If it is removed, the gland is dissected free of its surrounding structures,

including the hypoglossal nerve and the lingual nerve. The submandibular duct is identified and divided, and the submandibular gland is removed.

15. The vascular pedicle can now be traced over the superficial surface of the mylohyoid muscle; in cancer resections, all associated lymph nodes and adipose tissue are removed.

a. If comprehensive dissection of level I lymph nodes is not required, the adipose tissue can be left surrounding the pedicle and dissection does not have to extend onto the superficial surface of the mylohyoid muscle.

b. When the mylohyoid muscle is to be included in the flap for added bulk and pedicle protection, it is released off the mylohyoid line along the mandible superiorly and off the hyoid bone inferiorly.

16. The final inferior attachment of the anterior belly of the digastric muscle to the hyoid bone is then released.

17. Final flap elevation then proceeds by freeing the contralateral side.

18. If significant muscle bulk is not needed, the contralateral cutaneous flap can be elevated in a supraplatysmal plane.

a. This protects all neurovascular structures on the contralateral side including the marginal mandibular nerve.

19. If greater muscle bulk is desired, the contralateral platysmal muscle can be included, as can the contralateral mylohyoid and anterior belly of the digastric muscle.

20. The flap is now fully free and can be inset for reconstruction (see Fig. 171.4).

a. To increase perfusion pressure to the flap, the facial artery distal to the takeoff of the submental artery is ligated and divided.

21. Drains should be placed in the submental region owing to the high rate of seroma formation.

Common Errors in Technique

1. If a submental flap is desired for reconstruction when concurrent neck

dissections are to be performed, the flap is raised first to make sure that the vascular supply to the flap is identified and preserved.

2. Thinning of the underlying fascia between the pedicle and the overlying skin will compromise the skin perforators, particularly those overlying the digastric muscle.

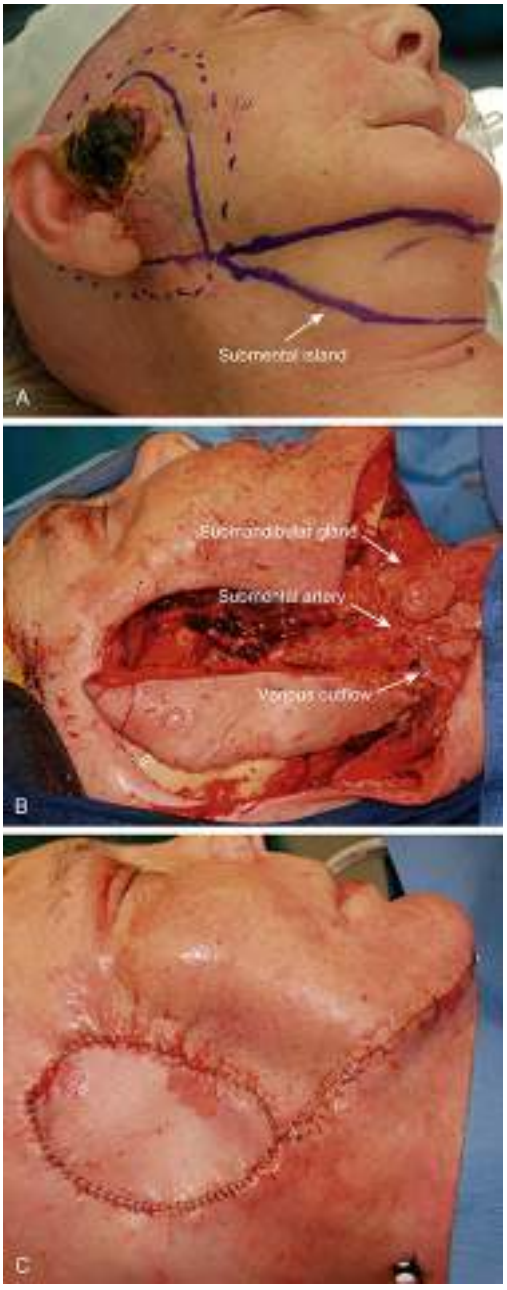

FIG. 171.4 Submental artery flap (A to C): A lateral temporal bone defect is slated for resection and submental island flap reconstruction.

A, The patient's primary malignancy is drawn on the skin. An ipsilateral submental island flap is drawn, with the superior incision along the inferior border of the mandible. **B,** The elliptical skin paddle has been elevated on the posterior vascular pedicle of the facial system and has been rotated into the defect. **C,** The flap has been inset and the flap harvest site is closed primarily along the inferior border of the mandible.

Postoperative Period for Flaps

Postoperative Management

1. Flap monitoring
    a. For pedicled flaps, the need for close flap monitoring is debatable, as pedicle compromise is unlikely.
    b. Frequency and need are at the surgeon's discretion.
        1) Typical flap monitoring can include monitoring with Doppler signal, capillary refill, color, and warmth.
2. Drains
    a. Drains should be remain in place until output has decreased significantly (<30 mL per 24 hours or less) and the content is clear.
3. No limitations on postoperative activity
4. Pain medication as needed

Complications

1. Flap viability can be compromised by multiple factors; therefore early identification is important to increase the chances of salvage.
    a. Arterial compromise
        1) Most commonly secondary to arterial compression from poor vessel geometry, pedicle stretch, or hematoma
        2) Typically requires return to the operating room for exploration

of the vascular pedicle and to see whether arterial flow can be reestablished

b. Venous compromise, more common than arterial compromise

1) Most commonly secondary to venous kinking or compression from vascular pedicle geometry or hematoma

2) Requires return to the operating room for exploration of the vascular pedicle and to see whether venous flow can be reestablished

3) If venous flow cannot be reestablished, the flap may be salvaged by the use of leeches and heparin scrub to provide venous outflow from the flap.

c. Infection

1) Usually a delayed source of flap compromise (>5 days postoperatively). Typically secondary to salivary leak. "Nothing by mouth" (NPO) status and good oral care may help to prevent this complication.

d. Poor microcirculation

1) Patients who are obese and those with diabetes, peripheral vascular disease, or prior radiation therapy constitute the population most at risk.

2. Hematoma

a. Rapid identification and evacuation are imperative to prevent compromise of the vascular pedicle secondary to compression. As part of the exploration of the hematoma, the establishment of hemostasis is imperative.

3. Seroma

a. May occur postoperatively, especially in cases with significant dead space

b. Can typically be managed in the office with repeat needle aspiration.

c. Failure to identify and evacuate a seroma may lead to infection and potential flap loss.

Alternative Management Plan

1. Healing by secondary intention

2. Skin graft reconstruction

3. Alternative regional flap reconstructions (pectoralis major flap, latissimus dorsi flap, etc.)

   a. See Chapters 174 and 176A.

4. Free flap reconstruction

   a. May be associated with increased operative times

   b. May be an appropriate choice for larger and more complex defects

   c. Allows for more versatility in reconstruction

Discussion

Evidence-Based Medicine Question

How does the use of the submental flap for the reconstruction of head and neck defects compare with the reconstruction of similar defects using free flaps?

Recent studies have compared the submental flap with radial forearm and anterolateral thigh free flaps for the reconstruction of glossectomy defects and lateral skull base defects.[4,5] Findings were that reconstruction with the regional submental flap resulted in reduced operative time and length of hospitalization compared with free flap reconstruction without any difference in functional outcomes or flap viability rates.

Editorial Comment

The cervicofacial flap, submental island flap, and supraclavicular flap are very versatile flaps for reconstructing defects of the face, oral cavity, pharynx, and lateral skull base. These flaps are relatively easy to harvest and are reliable. The color match is excellent for the face and neck. The flaps are very useful in patients whose necks are depleted of recipient

vessels and whose comorbidities may not allow prolonged anesthesia; that is, they serve well when time is of the essence.

Trapezius and Latissimus Dorsi Regional Flaps

Brittany Howard, and Trevor Hackman

Introduction

Regional pedicle flaps for reconstruction of the head and neck are most commonly harvested from ventral body surfaces due to the favorable patient positioning, location close to the primary defect, and familiar anatomy. Flaps from the dorsal body surface are advantageous because they can provide significant tissue bulk for reconstruction and a multitude of tissue types including cutaneous, muscular, and osseous options. Additionally, in patients who have undergone prior head and neck surgery, the vascularity of these flaps is often preserved compared to flaps from the ventral surface. The most common dorsal surface pedicled flaps used for head and neck reconstruction are the trapezius and latissimus dorsi flaps.

Key Operative Learning Points

1. Regional flaps from the dorsal surface can provide excellent reconstructive options for the head and neck region because they can provide large volumes of soft tissue and a variety of tissue types.

2. The latissimus dorsi regional flap is a reconstructive option for patients who have undergone prior neck surgery because its blood supply is from the subscapular system not from the neck.

3. The main cause of regional flap vascular compromise is poor pedicle geometry. Thus, flap planning and final inset should take this into consideration and ensure that the vascular pedicle lies easily without kinking, compression, or tension.

Preoperative Period

History

1. History of present illness:

   a. The cause of the defect should be determined because it can affect current and future reconstructive needs.

      1) In defects secondary to benign or malignant tumors, the risk of recurrence and possible need for future reconstruction should be considered. Donor sites that do not limit future reconstructive options are preferred (a supraclavicular flap may compromise future use of a lateral trapezius flap, because both are based on branches of the transverse cervical artery).

      2) In defects secondary to traumatic injury, the needs of immediate coverage must be weighed against goals of ultimate reconstruction. For example, a pedicled flap reconstruction may provide the most rapid/immediate solution for traumatic defect coverage. However, if a free flap would provide the best long-term results, a free flap may be the preferred reconstructive option despite the added time and complexity associated with this form of reconstruction.

   b. The extent and complexity of the defect requiring reconstruction should be determined.

      1) Reconstruction ideally replaces lost tissue with tissue of similar texture, thickness, and type. Thus, cutaneous tissue defects are ideally reconstructed with cutaneous tissue of similar color, thickness, and texture.

      2) A composite defect involving multiple tissue types is ideally reconstructed with equivalent tissue. Thus muscle is replaced with muscle, and bone is replaced with bone. Finding donor tissue matching the needs of the defect may guide a surgeon's decision when choosing between a regional flap and a free flap.

   c. Current function and future functional needs should be elicited.

      1) Preoperative swallowing and breathing should be evaluated.

2) Possible need for postoperative airway protection (tracheostomy) and nutritional support (nasogastric or gastric feeding tube) should be considered.

2. Past medical history

a. Prior treatment in the head and neck region:

1) History of surgery in the neck, axilla, and back may affect viability of regional reconstructive options.

2) Prior radiation may affect postoperative healing and flap viability.

b. Medical illnesses may affect flap viability and reconstructive outcomes:

1) Diabetes, especially if poorly controlled, can effect healing outcomes and flap viability.

2) Peripheral vascular disease may affect flap viability.

3) Coagulopathies may affect postoperative bleeding or coagulation.

4) Tobacco abuse/nicotine exposure is associated with arterial constriction and vascular insufficiency. This should be avoided in the perioperative period.

c. Family medical history:

1) Coagulopathies may affect postoperative bleeding or coagulation and thus flap viability.

d. Medications:

1) Consider the risks and benefits of discontinuing any drugs that may increase the perioperative risk of bleeding. A hematoma in the postoperative period can affect flap viability.

Physical Examination

1. Neck examination

a. The neck should be carefully evaluated for any scars or evidence of prior surgical intervention that the patient may have forgotten to mention during collection of the history of the present illness or past

medical history.

2. Extremity examination

   a. The axilla and extremity on the side considered for flap harvest should be carefully inspected for any evidence of scars suggesting prior surgery.

   b. The range of motion and strength of the extremity on the side selected for flap harvest should be carefully evaluated and documented preoperatively.

3. Doppler examination

   a. A Doppler examination to identify and trace the vascular pedicle should be performed prior to proceeding with surgery. This can be done in the office or on the day of surgery.

   b. The site of Doppler signals should be marked with a marking pen to facilitate future identification.

Imaging

1. No dedicated imaging of the neck, axilla, or back is required prior to planning or harvesting trapezius or latissimus dorsi flaps.

Preoperative Preparation

1. The side to be used for flap harvest should have the upper extremity marked “No Lines and No IVs” in the preoperative area. This extremity will be prepped into the surgical field.

2. Discontinue any medications that increase the risk of bleeding if medically safe.

Operative Period

Anesthesia

1. General anesthesia:

a. Due to the extent of dissection and positioning needs of the surgery, general anesthesia is necessary for the procedure.

b. Use of a paralytic agent is at the discretion of the surgeon. Some surgeons prefer paralysis during dissection because it relaxes muscles and makes manipulation easier. Others prefer no paralysis to aid in identification of motor nerves during dissection.

Positioning

1. Lateral decubitus

   a. Facilitates exposure of the back to the midline

   b. Requires placement of the axillary roll and careful positioning to prevent injury of the brachial plexus

2. Modified lateral decubitus

   a. Adequate exposure can be accomplished with placement of a bump or bean bag. There is less exposure of the back compared to a true lateral decubitus positioning.

   b. Does not require placement of an axillary roll

3. Prone

   a. Prone positioning may be preferred if trapezius or latissimus dorsi flaps are used to reconstruct the posterior neck or occipital defects.

Perioperative Antibiotic Prophylaxis

1. As indicated by the primary defect undergoing reconstruction

Monitoring

1. None necessary

Instruments and Equipment to Have Available

1. Handheld Doppler

2. Monopolar and bipolar cautery

3. Axillary roll

4. Bean bag

Operative Risks

1. Bleeding: Development of a hematoma must be carefully monitored because it can cause compression of the vascular pedicle and result in flap compromise.

2. Infection: Infection at the flap donor site is a relatively low risk, but the area may be contaminated by the defect undergoing reconstruction (especially in cases involving oral or oropharyngeal defects). Antibiotics should be chosen based on the primary site defect and associated risk of infection.

3. Scarring/cosmetic defect: It may be impossible to close donor sites primarily, and they may require split-thickness skin grafting. When split-thickness skin grafting is used, a less aesthetic donor site appearance will generally result, and a second donor site is created where the graft is harvested.

4. Flap loss: A significant risk in any flap reconstruction surgery is that of partial or total flap loss. In pedicled flaps, the most common cause of total flap loss is poor pedicle geometry with pedicle compression within a tunnel, kinking, or tension at time of inset. Care must be taken to avoid these situations. Partial flap loss may be due to numerous factors including the patient's peripheral vascular disease, perioperative hypo- or hypertension, rough handling of the tissue, and excess flap size resulting in random-pattern blood supply to distal flap tissues.

5. Damage to surrounding structures: During flap harvest and inset involving the trapezius flaps and latissimus dorsi flaps, there are multiple neurovascular structures at risk. The structures at risk include the brachial plexus and the accessory nerve. Damage to the brachial plexus can affect function of the shoulder and upper extremity. Damage to the accessory nerve or destabilization of key trapezius muscular insertions can result in shoulder droop and weakness.

Trapezius Flaps

Introduction

The trapezius muscle is a triangular muscle that extends from the occipital skull base, along the spine, to the level of the 10th thoracic vertebrae. It has insertions onto the lateral third of the clavicle, the spine of the scapula, and the acromion. The trapezius muscle is associated with three separate musculocutaneous flaps based on three separate vascular pedicles. These include the superior trapezius flap, the lateral trapezius flap, and the inferior trapezius flap. Because each of these flaps is based upon a unique vascular pedicle, they are considered, designed, and surgically elevated separately.

Superior Trapezius Flap

The superior trapezius musculocutaneous flap is based upon vascular contributions from the paraspinous muscular perforators and from branches of the occipital artery.[1] This flap requires a broad superior base to provide sufficient vascular supply and as such has a limited arc of rotation.[1] Although its limited arc of rotation decreases its applicability, it has the most reliable vascular supply of the trapezius flaps.[1]

Preoperative Period

Indications

1. Lateral neck defects. Due to the limited arc of rotation, this flap can only reach the lateral neck for defect reconstruction and hence has been supplanted by newer reconstructive options (i.e., supraclavicular flap).

Contraindications

1. Prior neck surgery that may have damaged the vascular supply from the occipital artery. However, the flap may be viable from paraspinous perforators.

2. Anticipated poor wound healing because the donor site often cannot be closed primarily and must be left to heal by secondary intention or with skin grafting

Operative Period

Surgical Technique

1. The flap is designed by incorporating the skin overlying the trapezius muscle with a superior and medial base.

2. The superior/anterior incision is placed along the anterior edge of the trapezius muscle.

3. The inferior incision is designed parallel to the anterior incision at the level of the scapular spine.

4. The lateral extent of the flap is designed at or beyond the level of the acromion.

5. The incisions are opened and the flap is elevated in a lateral-to-medial direction.

6. Laterally the flap is elevated in a plane deep to the deltoid fascia.

7. Once the acromion is reached, the trapezius is elevated sharply off its bony insertions.

8. The flap is lifted off the supraspinatus muscle deep to the muscular fascia.

9. The flap can now be rotated and inset for reconstruction of the defect.

10. The donor site is closed primarily or skin grafted.

11. The transverse cervical vessels are commonly identified during this portion of the procedure and should be divided.

Common Errors in Technique

1. Division of the transverse cervical vascular pedicle aids in elevation of the flap and improves the arc of rotation.

2. A back-cut at the lower incision beyond the midline increases the arc of rotation of the flap.

Lateral Trapezius Flap

The lateral trapezius is based upon the transverse cervical artery. Similar to the superior trapezius flap, it is designed overlying the superior portion of the trapezius muscle. Compared to the superior trapezius flap, the lateral trapezius flap has improved applicability because it allows harvest of a larger musculocutaneous paddle, has a better arc of rotation for head and neck defects, and the donor site can often be closed primarily. Additionally, the lateral trapezius flap can be harvested as an osseomusculocutaneous flap with incorporation of vascularized spine of the scapula.

Preoperative Period

Indications

1. Reconstruction of soft tissue defects of the lateral neck, lateral skull base, oral cavity, and oropharynx

2. Reconstruction of composite defects of the lateral mandible (as an osseomusculocutaneous flap)

Contraindications

1. Prior neck surgery that may have injured or divided the transverse cervical vascular pedicle

Operative Period

Key Anatomic Landmarks

1. The origin of the transverse cervical artery is variable, and it can arise from the thyrocervical trunk, suprascapular artery, subclavian artery, or

dorsal scapular artery.

Surgical Technique

1. The flap is centered on the transverse cervical artery. The long axis of the flap is designed between the vertebral column and the medial scapula edge. Typical flap size is 6 to 8 cm wide by 30 to 38 cm long. The inferior end of the flap can extend up to 13 cm distal to the trapezius muscle. A flap that extends past the trapezius muscle edge has a random-pattern blood supply.

2. Flap elevation begins with identification of the transverse cervical vascular pedicle in the neck. Once identified, the pedicle is traced to its entrance into the trapezius muscle. This ensures that the pedicle is preserved and not accidently divided during flap elevation.

3. The medial incision is then made down to the level of the trapezius muscle fibers. The trapezius muscle is then divided at the medial edge of the flap.

4. The muscle is elevated from medial to lateral identifying the previously preserved transverse cervical vascular pedicle on the undersurface of the muscle, deep to the fascia.

5. The lateral incision can then be opened through the muscular layer, again preserving the vascular pedicle.

6. The flap is elevated off of the deep tissues (latissimus and rhomboid muscles) working from inferior to superior. During this dissection, the dorsal scapular artery will be encountered as it pierces between the rhomboids and must be divided to allow flap elevation and rotation.

7. The flap can then be rotated and inset for reconstruction of the defect.

8. The donor site is closed primarily, and suction drains are placed.

Common Errors in Technique

1. If primary closure of the donor site is desired, the flap should not exceed 8 cm in width.

2. The spine of the scapula should be the superior extent of the dissection

to preserve the lateral attachment of the trapezius to the scapular spine and acromion. Shoulder function is preserved by maintaining these attachments. Dissection superior to this line can result in shoulder droop and weakness.

3. Anatomic variations have been described in which the transverse cervical vascular pedicle passes through portions of the brachial plexus. Flap harvest should not be pursued in these cases.

Lower Trapezius Flap

The inferior or lower trapezius musculocutaneous flap is based upon the dorsal scapular vascular pedicle. This is commonly considered the most versatile of the trapezius flaps because its long vascular pedicle from the dorsal scapular artery allows for a wider arc of rotation and reach.[2-5] Additionally, the lower trapezius flap is advantageous because the distal skin paddle is thin and pliable when compared to the other trapezius flaps.

Preoperative Period

Indications

1. Reconstruction of defects of the face, scalp, lateral skull base, neck, oral cavity, and oropharynx

Contraindications

1. Prior neck dissection resulting in disruption of the vascular supply to the dorsal scapular vascular pedicle (which can be a branch of the transverse cervical artery)

Operative Period

Key Anatomic Landmarks

1. The dorsal scapular artery originates from the transverse cervical artery or as a separate branch from the subclavian artery.

2. The dorsal scapular artery courses deep to the levator scapulae muscle. Its main branch to the lower trapezius flap penetrates between the rhomboid muscles. The vascular pedicle then runs inferiorly along the deep surface of the trapezius to supply the lower third of the trapezius muscle and the overlying skin.

3. Anatomic landmarks that should be marked at the beginning of the case include the margins of the trapezius muscle, the medial border of the scapula, and the thoracic spine with demarcation of the 12th vertebrae.

Surgical Technique

1. The flap is designed such that at least one-third of the skin island overlies the trapezius muscle. There is a greater density of perforating vessels medially near the thoracic spine compared to laterally (Fig. 172.1A).

2. The inferior extent of the flap should not exceed 10 cm distal to the inferior edge of the scapula. The cutaneous flap component that is not centered over the muscle is perfused by a random-pattern blood supply and is at greater risk of vascular insufficiency.

3. The medial incision is made first to the level of the trapezius muscle. The trapezius muscle is then divided, being careful not to injure the underlying latissimus dorsi muscle.

4. The dissection plane between the trapezius muscle and the latissimus dorsi muscle is then developed working from inferior-medial to superior-lateral.

5. During this dissection the course of the dorsal scapular artery can be seen as it descends along the deep surface of the trapezius muscle within the fascia layer.

6. With the vascular pedicle protected, the lateral flap incisions can be made to free the island flap.

7. The superior apex of the flap incision is then extended superiorly,

along the medial border of the scapula.

8. The vascular pedicle is traced, dividing the overlying trapezius muscle fibers to free the pedicle and increase its pedicle length.

9. The pedicle is traced until it is seen diving between the bellies of the rhomboid muscles.

10. At this point the flap can be rotated and inset for reconstruction of the defect, suction drains are placed and the donor site is closed primarily. (see Fig. 172.1B).

Common Errors in Technique

1. If the arc of rotation is insufficient to allow inset, the minor rhomboid muscle can be divided to improve the arc of rotation.

Latissimus Dorsi Flap

Introduction

The latissimus dorsi flap was the first regional musculocutaneous flap described. The latissimus dorsi muscle is a long, broad, and flat muscle that originates from the aponeurosis joining the posterior layer of the thoracolumbar fascia from about the sixth thoracic vertebra to the posterior iliac crest. The muscle then inserts into the intertubercular groove of the humerus. The reconstructive strength of the latissimus dorsi flap lies in the fact that it provides the largest volume of soft tissue and the greatest arc of rotation of any regional flap available to the head and neck surgeon. This versatile and reliable flap can include the entire latissimus dorsi muscle and its overlying cutaneous component, based upon musculocutaneous perforators.[6-8] When designed for reconstruction of head and facial defects, the latissimus dorsi flap is based on the thoracodorsal artery. This flap can also be harvested as a free tissue transfer and combined with other flaps in the subscapular system (scapula tip, scapular and parascapular flaps) for chimeric designs.

Preoperative Period

Indications

1. Reconstruction of lateral neck defects, oral defects, oropharyngeal defects, and lateral and posterior skull base or scalp defects

Contraindications

1. Inability to position in lateral or modified lateral decubitus position

2. Contralateral or midline defects (this limitation can be overcome by using the latissimus dorsi flap as a free flap)

Operative Period

Key Anatomic Landmarks

1. The thoracodorsal artery and vein form the vascular pedicle to the latissimus dorsi flap

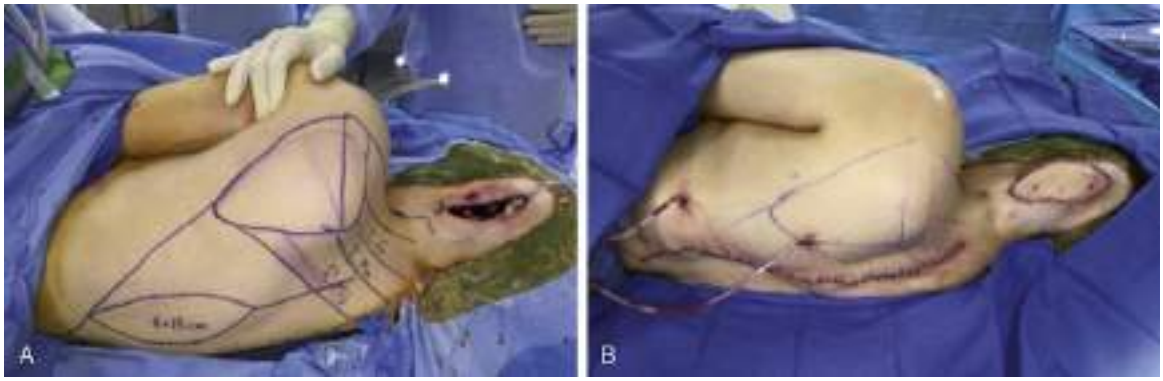

FIG. 172.1 Lower island trapezius flap; design and closure.

A, Pre operative flap incision planning ***B,*** Donor site closure after flap harvest. Courtesy of Jason Rich.

a. The thoracodorsal vessels typically originate from the subscapular

vessels separate from the circumflex scapular vessels (Fig. 172.2A).

b. The thoracodorsal pedicle enters the latissimus dorsi muscle 8 to 12 cm proximal to the humeral attachment of the muscle.

c. After entering the muscle, the pedicle divides into two primary branches that parallel the superior and anterior edge of the muscle.

d. The majority of cutaneous perforating vessels occur along the anterior edge of the muscle in the upper two-thirds.

2. The thoracodorsal nerve innervates the latissimus dorsi. Its course runs parallel to, and often intertwines with, the vascular pedicle.

Surgical Technique

1. Once positioned, the lateral edge of the latissimus is palpated and marked.

2. If a cutaneous component is to be harvested, it is designed as an ellipse or otter tail overlying the latissimus muscle. It is designed with its long axis parallel to the lateral muscle edge and located such that it captures the greatest density of perforators, which occur at the lateral, superior aspect of the muscle.

3. The arc of rotation is checked to ensure that the flap will reach the defect prior to placement of incisions.

4. Incisions are then made along the lateral edge and into the axilla. Dissection is carried down to the level of the latissimus muscle, and the anterior/lateral edge of the muscle is exposed along its full length.

5. The anterior skin flap is then elevated and undermined to expose the serratus muscle. This increases exposure and aids in future closure of the donor site.

6. With the lateral edge of the latissimus fully exposed, the thoracodorsal pedicle is identified by blunt dissection along the lateral edge of the latissimus muscle.

7. The pedicle is then traced to its origin from the subscapular system (see Fig. 172.2A). Vascular branches to the serratus and teres major muscle are identified and ligated. Dissection of the vascular pedicle is

aided by manipulation of the upper extremity by the surgical assistant to aid in exposure.

a. Various chimeric flaps can be created by incorporating the serratus anterior and fifth or sixth rib, the scapular system (skin and lateral bone border of the scapula) based on the circumflex scapula system, or the scapula tip (bone, muscle) based on the angular artery into the harvest.

8. The thoracodorsal nerve is identified and divided to aid in muscular atrophy and to prevent future accidental vascular compression by muscular activity.

9. The flap is then elevated in a distal-to-proximal direction. Distal division of the latissimus muscle is performed to allow adequate tissue to reach the defect to be reconstructed in a tension-free fashion.

10. Once the distal muscle is freed, the medial cutaneous incisions can be safely made, and the medial skin flap can be elevated to allow increased medial exposure.

11. Medial incisions through the latissimus muscle are made, and the flap is elevated off the underlying teres major muscle. Care is taken to divide and ligate any perforating vessels between the muscle bellies.

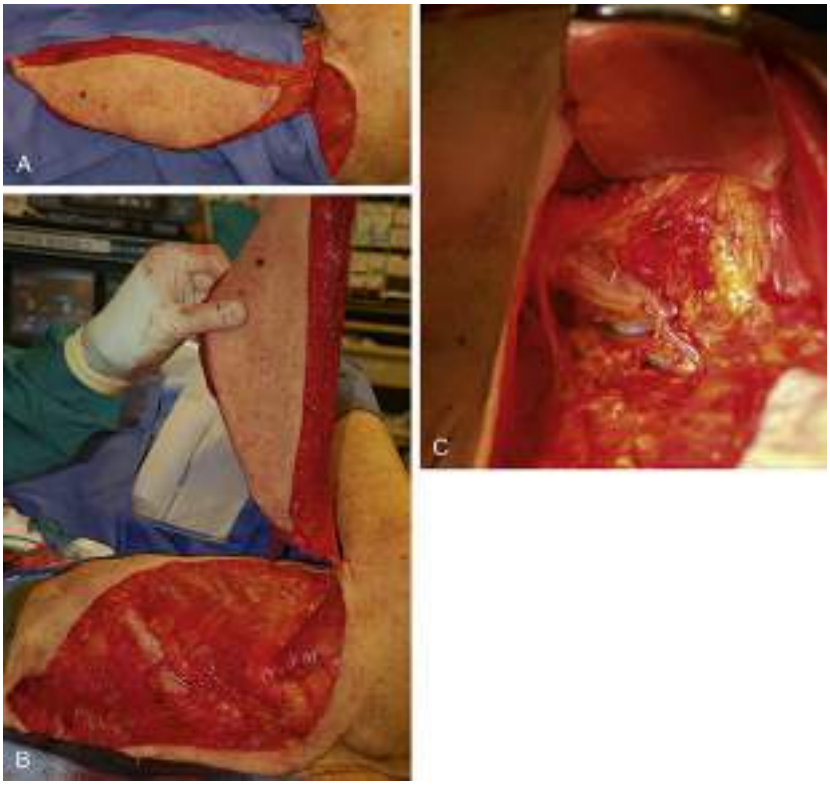

FIG. 172.2 Latissimus flap harvest.

A, Subscapular arterial system. **B** and **C,** Fully elevated latissimus flap pedicled on the thoracodorsal system.

FIG. 172.3 Defect and inset.

A, Left lateral skull base defect including craniectomy and neck dissection. **B,** Operative closure. **C,** Results 2 months after the procedure.

12. A tunnel is now created through the axilla to the neck.

a. Working from the axilla, a tunnel is created between the pectoralis major and minor muscles.

b. During this dissection, the thoracoacromial pedicle can be visualized and should be preserved to protect the pectoralis major flap for possible future use.

c. Working now from both the cervical and axillary incisions, a section of the clavicular head of the pectoralis major muscle is divided while protecting the thoracoacromial pedicle.

d. This sectioned muscle should be large enough to allow the operator's hand to easily pass between the neck and axilla. This ensures that the tunnel is large enough so that the latissimus muscle flap or pedicle will not be compressed.

13. Finally, the humeral tendon of the latissimus muscle is divided to finish freeing the flap (see Fig. 172.2B and C).

14. The flap is now rotated and passed through the tunnel into the neck. It can now be inset for reconstruction (Fig. 172.3).

15. Suction drains are placed and the incision on the back is closed primarily. When the width of the flap exceeds 10 cm, primary closure may not be feasible. In these cases, vacuum-assisted closure (VAC) devices can be placed within the closure line and serve as the suction drain for the site, obviating the need for drains, and assist with wound closure (Fig. 172.4).

Common Errors in Technique

1. Kinking of the vascular pedicle is common when it is rotated and passed through the tunnel. Care must be taken to ensure optimal pedicle geometry. Preservation of the circumflex scapular system may help anchor the vascular pedicle and allow a gentle curve without kinking.

2. Waiting until the final step to divide the latissimus dorsi humeral

attachments decreases the chances of the flap applying unsupported force on the vascular pedicle.

3. Care must be taken to prevent hyperextension or hyperabduction of the upper extremity during dissection because either event can result in injury to the brachial plexus.

Postoperative Period

Postoperative Management

1. Flap monitoring

   a. For pedicled flaps, the need for close monitoring of the flap is debatable because the likelihood of pedicle compromise is low.

   b. Frequency and need are at the surgeon's discretion.

   - Typical flap monitoring by nursing can include monitoring for Doppler signal, capillary refill, color, and warmth.
   - We routinely perform flap checks every hour for 24 hours, then every 2 hours for 24 hours, then every 4 hours after that.
   - The patient may need to be in the ICU or on an intermediate-level nursing floor to allow for frequent flap checks.

2. Drains: Suction drains should be placed to help evacuate fluid from the donor site dead space. They can be removed when drainage is clear and less than 30 mL per 24 hours.

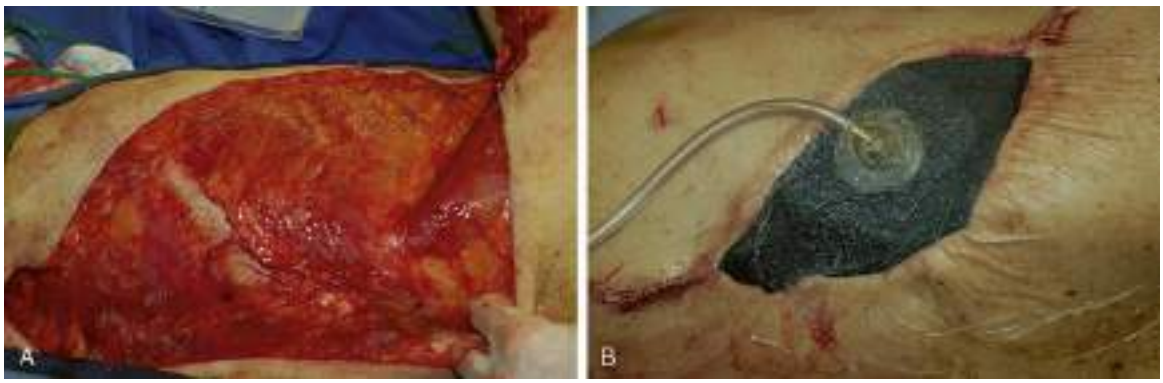

FIG. 172.4 Latissimus defect and closure.

A, Donor site defect (too wide for primary closure). **B,** Vacuum-assisted closure of the defect.

3. Pain medication: Patients often experience significant discomfort following harvest of these flaps. Typically, they initially require IV and oral/enteral pain medication postoperatively. They should be transitioned to oral/enteral pain medication within the first 24 to 48 hours.

4. Physical therapy: Early aggressive physical therapy is important to ensure that the patient regains maximum function in the operated shoulder and upper extremity. We initiate therapy within 48 hours of completion of surgery.

Complications

1. Flap viability can be compromised by multiple factors, and early identification is important to maximize the likelihood of flap salvage.

a. Arterial compromise

- Most commonly secondary to arterial compression from vascular pedicle geometry or hematoma
- Typically requires return to the operating room for exploration of the vascular pedicle and to see if arterial flow can be reestablished

b. Venous compromise, which is more common than arterial compromise

- Most commonly secondary to venous kinking or compression from vascular pedicle geometry or hematoma
- Requires return to the operating room for exploration of vascular pedicle and to try to reestablish venous flow
- If venous flow cannot be reestablished, the flap may be salvaged by the use of leeches and heparin scrub to provide venous outflow from the flap.
- Failure to treat venous compromise will progress to arterial compromise as pressures within the venous system overcome the perfusion pressure from the feeding artery.

2. Hematoma

   a. Early identification and evacuation are key to preventing complications of infection or flap compromise. This should be done in an urgent and sterile manner.

3. Donor site dehiscence

   a. Treat with local wound care, and allow to heal by secondary intention if the vascular pedicle is not exposed.

   b. If the vascular pedicle is exposed or at risk, the patient should be returned to the OR for revision of the wound.

4. Upper extremity and/or shoulder weakness

   a. The most common cause is brachial plexus traction injury. Reassurance should be provided because the majority of these will resolve, although full return of function may take several months. Aggressive physical therapy is necessary to maximize recovery.

   b. In the case of nerve injury or division, the mainstay is physical therapy to maximize recovery.

Discussion

Evidence-Based Medicine Question

What is the most appropriate nomenclature for describing the vascular pedicle supplying the lower trapezius flap? There are conflicting reports of it being based off the transverse cervical artery versus the dorsal scapula artery.

Historically, the lower trapezius flap has been described as receiving its blood supply from the transverse cervical artery and/or the dorsal scapula artery. This confusion stems, in part, from the fact that the dorsal scapula artery can be a branch of the transverse cervical artery (referred to in those cases as the deep branch of the transverse cervical artery). To address this, an extensive anatomic study of the vascular pattern supplying the lower trapezius flap in 124 cadavers was reported in 2004 by Haas et al.[2] The authors found that the vessel supplying the lower trapezius flap was a deep branch of the transverse cervical artery in 55%

of cadavers; however, 45% of the vessels originated directly from the subclavian artery (41%) or the costocervical trunk (4%). Thus, the vessel supplying the lower trapezius flap is best referred to as the dorsal scapula artery because it is anticipated to originate separately from the transverse cervical artery in nearly half of all cases.

Editorial Comment

With the ongoing challenges in health care resources and reimbursement, the importance of pedicled flaps cannot be underestimated. The cost savings, in addition to good functional results, make these flaps appealing. The trapezius and latissimus dorsi flaps provide coverage for multiple defects. Expertise in harvesting and insetting these flaps should be in the armamentarium of every reconstructive surgeon.

Review Questions

1. The latissimus dorsi musculocutaneous flap receives its arterial supply from which artery?

   a. Transverse cervical artery

   b. **Thoracodorsal artery**

   c. Dorsal scapula artery

   d. Circumflex scapular artery

2. The lateral trapezius flap receives its arterial supply from which artery?

   a. **Transverse cervical artery**

   b. Thoracodorsal artery

   c. Dorsal scapula artery

   d. Circumflex scapular artery

3. The lower trapezius flap receives its arterial supply from which artery?

   a. Transverse cervical artery

b. Thoracodorsal artery

c. **Dorsal scapula artery**

d. Circumflex scapular artery

4. The lateral trapezius flap can be harvested as an osseomusculocutaneous flap by including a portion of which of the following?

a. Lateral border of the scapula

b. Medial border of the scapula

c. **Scapula spine**

d. Scapula tip

Skin Grafting

Adam Terella, and John Song

Introduction

There are two basic types of skin grafts: full-thickness and split-thickness skin grafts (FTSGs and STSGs, respectively). Full-thickness grafts are composed of epidermis and full-thickness dermis, including adnexal structures, whereas split-thickness grafts are composed of epidermis and varying amounts of dermis without adnexal structures. Each type of graft has unique characteristics and indications for use in head and neck reconstruction. Although improved techniques with local or regional vascularized tissue transfer have resulted in the decreased use of skin grafts in reconstruction, there are circumstances in which skin grafts may still represent the best reconstructive option.

Key Operative Learning Points

- Choosing the correct thickness for a skin graft is critical (full vs. split) to optimizing function and aesthetics.
- In general, FTSGs will approximate skin color and texture and limit contraction better than STSGs.
- STSGs have a higher rate of survival on wound beds with minimal vascularity due to decreased metabolic demand.
- Meticulous hemostasis of the wound bed and immobilization and prevention of shearing forces on the skin graft by proper suturing and bolstering techniques enhance graft take through apposition of the graft to the recipient bed.

Preoperative Period

When considering using a skin graft for reconstruction, several factors must be considered in the preoperative period:

- Characteristics of the defect (certainty of margin status, location/surrounding anatomy, depth, vascularity of recipient bed)
- Characteristics intrinsic to the type of graft (full thickness vs. split thickness vs. allograft/xenograft)
- Characteristics of the patient (systemic illness, patient expectation, reconstructive goals)

With careful consideration of all of these factors, a well-developed reconstructive plan can be established.

Characteristics of the Defect

As with any reconstruction, facial aesthetic subunits must be considered when determining whether or not a skin graft is the most appropriate surgical repair. The face can be divided into aesthetic subunits, within which the skin will have similar characteristics. It is helpful in the preoperative period to mark the divisions of the facial subunits as they relate to the existing or proposed soft tissue defect. By doing so, scars can be placed along zones of transition between adjacent subunits, thus helping to camouflage a reconstruction. Occasionally, enlarging a defect to allow resurfacing an entire aesthetic subunit may be desirable.[1]

When using a skin graft, the surgical defect should not include a large portion of a free margin, such as the alar rim or vermillion border. If placed along a free margin, graft contraction during healing can result in distortion of the free margin, such as eclabium or ectropion.

The vascularity of the defect must be taken into account when considering a skin graft. To a large extent, the viability of a skin graft depends on acquiring a blood supply from the wound bed. Graft "take" requires an adequate vascularity of the recipient bed, direct contact between graft and recipient wound bed, avoiding hematoma or seroma formation, and preventing shearing forces. Hematoma, seroma, and shearing forces separate the graft from the bed and disrupt

revascularization.

Characteristics of the defect unfavorable for skin graft "take" include radiated tissue, exposed cortical bone, cartilage, tendon, or actively bleeding tissue. In general, grafts placed over avascular defects are unlikely to survive. When attempting to skin graft over cortical bone, survival is enhanced if a thin layer of the outer cortex is taken down with a 6-mm cutting burr until punctate bleeding is noted.[1] If this is not possible, coverage of the avascular defect with a fascial or muscle flap can provide vascularity for a skin graft.

Characteristics of Full-Thickness Skin Grafts

FTSGs will resist contraction and have a texture and pigmentation more similar to normal skin than STSGs. However, the increased dermal thickness results in increased metabolic demand and thus a need for a well-vascularized wound bed for survival. This may result in decreased rates of graft survival and longer healing times.[1]

Appropriate donor sites for FTSGs largely depend on the location of the defect and the characteristics of the tissue being replaced. Replacing "like tissue with like tissue" should be the goal. Commonly used donor sites include supraclavicular fossa, postauricular, preauricular, or upper eyelid. The supraclavicular region is best for harvesting large FTSG, due to significant laxity in the region and ease of primary closure. Postauricular skin is an optimal donor site in males because it is usually hairless and allows for a camouflaged donor site scar. In females, a preauricular skin graft provides better skin color match and usually is not hair bearing. Contralateral upper eyelid skin provides a thin, full-thickness graft that is desirable for shallow perioccular defects.[2]

Characteristics of Split-Thickness Skin Grafts

STSGs are composed of epidermis and partial-thickness dermis without adnexal structures. STSGs tend to have more exposed capillaries on the undersurface than FTSGs and thus can revascularize more quickly. They also have less tissue and thus have a lower metabolic demand than

FTSGs, improving graft survival when the wound bed has limited vascularity. In contrast to FTSGs, STSGs tend to contract and have a poor texture and color match with normal facial skin, resulting in a suboptimal cosmetic outcome.

For large defects, an STSG can be an expedient technique for providing wound coverage. In these situations, the STSG may be meshed at ratios of 1:1.5 or 1:3 to increase the area that can be covered, while improving take rates by preventing hematoma or seroma. However, depending upon the location of the defect the use of a meshed graft can give a suboptimal cosmetic result.

History

1. History of present illness
   a. Duration of wound (chronic vs. acute)
   b. Etiology of defect (basal cell carcinoma, squamous cell carcinoma, melanoma, traumatic)
   c. Margin status (if following resection of malignancy)
   d. Need for ongoing close tumor surveillance
   e. Cosmetic expectation of the patient
   f. Need for adjuvant treatment or radiation
   g. Evidence of active infection or inflammatory skin disease
2. Past medical history
   a. Prior malignancy
   b. Previous treatment or intervention of prior malignancy or defect
   c. Previous radiation to the head and neck
   d. Past surgery or trauma that may affect flap donor site or inability to use local or regional flaps
3. Medical illnesses: All of these negatively impact graft survival.[2]
   a. History of cardiopulmonary disease "Are you able to walk up a flight of stairs?"
   b. Diabetes

c. Hematologic disorders

d. Collagen vascular disease

e. Malnutrition

f. Immunosuppression (e.g., solid organ transplant, human immunodeficiency virus (HIV))

4. Medications

a. Anticoagulation

b. Immunosuppression

5. Social history[3]

a. Tobacco use: cigarettes, smokeless tobacco, nicotine replacement

Physical Examination

1. Determine the need for FTSG versus STSG versus the placement of a skin substitute.

2. Look for evidence of infection in the wound bed.

3. Gain an understanding of the vascularity of the wound base (bone, fascia, adipose tissue, muscle, granulation).

4. Is saliva bathing the graft site?

5. Feasibility of skin graft immobilization to prevent shearing forces

6. Evaluate potential depth mismatch with surrounding tissue. Evaluate actinic change and potential color mismatch with skin from proposed donor site.

7. Does the defect or wound approximate the boundaries of an aesthetic facial subunit?

8. Does the defect or wound involve greater than 50% of an aesthetic facial subunit?

9. Is the involved facial subunit a concavity or convexity?

10. Is the defect in close proximity to structures that may be distorted by graft or wound contraction (lower eyelid, alar margin, oral commissure)?

11. Evaluate donor sites for desirable characteristics.

Imaging

None necessary

Indications

Although there is virtue in using the simplest solution to a given problem, at times more complex methods of reconstruction may be preferred and will result in significantly better outcomes. For this reason, one should use the most appropriate level of reconstruction. Skin grafting may be indicated for any defect that:

- Primary closure would result in a suboptimal functional or aesthetic outcome
- Local or regional flaps result in undesirable distortion of anatomy (e.g., ectropion) or donor site morbidity
- Complete closure of a defect with a local flap/regional results in excessive flap tension and thus vascular compromise
- Is associated with deeply invasive tumors or uncertain margins, where close surveillance of the area is necessary
- Requires temporary closure of a defect pending definitive or staged reconstruction
- In patients who cannot tolerate long periods of anesthesia

Contraindications

- Contraindications to skin grafting include wound characteristics unfavorable for graft "take." In general, grafts placed over avascular defects, such as radiated tissue, exposed cortical bone, cartilage, tendon, or actively bleeding tissue, are unlikely to survive.

Preoperative Preparation

- Identify potential donor sites with desirable characteristics. For large FTSGs, the supraclavicular region is often best due to significant laxity that enables primary closure. For facial defects in males, postauricular skin is appropriate because it is usually hairless. In females, a preauricular skin graft provides an appropriate skin color match and usually is not hair bearing. Contralateral upper eyelid skin is an appropriate FTSG donor site for perioccular defects.
- When a skin graft is used on a wound with abundant granulation tissue, a 10-day course of antistaphylococcal antibiotics may be started 3 days prior to grafting. Granulating wounds commonly have high bacterial levels, which can negatively affect the take of the graft.

Operative Period

Anesthesia

- Some small skin grafts can be harvested under local anesthesia with or without conscious sedation. However, for larger grafts, general anesthesia is recommended, as it can be difficult to anesthetize a large donor site.

Positioning

- Patients are typically placed in a supine position or any position necessary to allow access to both the donor and recipient sites.

Perioperative Antibiotic Prophylaxis

- Appropriate antibiotic coverage for the primary site should be chosen and administered prior to resection.
- In general, amoxicillin-clavulanate, clindamycin, or cephalosporin and metronidazole all provide adequate antibiotic coverage. If drug-resistant skin flora exists, appropriate antibiotic coverage should be used in consultation with a specialist in infectious disease.

Monitoring

- Usual monitoring for general anesthesia

Instruments and Equipment to Have Available

- Powered dermatome (preferred for larger harvest sites):
  - Padgett, Davol, and Zimmer powered dermatomes all can be used. Zimmer dermatomes are most commonly used nowadays because they are more likely to harvest a graft of more uniform depth and width (Fig. 173.1).
- Nonpowered dermatome:
  - Weck knives, scalpels, and double blades can be used for small graft harvests. These instruments usually require practice and a higher level of technical skill to harvest grafts of uniform thickness.

Key Anatomic Landmarks

- Graft harvest sites should be designed as to minimize cosmetic and functional deficits.
- For split-thickness grafts harvested from the thigh, the graft site should be placed in the mid or lateral skin and at least four fingerbreadths from the patella, so as to not interfere with knee flexion and extension.
- FTSG harvested from the supraclavicular region should be harvested from the fossa, which avoids placing the resulting closure directly over the clavicle. Preauricular or upper eyelid harvests should be placed along the naturally occurring preauricular crease or supra tarsal crease, respectively.

Prerequisite Skills

- Basic soft tissue handling skills are required for harvest, transfer, inset, and bolster placement.

Surgical Technique

- STSG harvest with Zimmer dermatome
  - An appropriate-sized plate is selected so that the graft is approximately 10% to 15% wider than the size of the defect. The width of the graft should allow enough slack so that the graft can make full contact with the underlying recipient site and is not tented up (see Fig. 173.1A and B).
  - The thickness of the skin harvest is most commonly set for 0.012 inches. A thin graft will have a higher rate of take and be more resistant to infection (see Fig. 173.1C).
  - The donor site is lubricated with mineral oil. With an assistant providing constant countertraction, the Zimmer dermatome is engaged at a 30- to 45-degree angle. As the dermatome flattens along the harvest site, uniform pressure is applied, and the dermatome is continuously running until the predetermined end of the graft. The dermatome exits at the same 30- to 45-degree angle (Fig. 173.2A to C).
  - The surgeon can visualize the harvest as the landing and taking off of an airplane, using the same 30- to 45-degree angle.
  - It is critical that the dermatome is running throughout the entire harvest.
  - Lidocaine (1%) with epinephrine (1:100,000) is applied to the donor site and allowed to sit while the graft is inset into the recipient site. This technique allows for hemostasis as well as local anesthesia to minimize postoperative pain (see Fig. 173.2D and E).
  - A semiocclusive dressing for the donor site is placed. Adhesive is applied to the periphery of the donor site. Tegaderm is applied over the donor site and secured to the adhesive peripherally (see Fig. 173.2F). The transparent dressing allows for accumulation of serosanguineous fluid over the donor site and promotes more rapid epithelialization than either occlusive or nonocclusive dressings. Visual inspection of the fluid also allows for early detection of infection.
  - The skin graft can be meshed to increase its surface area, to create

slits to allow fluid to escape from beneath the graft, and to allow for better adherence to an irregular recipient site (Fig. 173.3A to C). The graft is meshed at a 1:1.5 or 1:2 ratio, as the space between the meshes has to heal by secondary intention. Meshing at a higher ratio can result in significant contracture of the wound, as well as a checkered appearance of the wound and increased healing time. Smaller meshes ("pie crusting") can be created by hand using a scalpel blade and may be preferred in recipient areas where a checkered appearance would have significant cosmetic impact.

- For graft inset, the graft is loosely draped over the recipient site with the dermal (lighter) side down. The graft should be loose enough to prevent tenting but not so loose as to create overlapping folds. 4-0 Vicryl sutures are used to secure the graft circumferentially to the edge of the recipient bed, as well as in between the meshes to increase its adherence to the bed (see Fig. 173.3C).
- A bolster is used to provide uniform pressure over the graft. Immobilizing the graft with an occlusive material prevents shearing and the accumulation of fluid under the graft. The bolster is secured with 2-0 silk sutures in a "star-burst" pattern radially. Xeroform gauze wrapped around moistened cotton balls is often used (Fig. 173.3D and E), but other bolsters including foam, Adaptic, or a wound vacuum-assisted closure (VAC/negative pressure wound therapy) system can also be used.

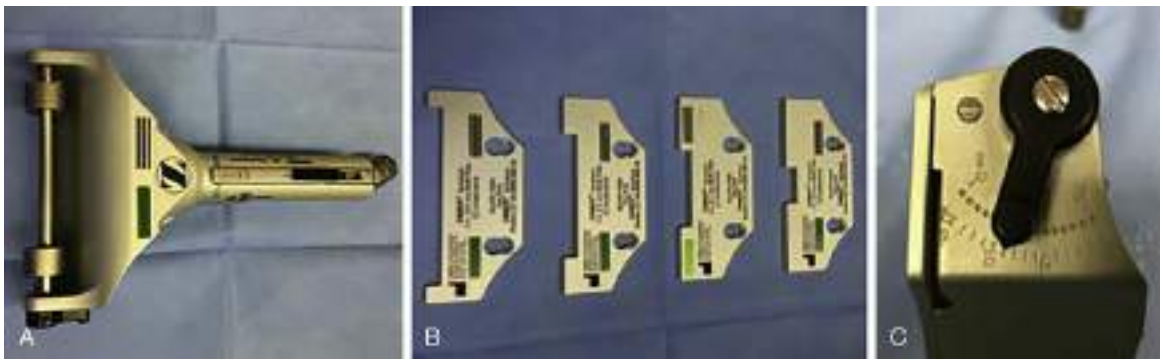

FIG. 173.1 **A,** Zimmer Air Dermatome. **B,** Serially sized harvest plates. **C,** Dermatome thickness is set at 0.012 inches.

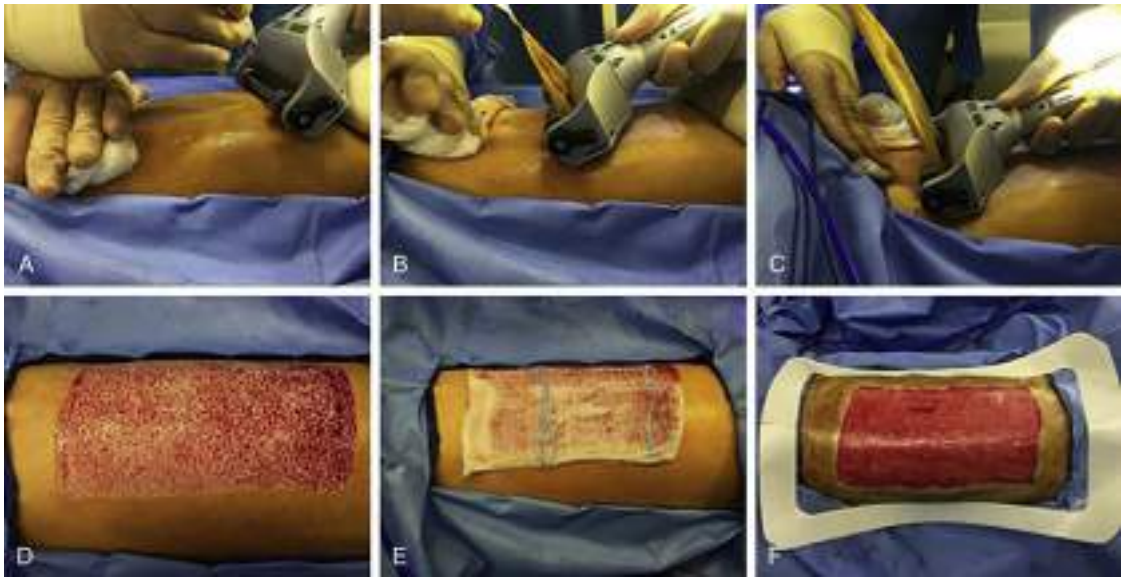

FIG. 173.2 **A** to **C,** The donor site has been lubricated with mineral oil. With an assistant providing constant traction, the dermatome is engaged at a 30- to 45-degree angle. Even pressure is applied, and the dermatome exits at the same 30- to 45-degree angle. The assistant retracts the graft as it is being harvested. **D,** Donor site appearance after harvest. **E,** Lidocaine (1%) with epinephrine (1:100,000)-soaked gauze is applied to the donor site for hemostasis and local anesthesia. **F,** A large Tegaderm dressing is applied after application of adhesive around the donor site.

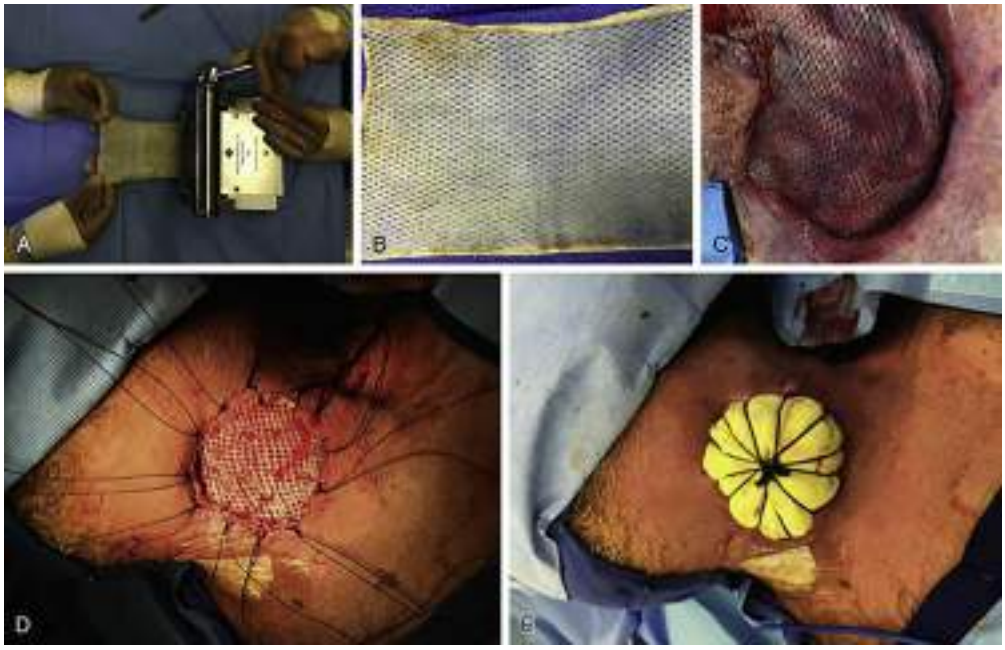

FIG. 173.3 **A** to **C,** Skin graft is meshed using a meshing device. This graft has been meshed to a 1:1.5 ratio. Meshing allows for better adherence to an irregular donor site surface and prevents fluid buildup under the graft. **D** and **E,** The graft is secured to the borders of the recipient bed with 4-0 Vicryl sutures. The same sutures are placed between the meshes to secure the graft to the recipient bed. A xeroform gauze is used as a bolster and is secured with circumferential 2-0 silk sutures in a star-burst pattern.

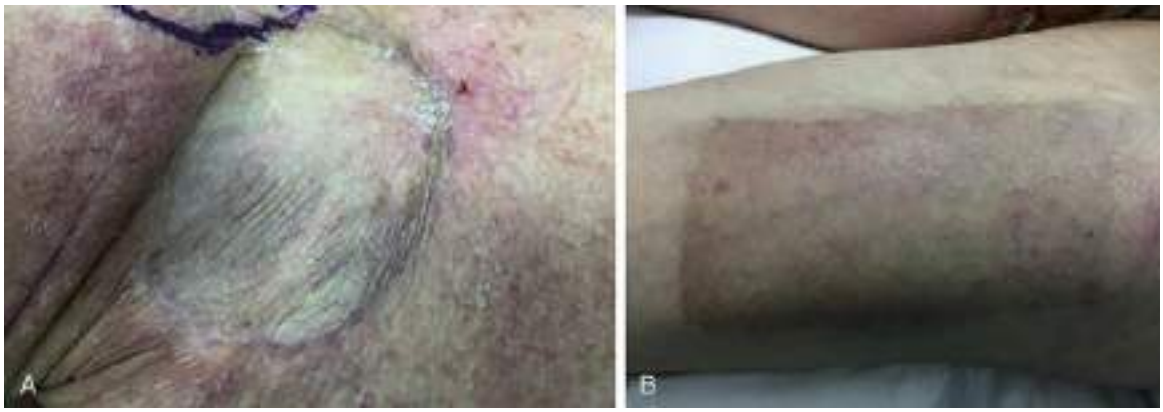

FIG. 173.4 **A** and **B,** Recipient and harvest sites at 4 weeks postoperative. The graft has 100% take, and the

donor site has healed evenly and is smooth to the touch.

- FTSG harvest
  - A template is made of the surgical defect using Telfa and oversized by approximately 10% to account for graft contraction. If local anesthesia is being used at the donor site, the graft should be designed prior to injection in order to prevent distortion of measurement due to tissue expansion. The graft is harvested deep to the dermis, attempting to leave subcutaneous adipose tissue off the graft surface. After being excised from the donor site, a curved Iris scissor is used to thoroughly remove all remaining subcutaneous adipose tissue, revealing the white dermis of the graft.
  - Graft inset: The graft is placed onto the donor site so as to maximize contact between graft and wound bed. Interrupted circumferential tacking sutures are placed, using a 5-0 chromic suture. If the graft is large, sutures are placed through the midportion of the graft to prevent "trampolining" of the graft off of the wound bed.
  - A few slits are made in the center of the graft to prevent hematoma formation similar to that of an STSG.
  - Bolstering is then completed as outlined above for split-thickness grafting.

Common Errors in Technique

- Engaging the dermatome at an angle less than 30 to 45 degrees will create a thin, irregular graft that will shear off the donor site in strips. An angle greater than 45 degrees will create a gouge within the donor site.
- Failure to provide countertraction of the donor site and not providing uniform pressure on the dermatome will result in a graft thinner than planned. The dermatome should be running fully before engaging (landing the air plane) as well as exiting (takeoff) the donor site to prevent the graft from becoming enmeshed in the blades. Retraction of the graft by the assistant also prevents this error in technique.
- Ensure that the dermal side is in contact with the recipient bed. Epidermis-to-epidermis contact will not heal and will lead to graft loss.

- Meticulous insetting of the graft (both to the edge of the bed as well as tacking the graft onto the bed) creates the maximum contact of the graft to the recipient bed and is the most important step in achieving good cosmetic results (Fig. 173.4A and B).
- Harvesting too thick a graft can result in poor graft take. We prefer a graft thickness of 0.012 inches because the rate of healing is inversely proportional to the thickness of graft harvested.
- Bolsters should be placed so that there is an even distribution of pressure throughout the graft. Stay sutures should be placed such that no part of the bolster is looser than any other area.

Postoperative Period

Postoperative Management

- The routine use of postoperative antibiotics is not routinely recommended. Patients with diabetes, who are immunocompromised, or with infected recipient sites may benefit from oral antibiotics.
- Full revascularization of the graft results in 6 to 7 days postoperative. Most bolsters can be removed safely after this period. The bolsters are moistened prior to removal to prevent lifting the graft from the recipient site. Any accumulated blood or fluid under the graft may be expressed by making small incisions into the graft.
- Donor site management (split thickness): If significant fluid volume accumulates under the Tegaderm, it can be aspirated and the site reinforced with an additional dressing. If the fluid becomes cloudy and infected, the entire dressing should be removed, the donor site cleaned with hydrogen peroxide, and a new sterile Tegaderm reapplied.
- Donor site management (full thickness): Bacitracin or petrolatum ointment is applied three times daily for 10 days.
- Wound contraction is inversely related to the thickness of the graft, with an FTSG having the least amount of contraction and STSG the most contraction. In functional or cosmetically important areas, a compression device, such as a Jobst dressing or facial mask, can be used daily to minimize contraction.

Complications

- Graft failure can occur due to:
  - Technical error (failure to place the dermal side down in contact with the recipient bed; tenting the graft by stretching it too tightly and thus preventing apposition with the recipient bed)
  - Hematoma or seroma formation under the graft preventing adherence to the wound bed and neovascularization. Poor vascularization or infection of the wound bed
  - Mobilization of the graft due to improper placement of the bolster or placement over tendons or joints
- Uninfected eschars can be maintained to act as a biologic dressing. Nonviable graft areas can be débrided but may risk damaging deeper viable graft tissue.

Alternative Management Plan

Using skin grafts with local flaps

- Using a skin graft as an adjunct to local flaps is an effective way to close large cutaneous defects of the head and neck. Local flaps may cause anatomic distortion by placing excessive tension on a free margin. Large flaps may also be under too much tension, resulting in vascular compromise of the flap. Rather than risking anatomic distortion or flap survival, a portion of the surgical defect can instead be closed with a skin graft. Grafts harvested from redundant tissue removed during flap closure (Burow grafts) can frequently be used, rather than creating a separate graft donor site.

Skin substitutes

- For large cutaneous defects with poor vascularity, the use of a skin graft may result in prolonged healing times, inadequate healing, or significant donor site morbidity.
- Skin substitutes are most concisely classified according to their origin—autologous, allogeneic, xenogeneic, or recombinant.

Allografts

- AlloDerm, an acellular human dermis, is an allograft commonly used in the reconstruction of soft tissue defects. It was shown to support fibroblast infiltration, neovascularization, and epithelialization.[4] Like split-thickness skin grafting, AlloDerm also has utility in the reconstruction of oral cavity mucosal defects, with an overall take rate of 90% with complete epithelialization noted within 4 weeks.[5]
- Allogenic skin substitutes are available as Apligraf (Organogenesis, Inc., Canton, Massachusetts). Apligraft contains living cells that produce growth factors that may aid in the recruitment of host cells. Apligraf is composed of type I bovine collagen, keratinocytes, and fibroblasts from neonatal foreskin. It is food and drug administration (FDA) approved for use in venous ulcers and diabetic foot ulcers but also has off- label applications in head and neck reconstruction.[6] Fig. 173.5A to C illustrates the wound-healing progression of a patient treated with a combination of a local flap and Apligraf.

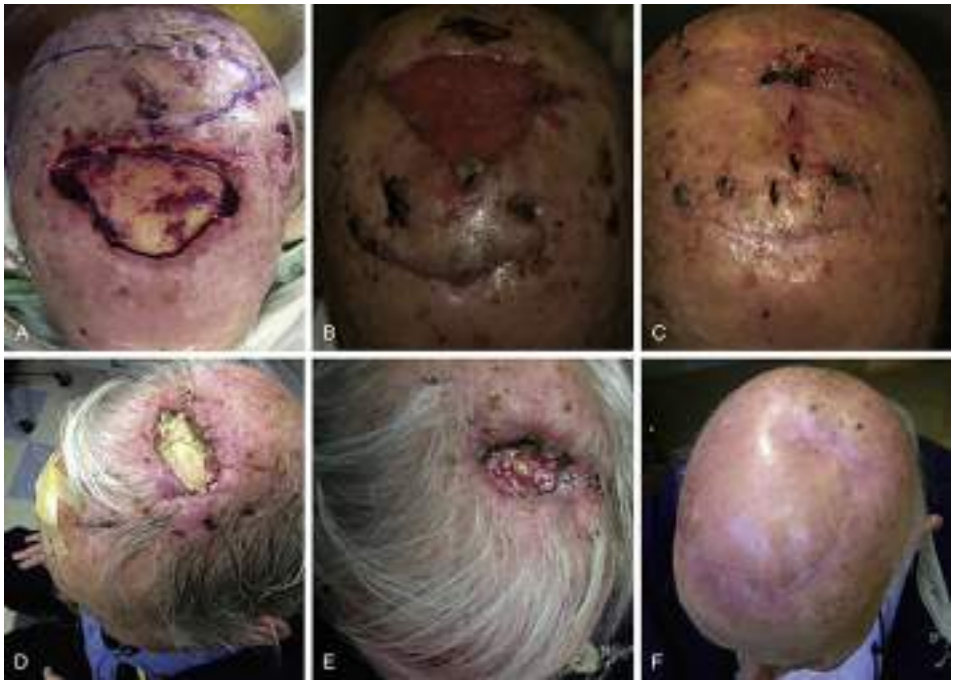

FIG. 173.5 **A,** An 87-year-old male status post (s/p) Mohs for squamous cell carcinoma (SCCa), very poor candidate for general anesthesia. **A,** No viable periosteum present to support grafting. Transposition flap to fill defect, resulting in a large donor site with viable pericranium. Apligraf used at the donor site. **B,** Three

weeks after one application of Apligraf. **C,** Two months after one application of Apligraf. **D,** A 90-year-old male s/p Mohs surgery for squamous cell carcinoma of the scalp vertex resulting in 7 × 7 cm defect. The pathology report suggests perineural invasion. Adjuvant radiation is planned. Large rotation and advancement flaps completed. Postoperative course was complicated by infection and then partial dehiscence of the wound. **E,** 2.5 weeks following application of MatriStem powder and a wound sheet. **F,** Two months following completion of radiation therapy.

Xenografts

- Xenografts are biologic materials transplanted from one species to another. Integra Dermal Regeneration Template (Intregra LifeSciences Corporation, Plainsboro, New Jersey) is a xenograft/semisynthetic bilayer. It has an outer thin silicone film that covers an inner porous matrix of cross-linked collagen and glycosaminoglycan. This collagen and glycosaminoglycan layer serves as a scaffold for the regenerating dermis. Integra is approved by the FDA in patients with extensive loss of skin and those with reconstruction of a complex surgical wound. Use of the dermal regeneration template is usually then followed by a delayed STSG.[7] It should be noted that a multicenter investigation of patients managed with Integra following release of scar contracture noted a concerning 20% rate of infection.[8]
- MatriStem MicroMatrix and MatriStem Wound Matrix are other xenografts composed of acellular porcine urinary bladder. They are available as a powder or as a single or multilayered sheet. The wound sheets are composed of extracellular matrix with an intact basement membrane that remains after processing. Data supporting its use are largely limited to case series and level III evidence. We have found utility in this xenograft for difficult-to-heal scalp wounds (see Fig. 173.5D and E).

Discussion

Evidence-Based Medicine Question

Skin graft failure due to infection is most commonly due to which causative agent?

a. *Pseudomonas* spp.

b. *Staphylococcus aureus*

c. *Enterobacteriaceae* spp.

d. *Acinetobacter* spp.

In a prospective, 3-year study[9] to evaluate skin-graft failure due to infection, *Pseudomonas* spp. was isolated as the most common causative agent (58.1%), followed by *S. aureus* (16.1%).

Editorial Comment

The use of skin grafts in reconstruction of the head and neck is often overlooked by the novice surgeon due to the wide use of fasciocutaneous free flaps. Skin grafts, particularly STSGs, have been successfully used in reconstruction of the oral cavity, preserving the floor of mouth sulcus for dentures and tongue mobility, the oropharynx and retromolar trigone to prevent trismus, and midface for lining of soft tissue for placement of an obturator. FTSGs and STSGs are very useful in reconstruction of the eyelids, for correction of ectropion, and for facial and nasal reconstruction of small Mohs defects. They are perhaps among the most versatile grafts in head and neck reconstruction and are useful in those who cannot undergo prolonged periods of general anesthesia due to medical comorbidities. In the past, there was a misconception that STSGs "did not work" for oral cavity reconstruction; this was typically due to improper surgical technique used by the surgeon.

Allografts are an excellent adjunct to STSGs and as replacement when there is a lack of skin available for grafting.

Review Questions

1. A split-thickness skin graft consists of the following skin layers

   a. **Epidermis and variable portions of the dermis**

   b. Epidermis and full-thickness dermis

   c. Epidermis, dermis, and variable portions of subcutaneous adipose tissue

   d. Epidermis only

2. When contemplating the use of a full-thickness graft versus split thickness, increased dermal thickness results in

   a. **Increased metabolic demand and thus a need for a well-vascularized wound bed for survival**

   b. Increased rates of graft survival and shorter healing times

   c. Increased graft contraction

   d. Improved color match

3. Why is a bolster used in skin grafting?

   a. It helps to ensure immobilization of the graft.

   b. Prevents hematoma/seroma formation

   c. Maximizes graft contact with the wound bed

   d. **All of the above**

Autologous Fascial Grafts and Acellular Allografts

Brendan Alleyne, and Brian Gastman

Introduction

Free fascial grafts and allogeneic options, such as acellular dermis like Alloderm, are available for use in various settings of head and neck reconstruction. There are many sources of these tissues including the fascia lata (FL), temporal fascia as well as those made from dermal sheets either autologous or "off the shelf" acellular versions. Not only are there many sources of these materials, but there are many uses. From soft tissue augmentation to supporting facial structures, surgeons have made many innovations using them to optimize function and form of the head and neck. In this chapter, we focus on a select few uses of these grafts. For instance, we describe the commonly used FL grafts in facial paralysis. We also demonstrates the use of Alloderm as a soft tissue augmentation material. The examples described are merely a sampling of the many uses of these tissues but highlight the potential of their use.

Key Operative Learning Points

- Soft tissue and defect assessment—What's missing?
- Reconstructive goals
- Harvest and inset of FL graft
- Considerations for Alloderm placement

Preoperative Period

Patient selection may prove to be even more vital to reconstructive success than the technical aspects. The patient's overall health and history may by default limit many surgical pathways. Additionally, the goals of care of the patient need to be verbalized, and both the surgeon and the patient should agree on the most reasonable reconstructive option in lieu of final treatment goals. Risks and benefits must be discussed in detail with consideration of the ultimate morbidity from reconstructive efforts such as the possibility of nonhealing wounds, increased donor sites and scarring, Alloderm-related infection or seroma, and future revision surgeries.

History

A history of wound healing issues, diabetes, and cardiopulmonary history should be obtained alongside our anesthesia colleagues to help be certain of adequate safety in proceeding with surgery. Nutrition should be assessed preoperatively as it bears direct consequences on wound healing. This is especially important when a second surgical site is created, as this is an additional wound, and this should be discussed at length with the patient.

1. History of present illness
    a. Risk factors for complication: smoking, diabetes mellitus, vasculopathy, vascular injury, radiation, chemotherapy
    b. Nutritional status
    c. Facial paralysis due to resection of facial nerve, trauma, or idiopathic, for example, Bell's palsy
2. Past medical history
    a. Diabetes mellitus
    b. Prior radiation to surgical field
    c. Vasculopathy
    d. Pulmonary disease
    e. Cardiac disease
    f. Immunosuppression

g. Chronic pain syndrome

h. Systemic vascular disease

3. Prior treatment of scalp, skull base, facial nerve, or parotid gland

a. Prior known cancer of the head and neck

b. Previous surgery of the head and neck

c. Previous chemotherapy or radiation

4. Current medications

a. Anticoagulants including antiplatelet agents and new generation coagulation cascade inhibitors

b. Herbal products

c. Allergies to antibiotics and pain medication

5. Social history

a. Psychologic: patient understands and can accept new deficits and issues related to reconstruction

b. Patient expectations

c. Support system: case manager or social worker is consulted to assess patient's support system and needs

d. Goals of employment

e. Substance abuse, particularly narcotics

Fascia Lata

When to Consider Fascia Lata

Physical Examination

1. Face

a. Examination of the facial and trigeminal nerve and overall functional deficits

1) Ptosis, facial nerve injury/paralysis

2) Oral competence

3) Signs and symptoms of dry eye

4) Eye closure

b. Baseline symmetry of soft tissue structures, eyebrows, lips, eyelids

c. Location of rhytids, quality of skin, evidence of hypertrophic or keloid scarring

d. Neurovascular involvement

1) Facial nerve involvement/resection

2. Health status

a. Nutrition/weight loss

b. Cardiovascular health

c. Pulmonary health

d. Mental status and sources of emotional support

e. Smoking status

f. Alcohol or narcotic addiction

Imaging

- Not usually necessary unless concern for recurrent disease

Indications (Fascia Lata Graft)

- Fascial sling for facial soft tissue support for facial nerve palsy following trauma, neoplasm, congenital sequelae, or cerebrovascular accident[1–3]
- Can also be used as a sling for brow elevation, lip ptosis, and orbital support
- Autologous in nature, relatively infectious resistant, incorporates well
- Does not stretch such as seen in dermal grafts or Alloderm
- Minimal donor site morbidity

- Can be harvested endoscopically

Contraindications

1. Patient factors
   a. Unstable health status
   b. Poor nutrition
   c. Inability to give informed consent
   d. Inability to accept postoperative morbidity
   e. Low Global Assessment of Functioning (GAF) or low social support
   f. Smoking
   g. Collagen-vascular disease
2. Surgical factors
   a. Prior harvest of fascia from the area
   b. Radiation to harvest area
   c. Prior surgery or trauma to the leg

Preoperative Preparation

1. Evaluations by
   a. Reconstructive surgeon
   b. Anesthesiology
   c. Physical medicine and rehabilitation

Operative Period

Anesthesia

- General

Positioning

- The entire face, neck, and selected donor site (lateral thigh and entire scalp and face) are sterilized and draped in the usual fashion.
- The surgery is done with the patient in a supine position or lateral to facilitate FL harvest but can also be repositioned for inset.

Perioperative Antibiotics

- Ideally, they are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Cefazolin
  - Clindamycin
  - Vancomycin
  - Ciprofloxacin

Monitoring

- Routine anesthesia care
- Muscle paralysis can be beneficial during FL harvest.

Instruments and Equipment to Have Available

- Basic soft tissue set
- FL harvest set
  - Long thoracic scissors
  - Long narrow Deaver retractor
  - Right angle clamp
  - Long thoracic Rider needle holder

FIG. 174.1 Lateral thigh incision for fascia lata harvest.

- Narrow hemostat (Jacobs)
- 3-0 chromic and 4-0 prolene on tapered needles
- FL stripper or long straight scissors

Key Anatomic Landmarks

- FL
  - Midline lateral thigh below iliac crest (Fig. 174.1)
  - Middle 1⁄3 from iliac crest to lateral knee

Prerequisite Skills

- Basic head and neck surgical skills

Operative Risks

1. Evaluations by:
   a. Anesthesiology and primary team
2. ASA guidelines
3. Typically FL harvest alone will carry a low postoperative risk of DVT and PE.

Surgical Technique

- Intraoperative evaluation
  - Soft tissue evaluation of laxity
  - Asymmetry
- Surgical approach
  - Anatomic landmarks are marked at the FL donor site.
  - Lidocaine with epinephrine is administered prior to the skin incision for hemostasis.
- Surgical approach FL continued
  - Midline lateral thigh below iliac crest (see Fig. 174.1)
  - 4-cm transverse incision at superior aspect of middle ⅓ from iliac crest to lateral knee (Fig. 174.2)
  - Incision down through fascia with retractor placed in subfascial plane
  - Scissors used to split fascia in line with fibers
  - Two transverse incisions may be needed for larger patients/fascial strips.
  - Fascial strip harvested en bloc (Fig. 174.3) (fascial strip to be at least 1.5 cm wide and 17 cm long)
  - Long scissors can be used in parallel with the fibers, while a right angle creates tension proximally.
  - The scissors undermine subfascially prior to using them to make the parallel cut.
  - Otherwise, a fascial stripper can be used to harvest the graft en bloc.

FIG. 174.2 View of fascial layer.

FIG. 174.3 Harvested fascial strip.

- FL reconstruction for facial paralysis-static sling
  - Use static fascial slings to restore facial symmetry in areas of neural weakness.
  - Fascial strips for anchoring soft tissues
  - Commonly employed for increasing oral competence

- Inset: FL for static fascial sling
  - 1.5- to 2-cm incisions within nasolabial fold (Fig. 174.4)
  - 1.5- to 2-cm incisions within hair-bearing scalp above lateral eyebrow (Fig. 174.5)
  - Fascia split to pass through lower lip wet vermillion incisions (Fig. 174.6)
  - Fascial strip encircling orbicularis and sutured on itself (Fig. 174.7)
  - Thoracic rider needle holder used to grasp fascial strip and pull toward temporal incision (Fig. 174.8)
  - Fascial strip, once anchored at orbicularis and modiolus, is directed through face toward temporal incision (Fig. 174.9)
  - Fascial strip pulled through temporalis fascia and then fixed to itself (Fig. 174.10)

FIG. 174.4 Labial and nasolabial markings.

FIG. 174.5 Lateral view showing nasolabial and temporal markings.

FIG. 174.6 Fascial strip passed into the lower lip incision.

- Tightness of fascial sling is adjusted through lower lip incisions, deliberately overcorrected (Figs. 174.11 and 174.12)

- Closure
  - The FL harvest site can be closed primarily with or without subcutaneous drain placement.

Common Errors in Technique: Fascia Lata

- Improper or inadequate anchoring of grafts leading to premature failure and loss of corrective support over time

FIG. 174.7 Preoperative lip and nasolabial fold markings fascial strip encircling the orbicularis and sutured on itself.

FIG. 174.8 Thoracic rider needle holder used to grasp the fascial strip and pull toward temporal incision.

FIG. 174.9 Fascial strip, once anchored at orbicularis and modiolus, is directed through face toward temporal incision.

FIG. 174.10 Fascial strip is pulled through temporalis fascia and then fixed to itself.

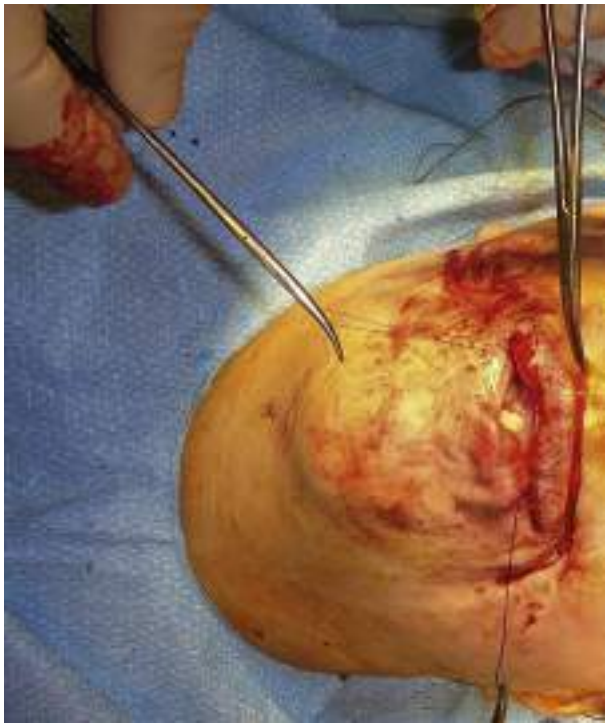

FIG. 174.11 Tightness is adjusted through lower lip incisions, deliberately overcorrected.

FIG. 174.12 Immediate postoperative view.

Postoperative Period

Postoperative Management

- Perioperative antibiotics are continued for 24 to 48 hours.
- Drains are removed when the volume of output decreases to less than

30 mL over a 24-hour period.

- Typically drains are removed 7 days postoperatively.
- Immediate postoperative facial analysis (inset of FL with overcorrection of tightness of strips)
- Nutrition
  - Oral feeding with a soft diet typically begins on postoperative day 1 and advances as tolerated.

Complications

- Hematoma
  - Most likely combination of muscle belly injury during fascia harvest and lack of hemostasis prior to closure
  - Will require immediate evacuation of clot and identification of bleeding source with washout and hemostasis with cautery and or suture ties
- Pain
  - Injury to lateral femoral cutaneous nerve
  - Pain control
  - Postoperative physical therapy
- Premature graft failure
  - Improper anchoring such as when using fascial strip for oral competence
  - Suture failure such as "cheese-wiring"
  - Will require elective re-anchoring of areas involving fascial sling rupture

Alternative Management Plan

Patient wishes should be discussed along with all reconstructive options. At times, the less invasive option will be the best option for a particular patient. Patients unable to receive a fascial autograft could elect to

undergo non-grafting techniques such as contralateral facial Botox or an ipsilateral facelift. For grafting techniques, a patient could undergo a palmaris longus tendon graft if available. Additional alternatives would include a free tissue dynamic reconstruction.

Alloderm

When to Consider Alloderm

Physical Examination

1. Assessment of the defect and overall concerns of function
    a. Dimensions of the actual or planned defect
        1) Measured area of defect in centimeters
        2) What tissue types will be missing?
        3) Exposed hardware or vital structure?
    b. Neurovascular involvement
        1) Facial nerve involvement/resection
2. Neck
    a. Look for previous scars, wounds; assess quality, quantity, and mobility of neighboring skin
3. Scalp
    a. Palpate with attention to areas of deformity, wounds with exposure of previous hardware
    b. Examine for previous surgical scars, quality, thickness of tissues, temporal hollowing
4. Face
    a. Location of rhytids, quality of skin, evidence of hypertrophic or keloid scarring
    b. Soft tissue contour abnormality
5. Health status

a. Nutrition/weight loss

b. Cardiovascular health

c. Pulmonary health

d. Mental status and sources of emotional support

e. Smoking status

Imaging

- Not usually necessary unless there is a concern for recurrent disease

Indications (Alloderm)[1–3]

- Augmentation of soft or hard tissue deficit
- Improvement in contour
- Mild to moderate soft tissue defects
- Patient's desire to not have a donor site for reconstructive tissues
- Cost:benefit versus surgical risk of donor site of autologous materials
- Post-parotidectomy
  - Prevention of Frey's syndrome
  - Elimination of dead space
  - Contour abrogating stigmata of the surgery
- Coverage of vital structures such as neck vasculature following parotidectomy or neck dissection or exposed cranioplasty
- For skull defects; impending cranioplasty exposure or craniofacial contour bony deformity improvement
- Commonly used for cosmetic augmentation such as in nasal dorsum

Contraindications

1. Patient factors

a. Unstable health status

b. Poor nutrition

c. Inability to give informed consent

d. Inability to accept postoperative morbidity

e. Low GAF or low social support

f. Smoking

2. Tumor factors

a. Unknown margins

b. Goals of reconstruction may become palliative

3. Surgical factors

a. Large defects involving bone may make Alloderm inadequate in isolation.

b. Infection

Preoperative Preparation

1. Evaluations by

a. Oncologic surgeon if necessary

b. Oncologists (radiation, medical and dental oncology) if necessary

c. Reconstructive surgeon

d. Anesthesiology

Operative Period

Anesthesia

- General

Positioning

- The entire face and neck are sterilized and draped in the usual fashion.

- The surgery is done with the patient in a supine position.

Perioperative Antibiotics

- Ideally, they are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Cefazolin
  - Clindamycin
  - Vancomycin
  - Ciprofloxacin

Monitoring

- Routine anesthesia care

Instruments and Equipment to Have Available

- Basic soft tissue set

Prerequisite Skills

- Basic head and neck surgical skills

Operative Risk

1. Evaluations by:
   a. Anesthesiology and primary team
2. ASA guidelines
3. Depending on other associated portions of the operation, Alloderm alone usually carries low postoperative risk of DVT, PE

Surgical Technique

- Intraoperative evaluation
  - Soft tissue evaluation
  - Vital structures exposed
- Surgical approach
  - Anatomic landmarks are marked.
  - Defect dimensions are measured and templated when appropriate.
  - Lidocaine with epinephrine is administered prior to the skin incision for hemostasis.
- Reconstruction using Alloderm
  - Evaluate defect dimensions.
  - Can aid in adding several centimeters of soft tissue bulk
  - Alloderm can be used effectively for smaller volume defects.
  - Need to thaw the Alloderm prior to use
  - It can be kept in sterile saline 10 to 15 minutes prior to inset.
  - Alloderm, adipose tissue, and fascia can be used to add volume in otherwise low-risk coverage areas.
  - It can be used to cover vital structures such as:
    - Exposed neck vasculature post-parotidectomy (Figs. 174.13 and 174.14).
    - Impending cranioplasty exposure. Note areas of thinning dermis on underside of reflected scalp flap, seen in magnified view at upper right corner (Fig. 174.15).

Common Errors in Technique: Alloderm

- Insufficient graft bulk leading to inadequate correction of contour
- Excess graft bulk that may require thinning either acutely or in a delayed fashion

- Use as an allograft sling can often lead to stretching over time and loss of corrective effect
- Closure
  - The Alloderm inset site can be closed primarily depending on with or without subcutaneous drain placement

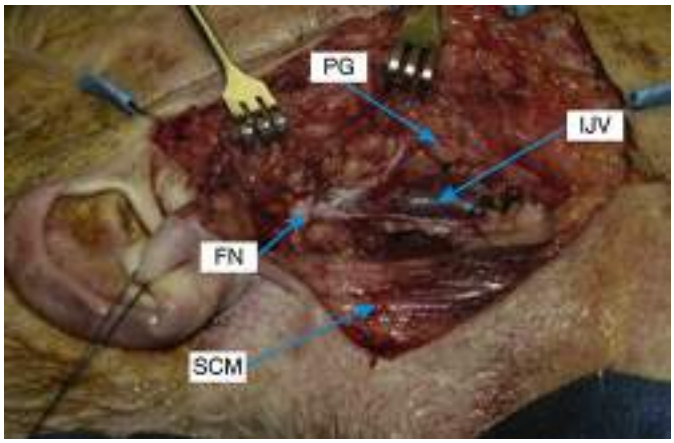

FIG. 174.13 Right soft tissue defect following parotidectomy with exposed neurovascular structures: internal jugular vein (IJV), marginal mandibular branch of facial nerve (FN), sternocleidomastoid (SCM), parotid gland (PG).

FIG. 174.14 Alloderm applied as soft tissue coverage of vital structures in the neck.

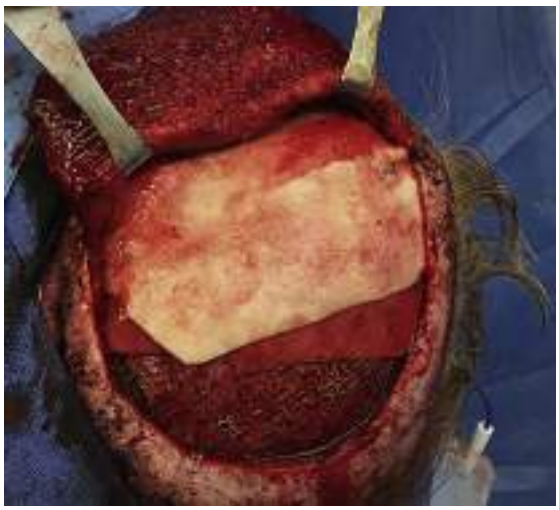

FIG. 174.15 Alloderm placed in subgaleal position to augment impending cranioplasty exposure through scalp. Note areas of thinning dermis seen in upper right magnified inset.

Postoperative Period

Postoperative Management

- Typically, an outpatient procedure depending on the nature of concurrent surgeries necessitating allograft placement
- Drains are removed when the volume of output decreases to less than 30 mL over a 24-hour period.
- Perioperative antibiotics are continued for 24 to 48 hours.
- Typically drains are removed 7 days postoperatively.
- Immediate postoperative facial analysis (evaluate inset of FL with overcorrection of tightness of strips)
- Nutrition
  - Oral feeding is typically begun on postoperative day 0.

Complications

- Hematoma

- Will require immediate evacuation of clot and identification of bleeding source with washout and hemostasis with cautery and or suture ties

- Pain
  - Pain control
  - Postoperative physical therapy
- Seroma
  - Common with using Alloderm and may require drainage and appropriate antibiotic therapy
- Premature graft failure
  - Premature Alloderm stretching when used as sling
  - Suture failure such as "cheese-wiring"
  - Will require outpatient operative exploration and correction

Alternative Management Plan

Patient wishes should be discussed along with all reconstructive options. At times, the less invasive option will be the best option for a patient. Many times, the use of an allograft such as Alloderm is an effective means of bridging the gap between patient reconstructive goals and risk-benefit of more invasive surgical procedures. In cases where this allograft cannot be used, autografts such as adipose tissue, dermatoadipose tissue grafts, or flaps can be used for soft tissue bulk. These modalities range in complexity and associated donor site morbidity.

Discussion

Evidence-Based Medicine Question

Is Alloderm a viable option for soft tissue coverage of the head and neck? [4]

Acellular dermal matrix, or Alloderm, has several desirable properties which have made it useful in the following reconstructions: nasal;

tympanic membrane; periorbital; extra and intraoral reconstruction; dura mater; and even soft tissue defects from parotidectomy, improving contour. Additionally, the FL graft and Alloderm are commonly used in the rehabilitation of facial nerve paralysis. They are static techniques used to suspend the soft tissues of the face and can be used alone or in combination with dynamic procedures. Alloderm has the advantage of no donor site morbidity. Both materials require overcorrection of facial symmetry at the time of procedure to account for postoperative stretching. However, in a small study by Boyette and Vural (2010), it was demonstrated that stretching the Alloderm graft prior to implantation required no overcorrection and decreased long-term elongation of the implant.

The following properties of Alloderm are desirable:

- There is no donor site.
- Processing limits immune response.
- It is helpful in augmenting soft tissue defects.
- Helpful in covering vital structures

Editorial Comment

Tensor fascia lata (TFL) and Alloderm are commonly used in the rehabilitation of facial nerve paralysis. They are static techniques used to suspend the soft tissues of the face and can be used alone or in combination with dynamic procedures. Alloderm has the advantage of no donor site morbidity. Both materials require overcorrection of facial symmetry at the time of the procedure to account for postoperative stretching. However, in a small study by Boyette and Vural (2010), it was demonstrated that stretching the Alloderm graft prior to implantation required no overcorrection and decreased long-term elongation of the implant.

Review Questions

1. When employing fascia lata as a fascial sling, it is important to

   a. **Overcorrect intraoperatively**

   b. Undercorrect intraoperatively

   c. Use wide strips

   d. Double layer strips

2. Indication for the use of Alloderm in facial reconstruction is

   a. Soft tissue reinforcement

   b. Infected field

   c. Coverage of vital structures

   d. **a and c**

   e. All of the above

Split Calvarial Graft

Catharine B. Garland, Jesse Goldstein, and Joseph Losee

Introduction

Calvarial graft may be the preferred bone graft for reconstruction of much of the craniofacial skeleton. Both cortical and cancellous bone can be harvested in relative abundance. Cortical calvarial bone graft is pliable, allowing for reconstruction of the complex three-dimensional contours of the facial skeleton. It is thin for orbital grafting and strong for recreation of the facial buttresses. These attributes make it ideal for both primary and secondary reconstruction after facial trauma and for reconstruction after tumor extirpation. Furthermore, when a coronal incision is already being used for exposure of the fracture or defect, using calvarial bone graft for reconstruction requires no additional donor site incisions.[1-3]

Calvarial bone graft may be harvested in several different fashions depending on the needs of the operation and the patient. We will review the standard harvest of a parietal bone graft through a coronal incision.[4] Other incisions may be used, such as a parasagittal incision in the hair-bearing frontoparietal scalp. We discuss harvesting cortical and cancellous graft as a split graft in situ, via an intracranial approach in which the graft is split ex vivo, and our preferred methods for harvesting particulate bone graft. A large quantity of particulate bone graft is available from the calvarium, which we have found particularly effective in reconstructing calvarial defects.

Using calvarial graft to reconstruct calvarial defects allows one to replace like with like. This is nearly always favorable to prosthetic reconstruction when possible, especially in the growing skeleton. Split calvarial bone graft can be used in older children and adults who have a well-developed diploic space. Using a template from the contralateral

skull leads to a symmetric autologous reconstruction. In the infant and young child, full-thickness calvarial bone graft may be harvested to reconstruct a defect. Young infants may regenerate the donor site defect fully when there is an intact, healthy dura below. Although regenerative capacity is thought to diminish with age, we have been successful reconstructing full-thickness defects with particulate bone graft in all ages using protected bony regeneration.[5,6]

Key Operative Learning Points

1. Parietal bone is usually thick with less curvature than other areas of the calvarium. Parietal bone is therefore the most common calvarial graft donor site.

2. Calvarial graft may be split in situ or ex vivo. When splitting calvarium ex vivo an intracranial approach is used and neurosurgical assistance is recommended.

3. Full-thickness calvarial bone graft may be used for reconstruction of the zygoma in trauma or in congenital anomalies.

4. Calvarium may also be used as particulate bone graft. Cortical bone may be harvested for particulate graft, or cancellous bone from the diploic space may be used when splitting the bone.

Preoperative Period

History

1. Surgical history: Does the patient have a history of prior surgery on the scalp or skull?

2. Bleeding history: Bleeding from the scalp incision and bone graft harvest site can lead to moderate blood loss and possibly require blood transfusion. Screen all patients for a history of bleeding disorders and for the use of aspirin, nonsteroidal anti-inflammatories, and other antiplatelet agents.

Physical Examination

1. Evaluate the scalp for scars that may impact the vascularity of the scalp flaps.

2. Palpate the skull for any bony irregularities or defects.

Imaging

Computed tomography (CT) scan is recommended for preoperative planning. Bone windows with coronal, sagittal, and three-dimensional (3D) reconstructions are ideal. Carefully evaluate the coronal images for the thickness of the native parietal bone and the width of the diploic space where one intends to split the bone. This careful preoperative planning can help avoid injury to the dura or venous sinuses during the operation.

Indications

1. In situ split calvarial graft: This may be performed in the adult patient with thick calvarial bone and a well-formed diploic space.

2. *Intracranial* ex vivo split calvarial graft: This is a better option for pediatric patients in whom the diploic space may be thin or poorly formed. When preoperative CT scan demonstrates irregularity of the bone, splitting the graft ex vivo is also preferable. Performing this as a team approach with a neurosurgeon is recommended.

3. *Particulate* calvarial bone graft: This technique may harvest a large quantity of particulate bone that is useful for reconstructing calvarial defects or for filling other bony spaces. We mix the particulate bone with several milliliters of blood from the field prior to packing this bone into the defect.

4. Calvarial reconstruction: Calvarial defects may be reconstructed either with full-thickness or split cortical graft or with particulate bone graft harvested from the calvarium. Even large defects may be filled with particulate bone graft if the underlying dura is healthy and the regenerate is protected.

Contraindications

1. Age less than 10 years is a relative contraindication for split calvarial bone graft. In this age group, the diploic space may not be well formed, and the bone may not be able to be split. High-resolution bone CT scan can inform preoperatively of when, or where, split calvarial bone grafting is possible.

Preoperative Preparation

Preoperative laboratory studies, including complete blood count, basic metabolic panel and coagulation studies

Type and cross for blood

Blood donation for donor-directed blood if desired

Operative Period

Anesthesia

General

Positioning

Supine: The patient's head is usually placed on a gel donut for stabilization. Ensure that the endotracheal tube is secured well and that the sterile drapes are placed to allow the surgeon to move the head in the operating room as needed.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Monitoring

Two large-bore peripheral intravenous lines are placed, given the potential risk of blood loss.

An arterial line is commonly used for intraoperative monitoring.

Instruments and Equipment to Have Available

Raney clips

Wide Obwegeser periosteal elevators

Straight and curved osteotomes

Thin, sharp osteotomes for splitting the bone

Bone bending forceps

Bone holding forceps

Bone cutter

Power drill/burr/saw

Safescraper bone scraper (Osteogenics Biomedical)

Hemostatic agents of choice (e.g., thrombin, Gelfoam, Surgicel, Tisseel, Floseal).

For intracranial approach:

Craniotome

Penfield dural elevators

Malleable retractors

Cranial fixation system: wire, plates, mesh, screws

Key Anatomic Landmarks

1. The parietal bone is most commonly used as the donor site. The bone to harvest should be marked at least 1 cm posterior to the coronal suture and 1.5 cm lateral to the sagittal suture (Fig. 175.1). This ensures that the surgeon is harvesting bone of adequate thickness away from the dural venous sinuses and major perforating vessels.

   a. Parietal bone is an advantageous donor site for many reasons: It is thick, it has less acute curvature than occipital or fontal bones, and any irregularities in the parietal area are likely to be covered by hair.

b. If frontal bone is being harvested, ensure that the donor site is cephalic to the level of the frontal sinus and behind the hairline. This avoids complications associated with the sinus and ensures that any bony irregularities are more likely to be hidden by the hair.

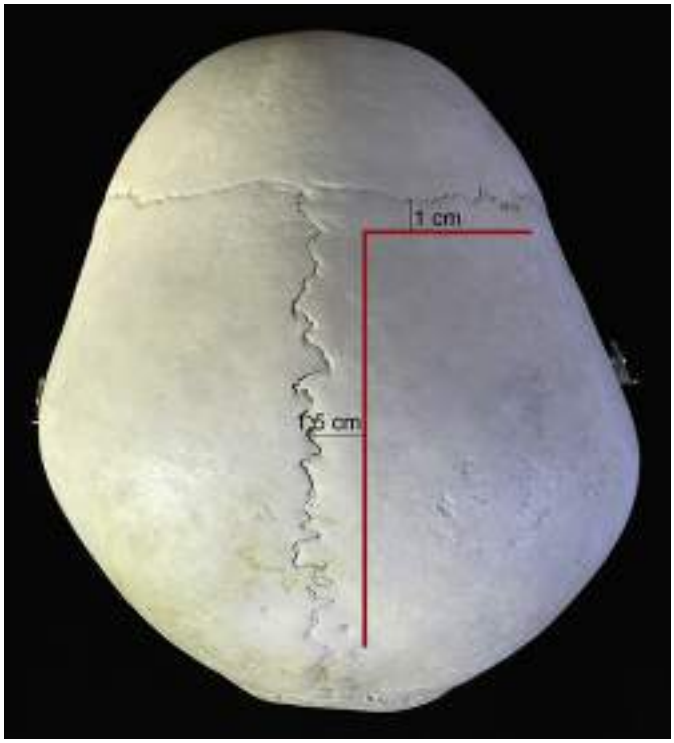

FIG. 175.1 Landmarks for marking a parietal bone graft.

Bone should be harvested at least 1.5 cm lateral to the sagittal suture and 1 cm posterior to the coronal suture.

FIG. 175.2 Coronal zigzag incision for harvesting bone graft.

2. A coronal incision should typically be made at the level of the ear (Fig. 175.2) just posterior to the coronal suture. The incision should not be too far anterior so as to allow some distance between the incision and the hairline. In men with male pattern baldness or at risk for male pattern baldness, the incision should be made somewhat more posteriorly to reduce its visibility. It should contain zigzags so that the hair will be able to grow over it.

FIG. 175.3 Intracranial approach to split calvarial bone graft for reconstruction of a calvarial defect.

A, Left parietal skull defect, with a template made for harvest of a right-sided parietal bone graft. **B,** After removing the right-sided parietal bone, it is split ex vivo using a sagittal saw and copious irrigation on the back table. **C,** Calvarial reconstruction with half of the split bone graft placed back into the right-sided donor defect and half reconstructing the left side of the skull.

Prerequisite Skills

Coronal exposure to the craniofacial skeleton

A team approach with a neurosurgeon is recommended for cases in which the intracranial approach is planned.

Operative Risks

1. Bleeding, blood transfusion: The scalp, bone, and dura are the primary sources of bleeding. These should be controlled before moving on to the next step. We often use a combination of electrocautery, bone wax, and

hemostatic agents such as Surgicel, Gelfoam, thrombin, Tisseel fibrin sealant, and Floseal hemostatic matrix as indicated.

2. Dural tear, cerebrospinal fluid (CSF) leak: Dural tears can nearly always be repaired with sutures or a dural patch at the time of injury. It is imperative that a dural tear is recognized and repaired to prevent a CSF leak.

Surgical Technique

1. The zigzag coronal incision should be marked (see Fig. 175.2) and the hair shaved along the incision. The hair and scalp should be washed with chlorhexidine scrub, and the hair should be combed. Often sterile surgical lubricant or bacitracin ointment is helpful in keeping the hair away from the surgical incision. In women or with longer hair, the hair may need to be secured in multiple places with small rubber bands.

   a. An alternative approach for harvesting a smaller piece of bone graft is to use a short straight or curvilinear incision directly over the harvest site on the parietal skull. This is often in a parasagittal location.

2. Infiltrate the scalp incision with a dilute epinephrine-containing solution (5 to 10 mcg/mL) to reduce the risk of bleeding.

3. Use a blade to open the scalp through the galea. Cautery should be used judiciously to avoid injury to the hair follicles near the incision. Raney clips are a useful adjunct for bleeding from scalp edges.

4. The scalp should be elevated in the subgaleal plane, leaving the pericranium intact over the bone.

5. Incise the periosteum with knife or electrocautery. Using wide Obwegeser elevators, raise a pericranial flap. If you are harvesting a parietal bone graft, it may be easiest to raise a laterally and inferiorally based flap. In other circumstances you may wish to raise the pericranial flap based anteriorly along the frontal bone or posteriorly toward the occiput.

6. Mark the proposed graft and harvest the bone.

   a. Intracranial approach, splitting the bone ex vivo (Fig. 175.3):

1) Neurosurgical assistance should be requested with this approach.

FIG. 175.4 Harvesting split calvarial graft in situ.

The osteotome is placed tangent to the bone to split and remove a strip of graft. Subsequent strips are removed in the same manner.

2) Burr holes are made as needed for adequate exposure to free the dura along the planned craniotomy incisions.

3) Penfield elevators are used to free the dura from the inner table of the bone.

4) The craniotome is used to complete the craniotomy and the bone flap is carefully removed.

5) Irrigating bipolar cautery and hemostatic agents are used as needed to achieve hemostasis of the dura and bony edges.

6) On the back table, the parietal bone flap is then split. This is ideally performed using gradually increasing sizes of sharp

straight and curved osteotomes.

a) For thick bone, a reciprocating saw may be used to harvest cortical graft. The bone and saw are copiously irrigated throughout the process. When a power saw is used, understand that the cancellous diploic bone is likely to be injured.

7) Half of the split bone is placed back onto the dura to reconstruct the calvarial defect and is fixated either with wires or small plates. In children, we use Vicryl or polydioxanone suture instead of wire and a resorbable plate fixation system.

8) The burr hole defects may be filled with particulate bone graft or cancellous bone from the graft harvest.

b. In situ split-thickness bone graft (Fig. 175.4)

1) A side-cutting burr or reciprocating saw is used to make this osteotomy through the outer table at the site of your proposed graft harvest. The diploe should be visible.

2) A 5-mm narrow strip of bone is removed first. This allows placement of the osteotome tangent to the calvarium so that the bone can be split. Progressively larger sharp straight and curved osteotomes from 8 to 15 mm in width are used, to separate the outer table. Typically the parietal bone is harvested in strips of up to 20 mm in width.

3) Cancellous bone from the diploic space may also be harvested, either as sheets using an osteotome or as particulate bone graft using curettes.

4) The edges of the donor site may be burred down to create a smoother transition.

5) Gelfoam or Surgicel is often placed over the donor site to decrease bleeding.

c. Particulate bone graft (Fig. 175.5)

1) Cancellous bone may be harvested by curette in pieces or by osteotome in sheets during either of the previously discussed techniques when split cortical bone is used.

2) The Hudson brace hand drill and bit (see Fig. 175.5A and B) are

traditionally used to harvest particulate bone from either the ectocortex of the bone or the endocortex in the case of the intracranial approach. This bone may be collected in a specimen cup and mixed with blood from the field until needed to fill the defect.

3) We have found the Safescraper device (see Fig. 175.5C) to be a less cumbersome way to capture particulate bone graft from the calvarium. This device is scraped along either the inner or outer cortical surface of the bone. It captures thin ribbons of bone in a 2.5-mL collection canister. This is then easily emptied into a larger specimen container on the field. When adequate bone has been harvested, it will be mixed with blood from the field until use.

4) Particulate bone is used to fill any calvarial defects left from graft harvest. For larger defects, protected bone regeneration is performed by packing the particulate bone graft between the dura and a bioresorbable mesh or between two sheets of mesh, as the situation dictates (see Fig. 175.5D).

7. The pericranial flap that was created should be placed over the donor site, and absorbable suture may be used to tack it into place.

8. A closed suction drain placed under the scalp flap may be used to prevent blood and fluid accumulation. The galea and skin should then be closed precisely.

Common Errors in Technique

1. Making the coronal incision too anterior: It is more likely to become visible, particularly if baldness develops.

2. Burning the bone with power saws and not using enough irrigation.

3. Not having sharp enough osteotomes to make a clean split.

Postoperative Period

Postoperative Management

1. A CBC should be sent postoperatively if there is significant bleeding during the operation.

2. The head should be kept elevated to prevent edema.

3. We typically treat the incision with bacitracin ointment for 1 to 2 weeks postoperatively to optimize healing.

4. When a drain is used, it is typically removed in 2 to 3 days when output has decreased and is serous rather than sanguineous in nature.

5. Any change in mental status should be taken seriously. CT scan of the head is recommended to rule out hematoma or other intracranial complication. Although extremely rare, this serious complication has been reported in the literature.

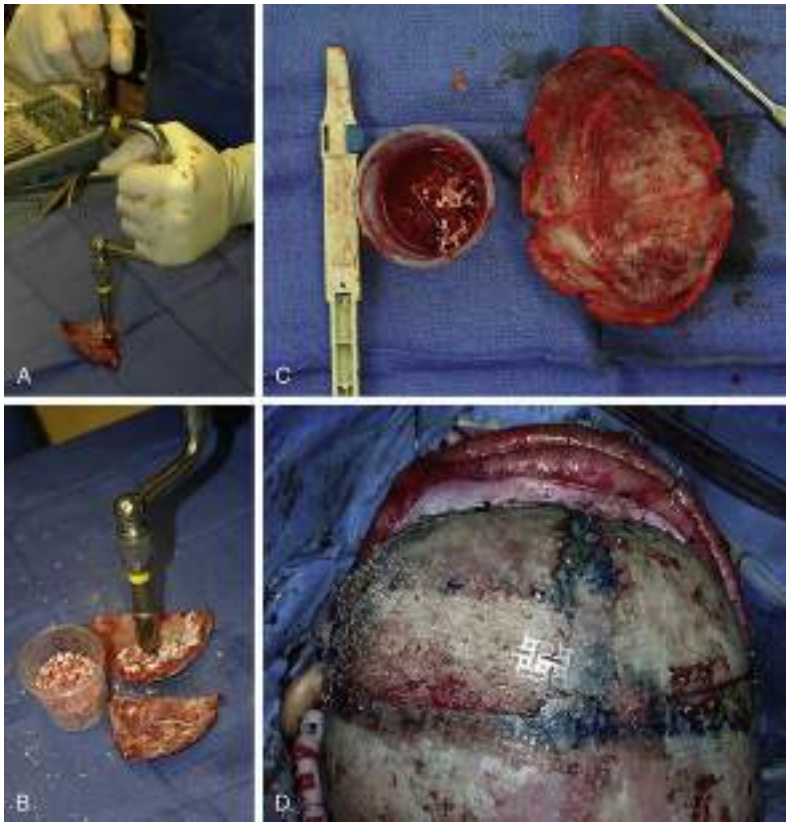

FIG. 175.5 Particulate bone graft.

A and **B,** Harvesting particulate bone graft using a Hudson hand brace. **C,** Safescraper device used for harvesting particulate bone graft from the endocortex of a calvarial bone graft. **D,** Reconstruction of a calvarial

defect with protected bone regeneration. Particulate bone graft is packed into the defect and protected with a bioresorbable mesh.

Complications

1. Hematoma/seroma: The incidence of hematoma/seroma is approximately 1%. Placement of a closed suction drain may reduce this risk.

2. Hypertrophic scarring/scar alopecia: This can be avoided by minimizing thermal injury along the incision line and meticulous closure of the galea and skin.

3. Calvarial irregularities: These are common in the in situ technique but are typically covered by hair.

4. Bone graft resorption

Alternative Management Plan

1. Alternative bone graft such as rib or iliac crest

2. Prosthetic reconstruction

Discussion

Evidence-Based Medicine Question

What is the incidence of major complication with split calvarial bone graft?

Major complications associated with split calvarial bone grafting are quite rare overall. The most feared complication of operating on or around the calvarium is that of neurologic sequelae from intracranial hematoma or major bleeding from a dural sinus. In a review of 586 bone grafts performed by a single author (Kline et al.), there were no neurologic complications.[7] Furthermore, the authors performed a widespread survey of craniofacial surgeons, finding only three such

complications in more than 12,000 calvarial graft harvests. An additional eight complications (four with permanent and four with temporary neurologic injury) were identified. These were all performed by surgeons with no or very limited training in calvarial bone grafting. Other smaller studies support these findings. Canella et al. report on a case in which a sagittal sinus laceration occurred with midline harvest.[8] However, other studies by Posnick et al. and Jackson et al. do not report any cases with neurologic disturbances or major bleeding.[9,10] Minor complications, such as hematoma, seroma, delayed wound healing, and wound infection, are also relatively infrequent occurrences, with the same literature suggesting a rate of 1% to 5%.

Editorial Comment

Calvarial bone grafts are widely used in reconstruction of the head and neck, including calvarial and midface defects. There are several types of bone grafts that may be taken: shaved corticocancellous outer table graft with attached pericranium; bone paste; split-thickness outer table grafts; and full-thickness parietal bone grafts and inner table grafts taken from a full-thickness bone flap. These grafts can be used in those who will require radiation therapy. The complication rate is overall low as is resorption rate. Harvest is relatively simple, and head and neck surgeons should become familiar with its harvest.

Review Questions

1. Split calvarial bone graft is harvested from the parietal bone. Significant bleeding is encountered. This is most likely because of which of the following?

   a. The osteotomy was made too anterior.

   b. The osteotomy was made too posterior.

   c. **The osteotomy was made too medial.**

   d. The osteotomy was made too lateral.

2. Which of the following patients is not a good candidate for

reconstruction with split calvarial bone graft?

a. A 21-year-old with bilateral Le Fort III fractures with comminution and bone loss

b. **A 2-year-old with a left frontal bone defect from trauma**

c. A 38-year-old with comminuted naso-orbito-ethmoid and nasal bone fractures

d. A 46-year-old with a parietal scalp defect following previous craniotomy

3. A patient who had a coronal approach to bilateral Lefort III fractures, reconstructed with split calvarial bone graft, has alopecia at her incision site. This is most likely because:

a. The incision was made too anterior

b. **The hair follicles were injured with electrocautery**

c. The galea was not reapproximated

d. The skin was under excessive tension

Rib Graft

Catharine B. Garland, Jesse Goldstein, and Joseph Losee

Introduction

Rib graft is a useful adjunct for the reconstruction of the craniofacial skeleton and can be harvested in multiple forms to fit different situations. Rib graft may be harvested as a long, pliable bone graft. This is commonly used for mandibular reconstruction. It may also be used to reconstruct the bony buttresses of the face after trauma or tumor resection. Rib bone can be split longitudinally through the thin medullary canal using an osteotome. Split rib graft is useful for reconstructing calvarial defects and defects of the midface, such as the orbital floor, where a thin autologous bone graft is ideal.[1,2]

The ribs are also a source of abundant cartilage for reconstruction of the nose, ears, and trachea. Costal cartilage from the ribs is the most common source of donor material for reconstructing the ear in cases of microtia. In secondary rhinoplasty, rib cartilage is often a necessary adjunct for recreating the support structures of the nose because septal cartilage may be weakened or absent in these cases.[3] Finally, ribs may be used as a composite costochondral graft containing both cartilage and bone for reconstruction of the mandibular condyle and for temporomandibular joint arthroplasty. The hyaline cartilage cap can act as a growth center in pediatric patients while withstanding the stresses of the temporomandibular joint.

Key Operative Learning Points

1. Rib cartilage and bone are commonly harvested from the fifth, sixth, and seventh ribs.

2. To maintain thoracic stability, when more than one rib bone graft is

required, harvest alternate ribs rather than two sequential ribs.

3. Rib bone cortex is thin and may not allow stable screw fixation. It is best fixated with wires.

4. Costal cartilage may be harvested as a large cartilage block from the synchondrosis of the ribs inferiorly if necessary.

5. After removal of the rib graft, evaluate for injury to the parietal pleura and the presence of a pneumothorax prior to closure.

Preoperative Period

History

1. Does the patient have a history of prior surgeries or rib graft harvest? This is a common situation in secondary rhinoplasty and secondary bone reconstruction. Although bone and cartilage can regenerate within the periosteal or perichondrial sleeve, the bony regenerate is thin and not of equivalent quality. In addition, performing a secondary harvest from the same site is often more difficult due to the presence of scar tissue. This may lead to an increased risk of penetrating the parietal pleura during the dissection and causing a pneumothorax. We advocate using the alternate side in these instances.

Physical Examination

1. Evaluate for any prior scars on the thorax.

2. Evaluate the shape of the rib cage. Understand that the curvature and location of the rib may differ if the patient has a long and narrow thoracic cavity rather than a short and wide thorax.

Imaging

Imaging is not necessary for rib graft harvest. However, some authors have advocated the use of limited computed tomography (CT) scan of the sternum in older patients prior to cartilage harvest. CT scan can preoperatively estimate the quality of the graft by demonstrating the

degree of calcification of the costal cartilages.

Indications

1. Bone (Fig. 176.1): Rib bone graft is useful for mandibular, orbital, and zygomatic reconstruction. It provides an abundant source of relatively pliable bone that also may be split. Split rib graft may be used for calvarial reconstruction.

2. Costal cartilage (Fig. 176.2):

   a. Costal cartilage can provide strong support grafts for cases of difficult primary or secondary rhinoplasty (see Fig. 176.2A and B). It is particularly useful for columellar struts, extended spreader grafts, and dorsal grafts. However, rib cartilage grafts have shown an incidence of warping ranging from 0% to 25% in studies. An alternative is to use rib cartilage for a diced cartilage-fascia graft.

   b. The synchondrosis of the sixth, seventh, and eighth ribs can be harvested as a cartilage block for microtia reconstruction (see Fig. 176.2C and D). A floating rib cartilage is also used to create the helix.

   c. Costal cartilage is also useful for laryngotracheal reconstruction in cases of laryngeal or tracheal stenosis.

3. Composite costochondral graft: This is most commonly used for reconstruction of the mandibular condyle and for temporomandibular joint arthroplasty.

Contraindications

1. Concomitant lung disease—Pain from rib graft harvest may lead to postoperative splinting or shallow breathing. This can increase the risk of atelectasis or pneumonia. Emphasize the importance of postoperative pulmonary toilet in all patients, and exercise caution in those with concomitant lung disease.

Preoperative Preparation

Routine

Operative Period

Anesthesia

General

Positioning

Supine for the majority of cases

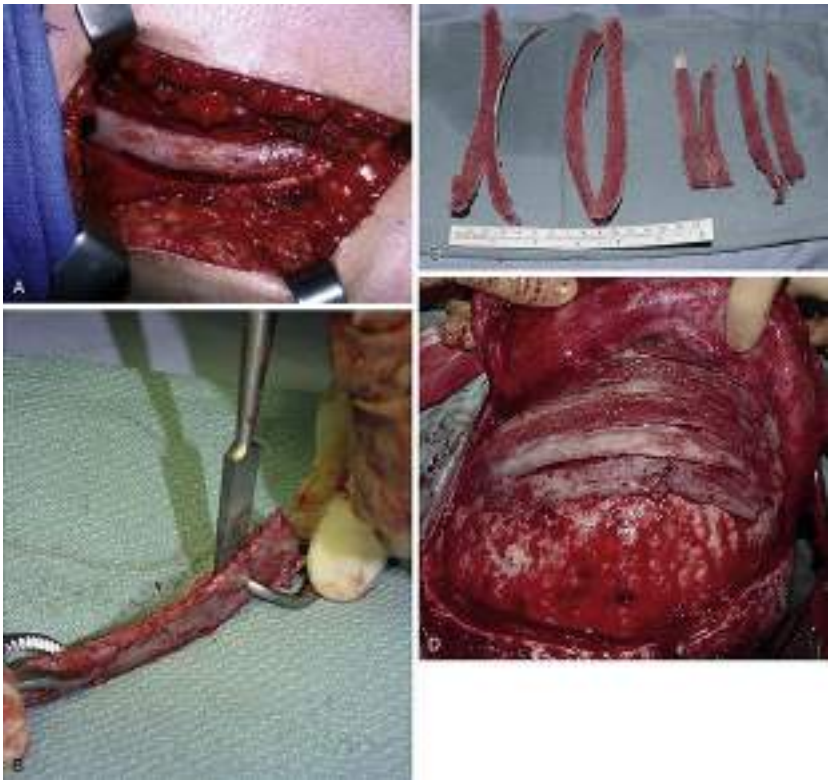

FIG. 176.1 Rib bone graft harvest.

A, Rib bone exposed in situ. **B,** Rib bone graft ex vivo, being split with a sharp osteotome. **C,** Several split ribs. **D,** Calvarial defect reconstructed with several split rib bone grafts.

Lateral: When harvesting a longer rib bone graft, it may be helpful to rotate the patient onto the contralateral side to reach the posterolateral portion of the rib more easily.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Periosteal elevators:
   a. A Cottle elevator or Molt periosteal elevator can be useful early in the dissection. The Cottle elevator can sharply release perichondrium from costal cartilage.
   b. Angled Semb elevators are used as the dissection proceeds posteriorly to reduce the risk of penetrating through the posterior periosteum and producing a pneumothorax.
   c. Doyen elevators complete the dissection and strip the periosteum and perichondrium circumferentially in a continuous fashion.
2. Retractors:
   a. Self-retaining retractors are useful if operating alone.
   b. Long rib retractors, such as Tessier rib retractors or Langenbeck retractors, are helpful for exposure along the length of the rib.
3. Costotome for dividing the rib bone graft laterally
4. Bone holding forceps
5. Bone bending forceps
6. Curved osteotomes for splitting rib when desired
7. Silicone carving block for cartilage grafts

Key Anatomic Landmarks

1. The manubriosternal junction denotes the location of the second rib. This is also typically the first rib that can be palpated below the clavicle. From here you may count the ribs down along the sternal border to identify the fifth, sixth, and seventh ribs.

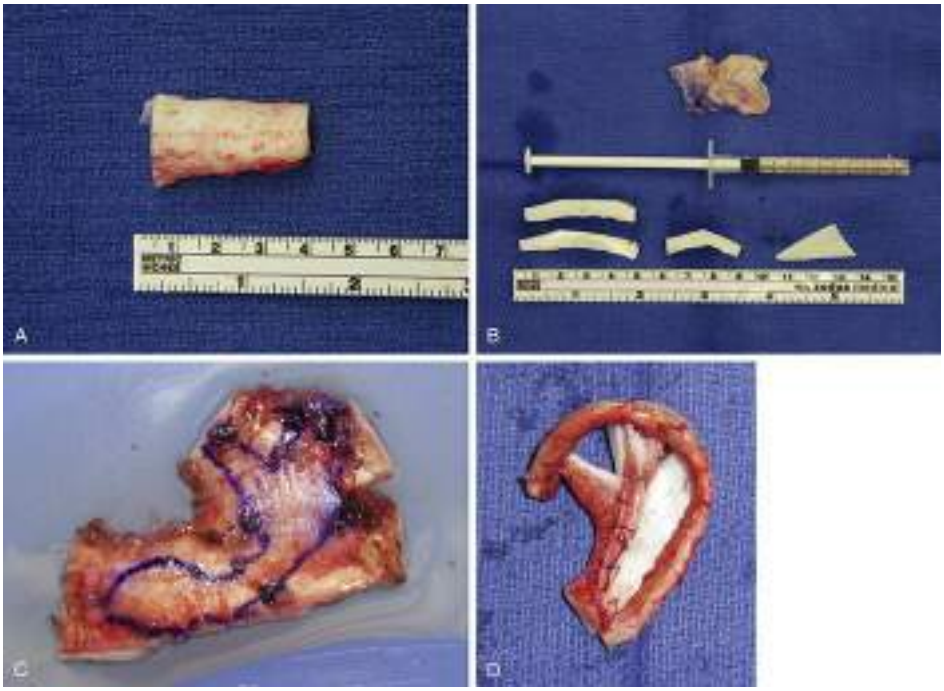

FIG. 176.2 Costal cartilage grafts for rhinoplasty and microtia reconstruction.

A, Sixth rib harvested for rhinoplasty. **B,** Cartilage cut into spreader grafts, columellar strut graft, and diced for a dorsal graft. Diced cartilage is placed into a 1-mL syringe for easy filling of a fascial envelope. **C,** Synchondrosis of the ribs harvested for microtia reconstruction. **D,** Cartilage carved and sutured together to create the auricle.

2. Identify the costal margin.

3. In female patients, mark the breast fold because you may hide your incision in this fold.

Prerequisite Skills

Gentle dissection technique including elevating periosteum and perichondrium

Manipulation of cartilage and bone

Identification and treatment of pneumothorax

Operative Risks

1. Pneumothorax

2. Injury to intercostal vessels and nerves: Recall that the intercostal neurovascular bundle travels in the costal groove, along the inferoposterior surface of the rib. Take particular caution in this region to avoid injury. Although the bleeding may be a nuisance, it rarely has any long-term effects if injured.

Surgical Technique

1. Mark anatomic landmarks as described previously.

2. Mark your incision (Fig. 176.3A): In women, use the inframammary fold. In men, your incision may be directly over the rib to be harvested. A short 3- to 4-cm incision may be used if it is positioned well. Use appropriate retractors to expose the rib as you work.

3. Incise through the superficial thoracic fascia and dissect directly down to the rib.

4. If harvesting cartilage graft, you will encounter the superior portion of the vertically oriented rectus abdominis muscle and fascia (see Fig. 176.3B). Incise the fascia and retract the muscle fibers laterally to access the costal cartilage below (see Fig. 176.3C). Try to avoid dividing the muscle fibers because this will reduce postoperative pain.

5. Incise the periosteum or perichondrium longitudinally over the central portion of the rib (see Fig. 176.3D). At each end of your planned rib harvest, make a perpendicular incision such that the final incision looks like an "H." Making these perpendicular extensions preserves the perichondrial and periosteal flaps and avoids tearing as you dissect around the posterior surface.

6. Using your elevators, carefully raise the periosteum off of the anterior rib. Over the soft costal cartilage, where it is easy to dissect into the cartilage itself, take care that you are elevating the perichondrium in the correct plane.

7. Use the Semb elevators to dissect out the superior and inferior borders of the rib, moving toward the posterior surface.

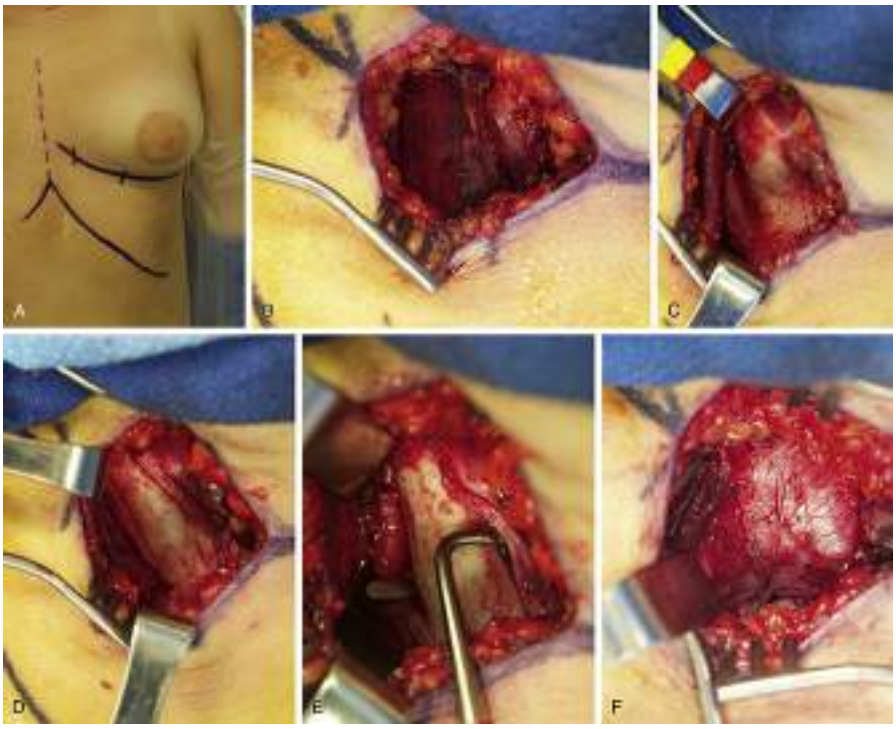

FIG. 176.3 Rib cartilage harvest.

A, Landmarks are marked, including costal margin, midline, and inframammary fold. The incision is planned in the inframammary fold to make it less noticeable. **B,** Incise through skin and subcutaneous tissue to the level of the vertically oriented rectus abdominis muscle. Here, anterior rectus fascia was removed for use as a graft. **C,** Retract the muscle fibers laterally to fully expose the costal cartilage with its overlying perichondrium. **D,** Incise the perichondrium along the length of the rib and perpendicularly at each end. Elevate the periosteum fully across the anterior surface first, then continuing to the superior, inferior, and posterior aspects of the cartilage.

E, The Doyen elevators are placed to complete the circumferential dissection. These are moved medially and laterally along the rib to fully strip the perichondrium from the posterior surface. **F,** After the graft is divided and removed, tightly close the perichondrium. Here we have also placed an indwelling pain catheter for postoperative analgesia.

8. After the dissection has proceeded circumferentially in one area, the Doyen elevators are used to complete the posterior periosteal dissection (see Fig. 176.3E).

9. Use a knife to cut cartilage or a bone cutter to cut the rib close to the costochondral junction.

10. Hold the free edge of bone with bone holding clamps. Complete the subperiosteal dissection laterally to the desired length. The costotome is used to divide the rib laterally.

11. Check for pleural tears by filling the wound with sterile saline and looking for bubbles while the anesthetist performs a Valsalva maneuver.

12. Close the perichondrium or periosteum tightly, and close the fascia and skin in layers (see Fig. 176.3F).

13. Placing a closed suction drain is optional but not usually necessary.

14. Placing a 0.2% ropivacaine pain pump in the wound through multiple fascial layers prior to wound closure reduces postoperative pain.

Common Errors in Technique

1. If harvesting more than one rib graft, do not take two contiguous ribs. Leaving a rib between them preserves the stability of the chest wall. Make the skin incision over the intervening rib. Using this single incision, you can then harvest a rib above and below it.

2. Do not dissect in the subcutaneous plane. All dissection should be down in the subfascial plane, on the rib to be harvested.

3. Failing to have the appropriate retractors prevents the necessary exposure as you dissect medially and laterally.

4. Dissecting too deeply on the posterior side of the rib increases the risk of pneumothorax.

Postoperative Period

Postoperative Management

1. Chest radiograph if there is any concern for pneumothorax

2. Continuous pulse oximetry overnight to monitor for desaturation

3. Incentive spirometry and pulmonary toilet. Ambulation as soon as able

Complications

1. Pneumothorax: This is relatively rare, with an incidence of less than 1%.

   a. If detected intraoperatively, place a red rubber catheter into the pleural space as you close the layers of the chest wall tightly. Have your anesthetist perform a Valsalva maneuver as you remove the catheter with your final suture.

   b. A small pneumothorax on postoperative chest radiograph may require no treatment if the patient is otherwise clinically stable. However, treating the patient with supplemental nasal cannula oxygen at a flow rate of 3 to 6 L/min increases the rate of pleural air absorption.

   c. If there is a larger pneumothorax or if the pneumothorax is clinically significant with increased work of breathing, chest pain, or hypoxemia, a pigtail catheter chest tube or small thoracostomy tube should placed to a chest tube suction system, such as a Pleur-evac. The chest tube may be removed when the pneumothorax has resolved in the first few postoperative days.

2. Bleeding: This is usually moderate and easily controlled intraoperatively. Bleeding most commonly occurs from the intercostal vessels. When dissecting cartilage medially, the internal mammary vessel may be encountered. However, harvesting from a more inferior rib reduces the risk of encountering these vessels.

3. Hypertrophic scarring: This is the most common negative outcome associated with rib graft harvest.

4. Chest wall deformity: This is more common when contiguous ribs are used. When harvesting the costal cartilage for microtia repair, the cartilage may regrow asymmetrically.

Alternative Management Plan

1. Alternative cartilage grafts include nasal septum and ear cartilage.

2. Alternative bone grafts such as split calvarial, iliac crest, or tibial bone may be used instead of rib graft.

Discussion

Evidence-Based Medicine Question

What is the incidence of rib cartilage "warping" in rhinoplasty, and what are some strategies to prevent this?

Costal cartilage grafts for rhinoplasty are common; however, complications including warping occur with some frequency. Two reviews of the literature report an incidence of cartilage warping of 5.2%[4] and 3.0%.[4,5] However, individual studies report rates of warping ranging from 0% to as high as 26%. Authors report different strategies to reduce warping; however, the data to support one technique over another are limited at best. Some authors advocate delaying the insertion of the graft for at least 30 minutes after harvest, and others soak the graft in water to allow the cartilage to change prior to insertion. Many authors cut the cartilage such that the most central segment is used. This is devoid of perichondrium and may have some efficacy in reducing the rate of warping. Finally, for dorsal augmentation, rather than a straight piece of cartilage, many surgeons advocate the use of diced cartilage grafts to eliminate the risk of postoperative warping.

Editorial Comment

The use of rib grafts for mandibular reconstruction has largely been replaced with free tissue transfer; however, in those unable to undergo free tissue transfer or in developing countries where resources may not be available, rib grafts remain a viable and good option. Rib grafts can also be used for mandibular reconstruction in the pediatric population, depending on the defect. Extirpative head and neck surgeons should become familiar with this technique for mandibular reconstruction.

Anna Pou

Review Questions

1. The intercostal neurovascular bundle is located:

   a. Anterior and superior to the rib

   b. Anterior and inferior to the rib

   c. Posterior and superior to the rib

   d. **Posterior and inferior to the rib**

2. The most common complication of rib graft harvest is:

   a. Thoracic instability

   b. **Hypertrophic scar**

   c. Pneumothorax

   d. Bleeding

3. Autologous cartilage for microtia reconstruction may be harvested from:

   a. The second, third, and fourth ribs

   b. The fifth and sixth ribs

   c. **The sixth, seventh, and eighth ribs**

   d. The ninth floating rib

Cranioplasty

Christian B. Ricks, Brian Jankowitz, and Paul A. Gardner

Introduction

Cranioplasty is the main reconstructive procedure in neurosurgery. Cranial defects can vary widely in size and etiology; they include traumatic, infectious, tumor, vascular, and iatrogenic defects. The majority of large defects created in modern neurosurgery are a result of decompression to relieve uncontrolled intracranial pressure (ICP) following trauma, stroke, or hemorrhage. Although decompressive craniectomy has been shown to decrease ICP and improve survival, the indications, methods, and timing are still controversial.[1] Regardless of the cause, it is generally accepted that nearly all cranial defects should be corrected with bone, mesh, or other rigid material to protect the underlying brain. In addition, cranial defects can lead to pain, significant cosmetic deformity, changes in cerebral metabolism, and perturbations in cerebrospinal fluid (CSF) dynamics, which can impair optimal rehabilitation. Infection and wound breakdown are the primary complication following cranioplasty. Other more serious complications, such as hemorrhage/hematoma, stroke, malignant edema, or seizure, are rare.

Key Operative Learning Points

1. The perioperative management of patients undergoing cranioplasty varies depending on the etiology of the cranial defect.

2. Wide exposure of the entire defect is critical for proper, safe, and cosmetically accurate reconstruction. This is generally best achieved through complete reopening of the prior incision but can present a challenge in the setting of trauma, by which bone may be lost beyond the

confines of a standard craniectomy.

3. The entire surgery should remain extradural when possible to avoid further brain injury or complications such as stroke and seizure.

4. Dissection of the temporalis muscle from the underlying dura is frequently challenging, and leaving the deep periosteum adherent to the dura may be the only option in many cases.

5. Care should be taken to avoid transgressing or communication with the frontal (or rarely sphenoid or maxillary) sinuses during exposure for cranioplasty or opening a pneumatized zygoma that can communicate with the mastoid air cells.

6. Complete dissection of the epidural plane to expose the inner cortex of the native skull is critical for replacement of autologous bone or polyetheretherketone (PEEK) implants in contrast to titanium mesh implants, for which only the outer cortex has to be completely exposed.

7. Wide undermining or even rotation of surrounding scalp is occasionally necessary to allow for proper cranioplasty coverage without tension on scalp/skin edges; the latter can lead to wound breakdown and loss of implant.

Preoperative Period

History

1. A thorough history is important to fully clarify the circumstances that led to the cranial defect. Patient factors that lead to wound healing problems or infection (e.g., diabetes, smoking, immunodeficiency, poor nutrition, ischemic necrosis from a helmet) should be corrected prior to cranioplasty to prevent a recurrent infection or wound dehiscence. Vascular compromise to the scalp flap can be a consequence of vasculopathy, trauma, or poor planning of the incisions. Other sources of potential contamination, such as the sinuses in cranial base defects, should be recognized in order to properly plan the cranioplasty. Finally, the need for further treatment of associated intracranial problems such as hydrocephalus must be understood prior to planning the cranioplasty, since this can affect the timing or complexity of reconstruction.

2. The underlying condition that has led to a cranial defect may require ongoing antiplatelet or anticoagulant therapy. The duration and extent of this issue must be thoroughly understood in planning the surgery. Often, cranioplasty must be performed with the patient on acetylsalicylic acid (ASA) to balance the risk of further vascular incident.

3. The overall condition of the patient and his or her wishes must be fully understood to provide the best result and determine the timing of the cranioplasty. In patients without coincident comorbidities who are recovering well, early cranioplasty can be considered to decrease the risk of infection and hasten recovery. Finally, a clear understanding of the patient's physical capabilities and available support will help to determine the best course of recovery.

4. Details of the course of neurologic or systemic recovery are critical to ensure the proper timing of the cranioplasty. Early cranioplasty can be key in the rare setting of the "syndrome of the trephined" (see further on) to ensure reversal of perfusion deficits or prevent further, delayed herniation.

Physical Examination

1. Patients should be examined for signs of systemic infection or indicators of poor wound healing, such as malnutrition.

2. Evaluation of the wound and the cranial defect is critical in planning for a cranioplasty. If the incision shows signs of ongoing infection or failure to heal, this must be resolved prior to surgery. In addition, any scalp retraction, though rare, should be noted in advance, as this can affect the surgical technique and even the type and size of the cranioplasty material.

3. If the bone has been placed in the subcutaneous tissue of the abdomen, it should be palpated to ensure that it has not resorbed. An anteroposterior abdominal radiograph can be used to evaluate further if there is concern for loss of volume.

4. A thorough neurologic examination is critical in understanding where the patient is in his or her expected recovery. The minor disruption of recovery caused by the repeated anesthesia required for cranioplasty must be balanced against improvements related to ease of mobilization,

recreation of normal cranial vault conditions, and even reversal of the "syndrome of the trephined" (see further on).

Imaging

1. Updated imaging is important prior to planning a cranioplasty. Problems such as hydrocephalus, deep infection, and continued edema or hygroma/hematoma formation must be identified preoperatively to ensure their proper management. Simple, noncontrast computed tomography (CT) is adequate in uncomplicated cases.

2. Vascular problems should be thoroughly understood or completely imaged to clarify their impact on remaining cerebral perfusion, scalp perfusion, the need for continued antiplatelet or anticoagulant therapy, or other treatment of associated conditions such as stenosis, dissection, or aneurysm/pseudoaneurysm. Often, CT angiography or MR angiography is adequate to assess associated vascular anomalies, but if follow-up digital subtraction angiography is warranted for full evaluation, it should be performed in advance of cranioplasty to ensure that further additional treatment is not necessary either prior or in concert with cranioplasty.

3. Any sign of superficial or deep infection should be further evaluated with either postcontrast CT, postcontrast magnetic resonance imaging (MRI) with diffusion-weighted imaging, or lumbar puncture to ensure that there is no contraindication to cranioplasty.

Indications

1. Stroke (Fig. 177.1). Three randomized controlled trials (DECIMAL, DESTINY, and HAMLET) have demonstrated reductions in mortality in decompressive hemicraniectomy (DHC) patients, with more favorable outcomes if performed within 48 hours of stroke onset.[2]

2. Trauma (Fig. 177.2). The controversial DECRA study showed that despite decreasing ICP, decompressive craniectomy (DC) was associated with a worse functional outcome in those managed surgically.[1] The recently released RESCUE ICP clarifies that surgical decompression for traumatic intracranial hypertension leads to lower mortality but higher vegetative states than medical management alone.[3]

3. Tumor or vascular malformations (Fig. 177.3). Defects associated with tumor resection are typically a result of local bone invasion by tumors such as meningiomas; therefore cranioplasty should be planned prior to tumor resection and performed at the same time (Fig. 177.4). This can even be done with planning software to create three-dimensional models and allograft plates in advance. More aggressive pathologies such as sarcomas or invasion of superficial tumors such as squamous cell carcinoma should be considered for delayed cranioplasty, allowing for completion of treatments such as adjunctive radiation without the introduction of nonvascularized cranioplasty materials.

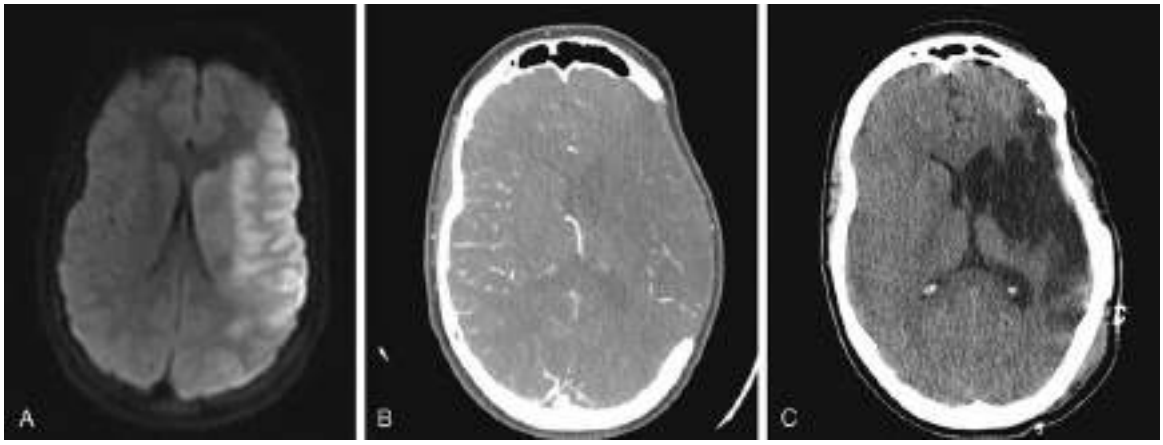

FIG. 177.1 Magnetic resonance imaging, computed tomography, and angiography scans showing, **A,** left middle cerebral artery (MCA) ischemic stroke, **B,** requiring left decompressive hemicraniectomy, **C,** followed by autologous cranioplasty.

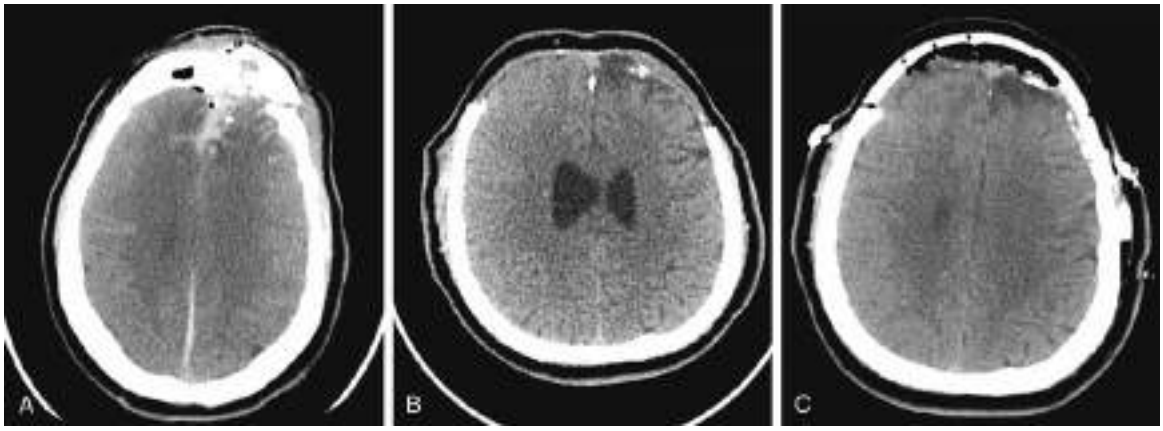

FIG. 177.2 Noncontrast computed tomography scans showing left frontal gunshot wound, **A,** requiring bifrontal decompressive craniectomy, **B,** and polyetheretherketone cranioplasty, **C.**

4. Infection (Fig. 177.5). Includes meningoencephalitis, encephalitis, empyema, posttraumatic and iatrogenic or postoperative infection of the bone flap

5. Flap contamination (dropped flap). There is some evidence that sterile washing with antibiotic solution and betadine is adequate to prevent infection in the setting of a contaminated flap.[4] However, if this is not possible or if there is concern about this technique, then an allograft can be used as a replacement.

6. "Syndrome of the trephined" or "sinking flap syndrome" (Fig. 177.6). This occurs in 10% of DC patients.[5] The sinking flap can cause pressure on the underlying cortex affecting perfusion and CSF flow, which can lead to neurologic deterioration. Severe forms can cause "paradoxical herniation," usually exacerbated by CSF diversion.

7. Damage to unprotected cerebrum requiring use of a helmet[6]

8. CSF alterations. DHC can precipitate hydrocephalus, subdural hygromas, and CSF leaks or fistulas, which may improve once the cranioplasty is performed (see Fig. 177.6).

9. Dural sinus thrombosis. This is rarely treated with DHC but may have a prolonged course of increased ICP compared with an arterial infarct, potentially affecting the timing of the cranioplasty.

Contraindications

1. It is essential to rule out ongoing systemic or local infection before proceeding with the cranioplasty. The preoperative collection of seromarkers of infection—including complete blood count, C-reactive protein, and erythrocyte sedimentation rate—is strongly encouraged. A noncontrast head CT or lumbar puncture can also be helpful in screening for active infection. Residual/recurrent intracranial air or an elevated CSF white blood cell count is especially concerning.

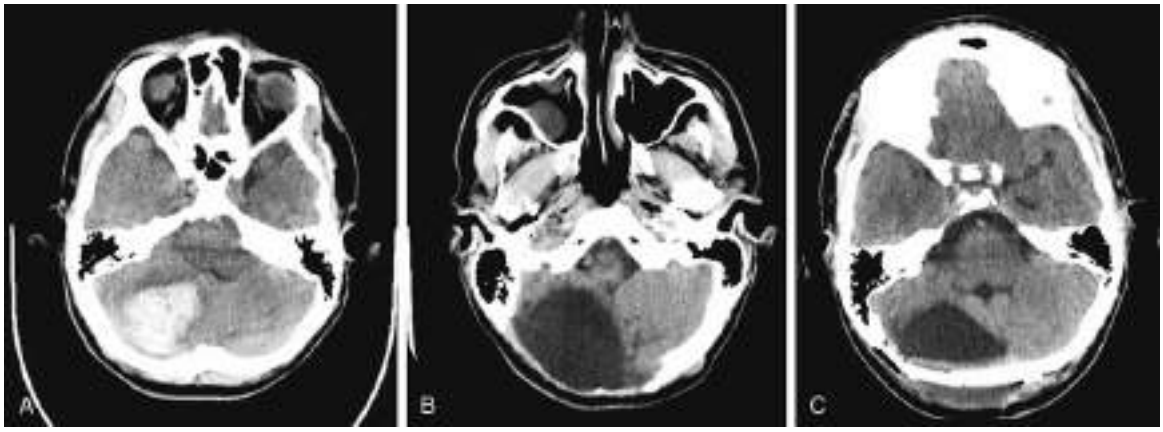

FIG. 177.3 Noncontrast computed tomography scans showing right cerebellar hemorrhage from an arteriovenous malformation, **A,** requiring suboccipital craniectomy, **B,** and polyetheretherketone cranioplasty, **C.**

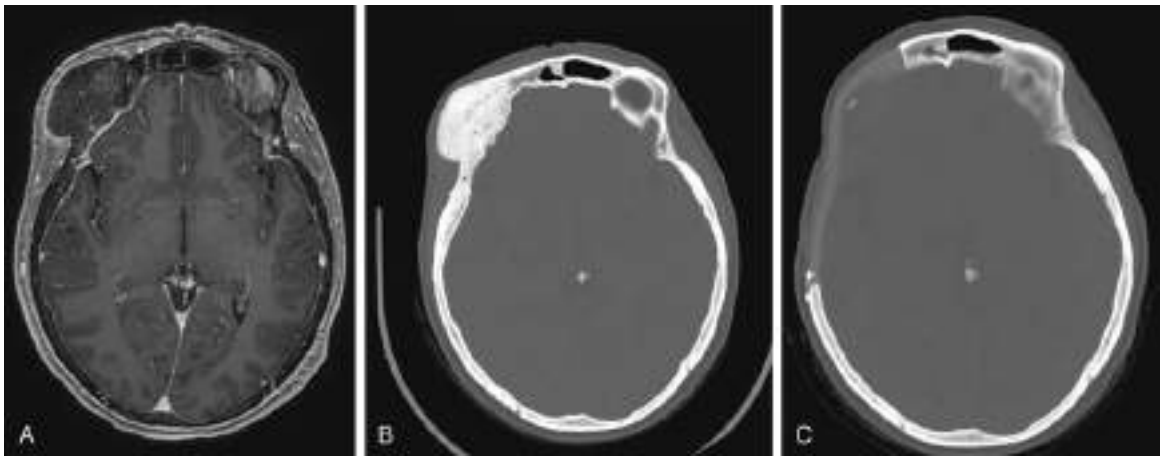

FIG. 177.4 **A,** Contrast magnetic resonance imaging showing intraosseous meningioma. **B,** Preoperative fine-cut computed tomography of the head, **C,** used to create an allograft polyetheretherketone implant using three-dimensional planning software at the time of surgery.

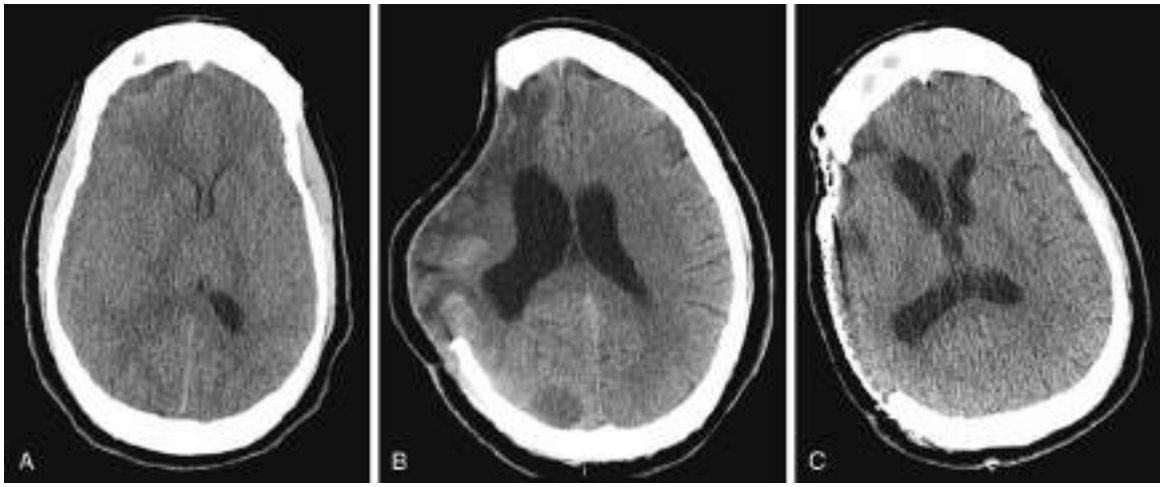

FIG. 177.5 Noncontrast computed tomography scans showing right subdural empyema, **A,** requiring decompressive craniectomy, **B,** and titanium mesh cranioplasty, **C.**

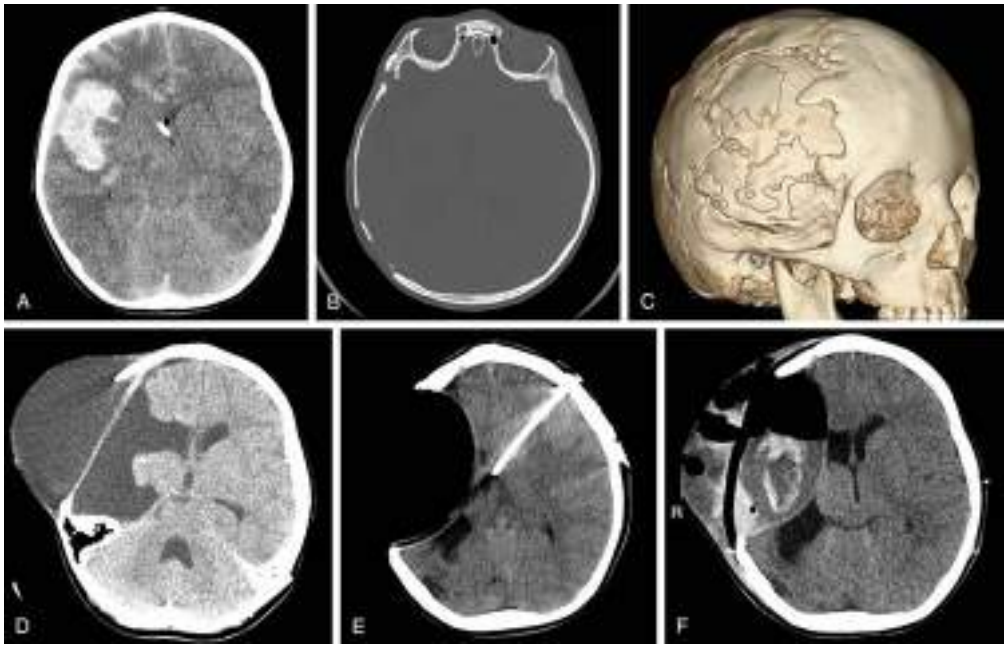

FIG. 177.6 Noncontrast computed tomography scans of a patient with a traumatic brain injury, **A,** requiring right hemicraniectomy. After cranioplasty, bone eventually reabsorbed, **B, C.** Accumulation of extra-axial fluid collection in epidural and subdural spaces as well as hydrocephalus requiring shunting, **D,** followed by sinking flap syndrome, **E,** and postcranioplasty hemorrhage, **F.**

2. Small areas of ischemia, decubitus ulcers, or suture abscesses causing skin necrosis can usually be addressed through intraoperative skin flap techniques or use of a dermal matrix.[7]

3. Continued symptomatic cerebral edema is an obvious contraindication to cranioplasty. The optimal timing for cranioplasty is typically more than 6 weeks to allow for the resolution of edema or evolution of encephalomalacia. If there is any doubt about the timing of cranioplasty, it should be delayed.

4. Adjuvant treatments such as chemotherapy or radiation should be completed and cranioplasty delayed until systemic or local effects have ceased or been minimized as much as possible. Animal studies suggest waiting at least several weeks after surgery to administer radiation to prevent wound complications, but no consensus on the timing of surgery before or after adjuvant therapy exists.[8] A common minimal requirement is to schedule radiation and chemotherapy 2 weeks before and 2 weeks after surgery.

FIG. 177.7 Positioning for a left decompressive craniectomy cranioplasty. **A,** Supine with a shoulder roll to allow for moderate head rotation to bring the craniotomy to the apex of the surgical field without impeding jugular outflow. **B,** Surgical site preparation

including clipping the hair with area for exiting drain, washing with scrub brush, and wiping with chlorhexidine gluconate cloths prior to ChloraPrep sterilization.

5. Systemic conditions such as diabetes mellitus or smoking must be properly addressed prior to cranioplasty. Evaluation of hemoglobin A1c levels and documentation of adequate glucose control are key for diabetics, and, in general, smoking should be stopped prior to any reconstructive procedure.

6. Multiple repeated intracranial infections, wound breakdown, or failed cranioplasties should be considered as a relative contraindication for further replacement. Indolent infections such as *Propionibacterium acnes* should be explored; these often require observing wound cultures at least 7 days. Rare cases require that patients live long periods of their lives without a bone flap, a condition that is usually but not always safe.

7. Patients who are at high risk for general anesthesia must be carefully assessed to determine their risk-benefit ratio for cranioplasty. Frailty indices such as the risk assessment index (RAI) can be used to help decide whether anesthesia can be performed safely.

Preoperative Preparation and Materials

1. Preoperative evaluation of the cranioplasty material is a necessity. The availability and suitability of the patient's bone flap (if removed and saved in a sterile fashion) or commercial implant are critical to confirm. If the bone flap is placed into the abdomen, a radiograph or CT of the abdomen should be obtained to ensure that the flap has not resorbed.

2. The ideal material for reconstruction in the absence of autologous bone should be biocompatible, inert, osteoconductive, and easy to manipulate yet mechanically resistant. The choice of materials depends on the patient's age, size of defect, underlying pathology, fullness of underlying brain, and surgeon preference.[9]

3. The patient's own bone is the first choice for calvarial reconstruction, given biocompatibility, fit, cost, and strength characteristics. The viability of harvested bone flaps can be preserved through freezing, gas sterilization, or implantation in an abdominal subcutaneous pocket. With

the advent of improved sterilization techniques and the adoption of computer-aided allograft creation, autologous bone harvest for split-thickness graft creation is no longer a reasonable option.

4. Alternative materials are generally reserved for cases where autologous cranioplasty has failed (owing to infection or reabsorption), is unavailable, or bone is fractured beyond repair. These materials include synthetics such as PEEK, titanium, and polymethylmethacrylate (PMMA) as well as biomimetics like hydroxyapatite, which behaves like bone and can expand with growth. Preoperative, fine-cut, three-dimensional reconstructive CT scans can be used to create prefabricated custom prostheses,[10] albeit at a significant expense.

5. Larger defects (>25 cm^2) or those in cosmetically important locations should receive custom-made implants, with small defects in hair-covered areas reserved for hand-modeling.

Operative Period

Anesthesia

1. Neuroanesthesia principles should be maintained and appropriate agents administered to avoid inducing intracranial hypertension. Systemic hypotension should be avoided as well, especially in patients with a history of a prior stroke, as there may be penumbral regions of ischemia or the patient may be at risk for watershed infarcts in the setting of vascular occlusion.

Positioning

1. Proper position depends on the type of cranioplasty being performed. In general, the craniectomy defect should be at the apex of the surgical field, which can usually be accomplished by positioning the patient supine with a horseshoe headrest (Fig. 177.7).

2. The neck should not be overly rotated, and a shoulder roll should be used to maximize rotation of the torso while preventing kinking of the internal jugular vein to maintain intracranial venous drainage.

Perioperative Prophylaxis

1. A single dose of weight-based preoperative cefazolin has been shown to reduce infections in craniotomies and is generally repeated postoperatively for 24 hours. Vancomycin and clindamycin are alternatives in patients with beta-lactam allergies.

2. Given the risk of postoperative seizures in supratentorial craniotomies, a single preoperative dose of an anticonvulsant (usually levitiracetam) is often administered, although there is no evidence to support antiepileptic drugs (AEDs) for a cranioplasty. If the dura is not abrogated and there is no evidence of a postoperative seizure, these medications should be stopped immediately or at hospital discharge.

Monitoring

1. Given the noninvasive nature of cranioplasty, intraoperative neurophysiologic monitoring is generally not required.

Instruments and Equipment to Have Available

A standard craniotomy set generally provides the necessary tools. Additional items to have include the following:

1. Raney scalp clips

2. Bovie

3. Bipolar electrocautery

4. Rubber bands

5. Titanium plating system

6. Hemostatic gelatin powder

7. Sponges

8. Jackson-Pratt drain

9. A dural substitute or dural suture should also be on hand in the advent

of a large dural tear.

Key Anatomic Landmarks

1. The necessary landmarks depend on the location of the cranioplasty. For all types of bicortical bone, exposure to the epidural plane must be accomplished circumferentially to allow proper placement of the graft.

2. For hemicraniectomy defects, the circumferential exposure extends inferiorly to the root of the zygomatic arch and sphenoid wing and anteriorly to the superior margin of the frontal sinus. The superior sagittal sinus is sometimes exposed with a hemicraniectomy and always with a bifrontal craniectomy; it should be identified and protected.

Prerequisite Skills

Detailed knowledge of head and neck anatomy and training in head and neck or neurosurgery

Operative Risks

Intraoperative risks include blood loss, dural tears, brain contusion, sinus injury, parenchymal edema and swelling with difficulty placing graft, poor graft fitting or malpositioning, and inability to reapproximate skin from excess tension. See “Complications” further on for complete perioperative risks.

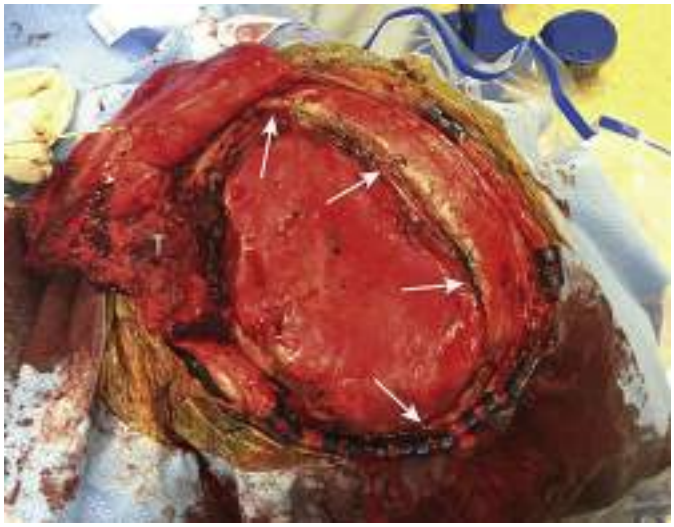

FIG. 177.8 Opening of entire incision, hemostasis with Raney clips, and blunt dissection staying in the epidural plane. Temporalis muscle *(T)* is identified inferiorly above the zygoma and reflected with a myocutaneous flap, followed by circumferential exposure of bicortical bone *(arrows)*.

Surgical Technique

Intraoperative

1. After positioning, the hair is clipped with an electric razor along the prior incision allowing for a small area posteriorly for a drain to be tunneled (see Fig. 177.7) and the surgical field sterilized with chlorhexidine gluconate cloths, followed by ChloraPrep. A complete head shave is not necessary.

2. The original incision is opened in its entirety; bovie electrocautery is used to expose the underlying bone, and Raney clips are placed for hemostasis (Fig. 177.8). Care must be taken in areas where the incision is not over bone so as to stay superficial to the dura.

3. Bicortical bone is exposed circumferentially around the defect. For a standard DHC, this will require extending the dissection inferiorly to the root of the zygomatic arch and anteriorly to the orbital bar and pterion.

4. The myocutaneous flap is gradually dissected from the underlying

dura or dura substitute and brought forward to the superficial temporal line. The plane between dura and temporalis is best found inferiorly above the zygoma and is used to elevate the temporalis muscle with the myocutaneous flap. Dissection superficial to the periosteal temporalis layer is sometimes necessary to prevent durotomies, as this vascular layer is generally adherent to the underlying dura or parenchyma.

5. After careful hemostasis, the bone or implant is plated and advanced anteriorly to minimize bone gaps in the most cosmetic locations before securing it to the skull (Fig. 177.9). If a large gap exists in the inferior temporal region, a mesh plate can be added for cosmetic purposes, although small gaps are well tolerated due to the overlying temporalis muscle.

6. Hydrocephalus or persistent cerebral edema may disallow replacement of the flap, particularly if the graft is placed within the defect, as with an autologous or PEEK cranioplasty. In these circumstances, if hyperventilation, head elevation, and mannitol are not enough, then one may consider placement of a temporary external ventricular drain through the open defect in Kocher's point to allow enough CSF drainage to easily place the cranioplasty.

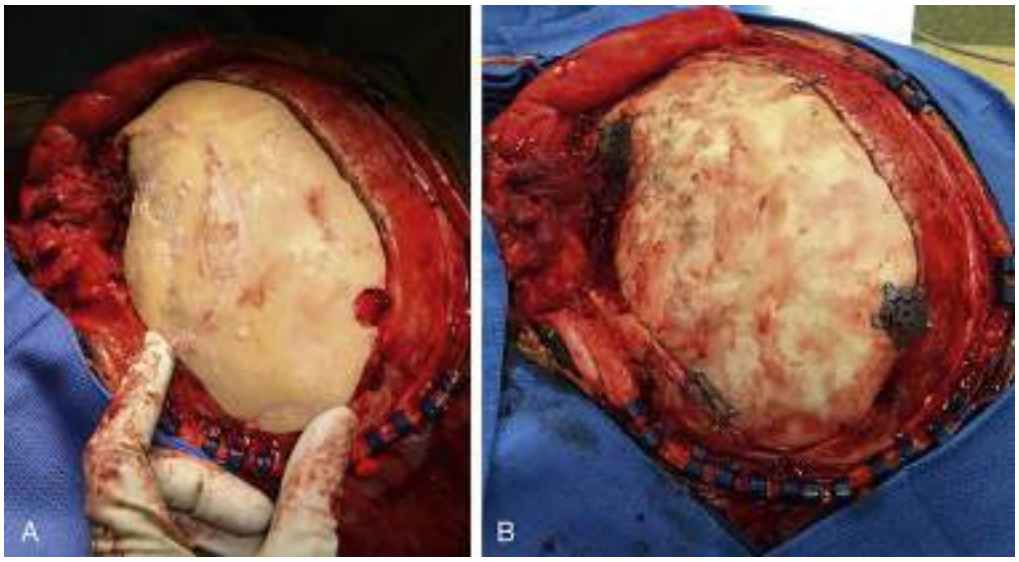

FIG. 177.9 Bone flap is advanced anteriorly, **A,** and plated, avoiding hardware placement under the forehead, **B.**

Closure

1. A 7 or 10 Jackson–Pratt drain is placed below the temporalis muscle for maximal efficacy and tunneled posteriorly. Copious irrigation is followed by closure of the temporalis with interrupted absorbable suture, followed by standard galea fascia approximation using buried interrupted absorbable suture and finally skin closure with either a running Vicryl suture or staples (Fig. 177.10).

2. Larger defects may experience progressive cutaneous retraction, leading to difficulty with closure. This is most commonly encountered along the inferior and posterior limbs of the incision, behind the ear. One should consider approximating this segment first. The incision should have minimal tension to prevent wound healing issues. If the tissue gap is small, parallel incisions in the subgaleal fascia are useful to greater scalp mobility. One may also perform a subperiosteal dissection posteriorly or across the midline to mobilize more scalp tissue for closure. Larger defects may require the use of tissue expanders or plastic surgery assistance. Vertical mattress sutures can be useful for tissue reapproximation and eversion in focal areas of difficulty.

Common Errors in Technique

1. Dissection superficial to the temporalis muscle is a common error. Leaving the muscle on the dura can create a significant residual mass below the cranioplasty. The loss of its scalp attachment can also precipitate temporalis dysfunction and atrophy.

2. To limit cosmetic deformity after cranioplasty, the graft should be advanced as far anteriorly as possible, titanium plates avoided underneath the forehead, and titanium mesh used for large temporal defects extending to the floor of the middle fossa.

3. Excessive tension of the skin closure can be avoided using subgaleal incisions, galeal fascia reapproximation, and vertical mattress sutures when needed

Postoperative Period

Postoperative Management

1. Although the use of preoperative antibiotics has been established to prevent infectious complications in craniotomies, meta-analyses evaluating postoperative duration have revealed no clear association. In general, antibiotics are continued for a total of 24 hours, with cefazolin the preferred agent unless a beta-lactam allergy exists, in which case vancomycin or clindamycin is used.

FIG. 177.10 Jackson-Pratt drain tunneled posteriorly is placed beneath retracted temporalis muscle followed by tensionless closure of galea fascia and skin staples for optimized skin eversion.

2. Approximately 14% of patients have postoperative seizures. Factors increasing this risk include male sex, increased age, and graft infection. Unfortunately meta-analysis has not shown a convincing impact on seizure frequency with the use of perioperative AEDs. In patients not already on AEDs, a preoperative single dose is commonly given, with the duration usually lasting until discharged from the hospital.

3. A noncontrast CT of the head is generally advised to ensure proper graft placement and to rule out a subdural hematoma or parenchymal contusion.

4. Restarting antiplatelet agents is generally avoided until outpatient follow-up; however, high-risk patients can immediately resume such

treatment; some studies have even shown no increase in hemorrhagic complications in patients taking acetylsalicylic acid.

Complications

1. Hemorrhage (see Fig. 177.6)—A new ipsilateral hematoma occurs in 3.6% of patients undergoing cranioplasty.[5]

2. Wound healing—The healing of a long flap based on a limited blood supply is exacerbated if the superficial temporal artery is sacrificed. Immobile patients can exert pressure on the wound; this occurs in up to 10% of patients and must be carefully avoided.[5]

3. Infection—3.8% of patients develop abscesses or epidural empyema. Meningitis has occurred in 4.5% and infection of a bone flap 5.4%. Synthetic dura and biomaterials are associated with higher rates of infection.

4. Hydrocephalus, or subdural effusions (see Fig. 177.6)—seen in 5.8% of patients compared with 25% of those following DC[5]

5. Bone resorption (see Fig. 177.6)—occurs in 9.5% of cases and may require reoperation.[5] Long storage time before implantation is a modifiable risk factor.

6. Cranioplasty dislocation—seen in 5.9%

7. Seizures—14% of patients have postoperative seizures, although a proportion of these already have a diagnosis of epilepsy.

Alternative Management Plan

1. Patients with small cranial defects should be considered for observation, since bone ingrowth or scar hyperplasia can eventually cover many small defects. Methylmethacrylate or calcium phosphate–based compounds, which start as a putty and harden within minutes, are another alternative to fill in small defects with an excellent cosmetic result.

2. Patients with very large defects and poor neurologic status, significant comorbid disease, or multiple infections should be considered for chronic

helmeting to avoid the risks of additional surgery.

Discussion

Evidence-Based Medicine Question

What factors contribute to periprocedural complications of cranioplasty?

1. Complications—including hydrocephalus, infections, hematomas, bone resorption, seizures, and wound breakdown—are common after cranioplasty, which has a 31% complication rate. One study examining patient variables in 348 cases found, through multivariate analysis, that predictors of complications included hypertension, hemorrhagic stroke, advanced age, diabetes mellitus, seizures, repeat surgery, and bifrontal cranioplasty.

2. Many of these variables are the same, having contributed to the initial pathology requiring craniectomy, and are nonmodifiable. Further investigation regarding the modification of these variables, such as improved glucose control, would be beneficial to alter management strategies.

Editorial Comment

Cranioplasty is a common neurosurgical reconstructive procedure that is best managed using a multidisciplinary approach. In addition to the indications mentioned in the text, cranioplasty can be used in the repair of craniosynostosis, lack of skull expansion, and birth defects. Depending on the situation, the bone may be removed, reshaped, or replaced.

Review Questions

1. Which of the following statements is true? The optimal timing for a cranioplasty is

a. 1 to 2 weeks

b. **6 to 12 weeks**

c. 6 to 12 months

d. At any time

2. Which of the following is NOT an appropriate cranioplasty graft in the setting of an infection?

a. Titanium mesh

b. Polyetheretherketone

c. **Autologous bone**

d. Methylmethacrylate

3. The most likely site of wound breakdown after a cranioplasty is

a. Anteriormost aspect near the widow's peak

b. Inferiormost aspect near the zygoma

c. Superiormost aspect near the sagittal suture

d. **Posteroinferiormost aspect behind the ear**

4. Which statement is true regarding perioperative antiepileptic drugs and antibiotics?

a. Several studies show decreased postoperative complications with perioperative administration.

b. **Studies suggest that preoperative antibiotics but not antiepileptic drugs affect postoperative complications.**

c. Studies suggest that preoperative antiepileptic drugs but not antibiotics affect postoperative complications.

d. There is no supporting literature for the perioperative administration of either.

Nerve Graft Techniques

Laura Hetzler, and Anna Pou

Introduction

Neural injury, repair, and subsequent recovery are widely studied, since these topics relate to the entire human body. There are few other regions of the body where impaired nerve function can be more devastating than in the head and neck. Peripheral cranial nerves contribute to our most personal attributes, such as speech, facial expression, and the complex neural coordination of deglutition. The technical aspects of nerve repair have been refined; however, challenges persist in terms of the functional outcomes.

Any patient undergoing head and neck surgery faces risks to multiple cranial nerves. Often in our field, a nerve must be identified and dissected for preservation or resected as part of an oncologic procedure. Oncologic goals supersede the preservation of neural structures when there is curative intent; however, even when the nerve can be preserved, extensive dissection can cause functional issues that may not be entirely relieved.

The facial nerve (FN) is the most commonly reconstructed nerve in the head and neck. The FN is also the most studied in regard to outcomes. The loss of facial expression removes the visible thumbprint of our personalities in day-to-day interactions and can be devastating both emotionally and functionally. Unlike some of the other cranial nerves that are affected in oncologic surgery or even with the removal of benign tumors—such as cranial nerve VIII during acoustic neuroma surgery or the spinal accessory during radical neck procedures—a repair of the FN may be neither indicated nor performed.

Key Operative Learning Points

1. Tension-free repair is imperative. Placing the nerve in a "lazy s" configuration within the wound is helpful to ensure that there is adequate laxity.

2. Preoperative assessment of the patient's smile on the normal side of the face should determine what facial motion and vector are needed to recreate a natural reanimation of the paralyzed side.

3. Success in cross-FN grafting for smile reanimation relies on choosing the appropriate donor nerve that is associated only with movement of the oral commissure and upper lip, that is, the nerve that mimics the preoperative smile of the normal side.

Preoperative Period

History

Patient Selection

The severity and anatomic location of the injury are important predictors of how or when a repair should be performed.

- The viability of the proximal nerve, distal nerve, and musculature and motor end plates are key variables in the algorithm of neural repair.
- The time from injury to repair plays a key role in designing a reconstructive plan.
- Immediate repair will typically yield the best outcome, as Wallerian degeneration is complete after 3 days, after which the distal nerve segments can no longer be stimulated.
- The patient's goals and wishes must be discussed prior to intervention. Patient expectations must be managed to prepare for incomplete recovery, which can occur even with the best of reconstructive efforts.

Past Medical History

- History of diabetes mellitus and smoking may impair wound healing.
- Medical comorbidities may limit the use of general anesthesia and

therefore also the reconstructive options.

- History of soft tissue loss in the face should be noted.
- Negative margins or absence of recurrent tumor must be confirmed.

Past Surgical History

- History of previous FN repairs
- History of previous facial surgeries, including skin cancers
- Surgery performed on potential donor sites

Physical Examination

- Extent of facial paralysis throughout the regions of the face—that is, paresis versus paralysis, upper versus lower division, individual nerve branches
- Presence of soft tissue loss
- Evaluation of donor sites (neck, leg, groin)

Imaging

None necessary

Indications

- Suspicion of injury to the FN with immediate loss of function
- Mechanism of injury consistent with FN disruption
- Resection of FN segment as part of en bloc cancer surgery
- Iatrogenic injury during surgery involving the tissues surrounding the FN

Contraindications

- Chronicity of facial paresis such that the motor end plates associated

with the muscles of facial expression are no longer viable

- Resection of distal FN branches and facial musculature
- Comorbidities precluding general anesthesia
- Unrealistic patient expectations as to level of recovery with nerve repair and grafting

Preoperative Preparation

Considerations for Type of Procedure to Be Chosen

- All attempts should be made to do a primary neurorrhaphy when there has been traumatic or iatrogenic injury.
- In the traumatic or oncologic setting, there may be loss of tissue so that the surgeon will be unable to perform a tension-free coaptation. In this situation the patient should be asked for consent to the use of appropriate donor sites for nerve graft harvest.
- Donor nerves are selected based on the caliber, length, and branching pattern needed.
- The anticipated viability of proximal and distal nerve segments will dictate whether or not an interposition graft can be used versus an alternate neural input such as a nerve transposition. Preoperative photos should be taken in order to document a visible deficit.

Surgical Considerations

- Nerve composition may be variable even along the length of the same nerve, depending on the location.
- Presence or absence of a nerve sheath or epineurium may require alternative techniques for nerve repair—that is, FN repair.
- The proximal FN is devoid of a nerve sheath at the cerebellopontine angle. As the seventh cranial nerve travels through the temporal bone, it develops more of a covering. This nerve sheath offers some protection with surgical manipulation, thus allowing the extratemporal nerve to be more resilient to extensive dissection.

- Epineurial repair is the standard technique of neurorrhaphy. Perineurial and endoneurial or fascicular repairs have been discussed; however, they have yet to prove beneficial.

Operative Period

Anesthesia

- In the situation of early nerve repair where distal branches can be stimulated, the anesthesia team must be advised that no long-lasting paralytics should be administered.
- Epinephrine 1:100,000 should be used without xylocaine if nerve stimulation will be necessary. Most operative suites will have 1:1000 epinephrine available. Dilution to 1:100,000 epinephrine is performed by mixing 0.1 mL 1:1000 epinephrine with 9.9 mL injectable saline for hemostasis without nerve inhibition.

Positioning

- Most of these operations are performed with the patient in the supine position with the donor site exposed.

Perioperative Antibiotic Prophylaxis

Antibiotic prophylaxis should be given according to established guidelines. In the case of a truly clean procedure with no entry into the middle ear or oral cavity, weight-appropriate antistaphylococcal antibiotics should be given preoperatively and discontinued 24 hours postoperatively.

Monitoring

- Handheld nerve stimulator
- Routine monitoring by anesthesia team

Instruments and Equipment to Have Available

- A microscope should be draped and optics arranged to allow appropriate assistance.
- Microinstruments should be used for the handling of neural tissues.
- Nylon suture 8-0 and 9-0
- A blue or green background should be available to allow for tissue discrimination.

Key Anatomic Landmarks

- FN(main trunk):
  - Posterior belly of the digastric muscle: (FN lies 1 cm deep to the medial attachment of the muscle to digastric groove)
  - Tragal pointer (FN lies approximately 1 cm deep and slightly anterior and inferior to pointer)
  - Tympanomastoid suture line (FN lies 6 to 8 mm deep)
- Sural nerve:
  - The nerve is located 2 cm posterior to the lateral malleolus running anterior to the small saphenous vein.
- Medial antebrachial cutaneous (MABC) nerve
  - The MABC nerve runs down the ulnar side of the arm medial to the brachial artery and pierces the deep fascia with the basilic vein.
- Great auricular nerve:
  - Midportion of sternocleidomastoid muscle (SCM) approximately 1 cm from the external jugular vein.

Prerequisite skills

- Proficiency in microsurgery

- Detailed knowledge of FN anatomy

Operative Risks

- Bleeding
- Inability to obtain adequate donor nerve/length
- Inability to locate cut ends of FN branches
- Associated donor site morbidity
  - MABC nerve: injury to median nerve

Surgical Technique

Primary Neurorrhaphy

The best possible outcome after neural injury follows primary neurorrhaphy.[1] Direct coaptation of proximal and distal nerve segments should be performed only if a tension-free neurorrhaphy can be achieved. Standard microsurgical techniques apply, and microscopic magnification should be used.

- Nerve ends should be carefully using microinstruments.
- The nerve ends should be trimmed of necrotic tissue with sharp microscissors or a 15-blade knife stabilized on a firm surface, such as a tongue blade.
- Trimming should proceed in such a fashion that the axons do not extend beyond the nerve sheath. This allows for gentle approximation of the axons end to end.
- A standard epineurial repair done under magnification with interrupted 8-0 or 9-0 monofilament sutures should be performed on a blue or green background, allowing for tissue discrimination and visualization.
- The number of sutures used depends on the location of the nerve as well as its caliber. We typically perform only the number needed to ensure that all fascicles are tucked nicely within the epineurium

(Fig.178.1).

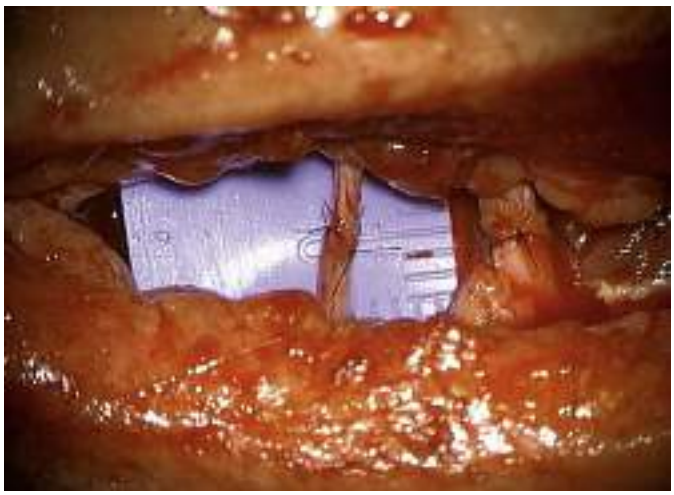

FIG. 178.1 Primary neurorrhaphy of a large buccal branch of the facial nerve following trauma *(left).* The larger structure in the image *(right)* is a repaired parotid duct.

FIG. 178.2 Great auricular nerve cable interposition extending from the main trunk of the facial nerve to the hypoglossal nerve. The patient had a facial neuroma extending to the stylomastoid foramen; therefore a primary neurorrhaphy could not be performed, necessitating an interposition graft. Note the laxity in the bridging nerve.

Interposition Graft

If an intervening segment of nerve is lost and tension-free repair is not possible, an interposition graft is used. The identical microsurgical technique used in primary neurorrhaphy is employed; however, there are two coapted sites on either end of the nerve graft (Fig.178.2).

- The great auricular nerve is the most commonly used nerve graft in the head and neck. Other nerve graft options in these areas include the lesser occipital and transverse cervical nerves.
- If a longer nerve graft is needed, attention may be turned to the upper and lower extremities for donor sites.
  - The sural nerve in the lower extremity is an excellent resource when length is needed.
  - The medial anterior brachial cutaneous nerve in the upper extremity is useful because it has an excellent match to the FN diameter as well as an ideal branching pattern.

FIG. 178.3 Skin markings for locating the great auricular nerve. This nerve will be located at the bisection of a line between the angle of the mandible and the mastoid tip. Notice its proximity to the external jugular vein (prominence seen at the inferior neck).

FIG. 178.4 The great auricular nerve seen running anterosuperiorly on top of the sternocleidomastoid muscle *(arrow)*.

Great Auricular Nerve Graft

The great auricular nerve (GAN) is a branch of the cervical plexus that passes reliably over the sternocleidomastoid muscle.

- The GAN passes 1 cm inferior to the external jugular vein.
- Lengths of up to 6 to 7 cm with a distal branching pattern can be harvested.
- The GAN can be located by drawing a line between the mastoid tip and the angle of the mandible. Bisecting this line with a perpendicular line marks the approximate location of the GAN (Fig. 178.3).
- In performing an ipsilateral surgery where a nerve graft may require the use of the GAN, care should be taken when the subplatysmal skin flaps are being raised so as not to damage the integrity of the nerve (Fig.178.4). Consideration must be given to using the contralateral great auricular nerve in the presence of malignancy, where perineural invasion could be present ipsilaterally.

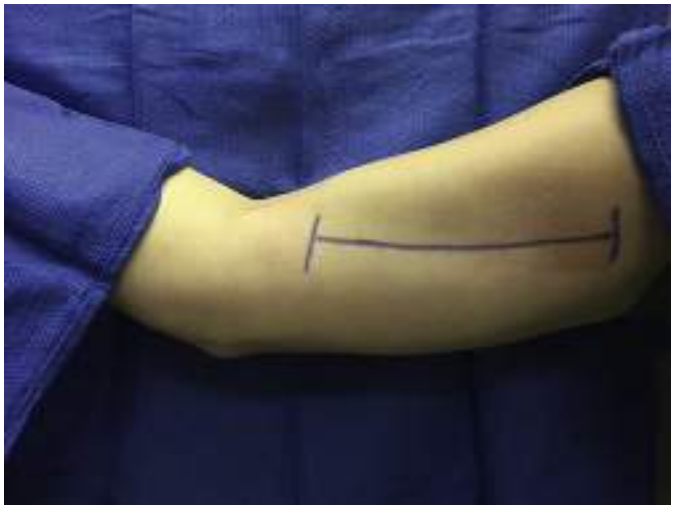

FIG. 178.5 Skin incision marking for harvesting the medial antebrachial cutaneous nerve along the bicipital groove in the upper right arm.

Medial Antebrachial Cutaneous Nerve Graft

The MABC nerve is a sensory nerve of the forearm used extensively in the repair of peripheral nerves.

- The MABC nerve is located in the plane between the biceps and the triceps in the upper arm; it has a grafting length of 15 to 25 cm.
- The branching pattern and caliber are similar to those of the distal FN, and donor site morbidity is minimal.
- Recommendations have been made to use epinephrine only so that the median nerve can be stimulated; however, we do not find that imperative for this technique.
- The MABC nerve can be harvested from the elbow to the axilla, depending on the length needed.

Positioning

- A two-team approach is made possible by prepping the arm into the field of surgery at the time of ablation.
- The arm should be positioned in such a way that the surgeon can visualize the ventral surface.

Surgical Technique

- The bicipital groove is the primary landmark and should be marked and injected with local anesthetic (Fig.178.5).
- Incision through the skin with a #10 blade scalpel is performed.
- Electrocautery can be used to dissect through any dense subcutaneous adipose tissue.
- Once the two major muscle groups are visualized, the dissection can be carried into the fascial plane between them. The next major landmark to be seen is the basilic vein.
- The MABC nerve can be found just superior to the basilic vein.
- The median nerve is quite large and lies inferior and deep to the vein, with a smaller cutaneous nerve just anterior to the vein as well.
- The MABC is a single cable of nerve with a branching pattern near the elbow that can be seen passing more anteriorly into the cutaneous structures (Fig.178.6).
- Closure of the incision with 4-0 Monocryl followed by a 5-0 Monocryl running subcuticular suture is appropriate.

FIG. 178.6 Nerve hook underneath the medial antebrachial cutaneous nerve in the left upper arm. Note the distal branching and the basophilic vein and median

nerve deep to the medial antebrachial cutaneous nerve.

- Typically no drains are needed, but the arm may be wrapped with Kerlix and an Ace bandage.

Sural Nerve Graft

The sural nerve is frequently used for cranial nerve repair; its diameter is ideal for a variety of repairs. The sural nerve provides sensation to the lateral and dorsal aspects of the foot.

- A two-team approach is recommended and is quite feasible.
- A donor nerve length of up to 40 cm can be achieved with minimal donor site morbidity.
- Preoperatively, any history of trauma to the donor site must be ruled out.
- Caution must be used in diabetic patients as these wound care issues could be intensified in patients with diabetic neuropathy.

Positioning

- The entire lower leg should be prepped and draped with the lateral surface visible for ease of harvest.

Surgical Technique

- The most direct approach to harvesting this nerve uses a vertical incision running from its location at the lateral malleolus and extending superiorly along the lateral leg for the length needed. A preferred alternative to this is to perform horizontal stair-step incisions at intervals along the length of the nerve extending superiorly in the lateral leg (Fig.178.7).
- A fascia stripper can be used for minimally invasive nerve harvest. Most recently, endoscopic harvest has been popularized in many centers with emphasis on cross-FN grafting.
- The nerve will be located 2 cm posterior to the lateral malleolus

running anterior to the small saphenous vein.

- The initial incision should be made approximately 2 cm above the lateral malleolus to make sure that the nerve has not yet branched.
- Blunt dissection should be performed once the incision is extended into the immediate subcutaneous tissue.
- Generally three superficial branches can be seen distal to the lateral malleolus; these should be preserved (Fig.178.8).
- Dissection along the length of the nerve can be performed for 3 to 4 cm using lighted retractors.
- A second stair-step incision can be made 6 to 8 cm superior to the initial incision, and dissection can be carried inferiorly to the initial dissection plane.
- Subsequent stair-step incisions can be created until the desired length of nerve has been harvested.
- Closure of each incision with 4-0 Monocryl, deep as well as running subcuticular suture, and overlying Steri-Strips is appropriate.
- The leg may be wrapped with Kerlix for compression.
- No drains are needed.

Cross-Facial Nerve Grafting

Cross-FN grafting is unique in regard to facial reanimation. The goal of all facial reanimation is to restore a mimetic spontaneous smile. Reanimation of the face using the contralateral FN is ideal in that it offers elegant coordination with the normal side of the face. In contrast to nerve transposition procedures, where movement of the tongue or jaw produces facial movement, cross-FN grafting on the paretic side is powered by the facial nucleus for the contralateral normal nerve, offering better symmetry of motion. The downside of cross-FN grafting is of course the risk to the function of the normal FN; however, this is rarely noticed. Other criticisms include less power given the smaller caliber of nerves.

FIG. 178.7 Left lower extremity stair-step incisions for harvesting a sural nerve graft.

FIG. 178.8 Up to 40 cm of sural nerve can be harvested from each lower extremity.

Many techniques have been described, such as segmental end-to-end neurorrhaphy extending from the donor nerves to the paretic nerve end to side versus end-to-end coaptation. This procedure, just like any nerve graft, must be customized to the individual. Cross-FN grafting is also used to power free muscle transfer for facial reanimation in a two-stage operation.

One- or two-stage cross-FN grafting depends on the status of the contralateral face. Typical two-stage cross-FN grafts occur in the setting

of free tissue transfer for reanimation of the smile. The first stage of a two-stage cross-FN grafts can also be performed at the same time as a "babysitter" procedure (typically nerve transposition) to allow for neural input into the facial musculature prior to coaptation of the distal end of the cross-FN graft during the second stage.

Positioning

- A two-team approach for sural nerve harvest and facial wound prep can be used.
- The bed is typically turned 90 or 180 degrees depending on room orientation. If 90 degrees is turned, then the donor leg should be away from anesthesia for ease of harvest.

Anesthesia

- If the nerve graft is to be tunneled in the upper lip, an oral ring adair elwyn (RAE) tube secured to the lower lip in the midline is ideal, and the entire face should be prepped.
- The normal (not paralyzed) side of the face is injected with epinephrine 1:100,000 (no lidocaine) (Fig.178.9).

Technique

- A facelift incision can be made using a #15 blade, and a skin flap can be elevated over the parotideomasseteric fascia extending out to the anterior border of the parotid gland.
- The incision can be extended in a modified Blair fashion to allow for adequate exposure, but this is rarely needed.

FIG. 178.9 Skin markings for the left, previously reanimated side of the face (post-"babysitter" XII–VII) at the time of cross-facial nerve grafting. Note extension into the hairline rather than utilization of the full neck incision for this nerve transposition. Note: The babysitter nerve is defined in the section titled Cross-Facial Nerve Grafting.

- Extension into the temporal hair is often all that is required for adequate exposure.
- FN branches are then identified anterior to the parotid gland and isolated with vessel loops (Fig.178.10).
- When reanimation of the contralateral oral commissure and smile is the objective, the nerve selected should provide motion of the oral commissure with little effect on the surrounding musculature of the eye, nose, or neck.
- Typically four to five branches with cross-innervation can be located.
- The sural nerve is then coapted end to end to the donor facial branch in the standard epineurial fashion, as described earlier.

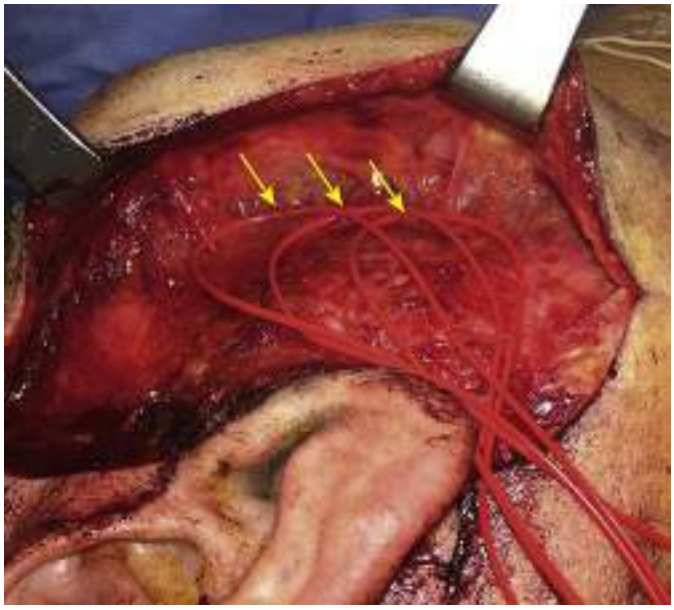

FIG. 178.10 *Right* (donor) side of cross-facial nerve graft with three large buccal branches identified at the anterior border of the parotid overlying the masseteric fascia *(arrows)*.

- The grafts, depending on the recipient branch, are tunneled above the supraorbital ridge and within the brow for the orbicularis oculi, or they are tunneled within the upper lip for the zygomatic and buccal branches.
- A Penrose drain may be placed and removed on postoperative day 1.
- The skin is closed with 4-0 Monocryl in a deep, buried fashion and 5-0/6-0 nylon on the skin.
- A pressure wrap may remain in place for 1 to 3 days.

Common Errors in Technique

- Tension on the suture line
- Failure to clean nerve ends prior to repair, which can lead to ingrowth of scar tissue and formation of a neuroma

Postoperative Care

- Incisions should be kept clean with shower, soap, and water after 36 hours.
- Nonreactive and nonmedicated emollients should be used on all incisions.
- Ocular care in the setting of FN paralysis is important to avoid permanent loss of vision.
- Reassurance and management of patient expectations are imperative, as the return of function will take months to occur. Nerves grow at a rate of 1 mm per day; thus, for a graft such as cross facial nerve grafting (CFNG), this may take more than 6 months.
- Facial physical therapy is recommended once facial motion is noted (Fig.178.11).

Complications

Complications: Common to All

- Bleeding: Bleeding is typically minor in nature; care is taken to adequately ligate named vessels, and bipolar cautery is used to control oozing or bleeding near the nerve endings. Scarring (particularly involving incisions on the face/neck and donor sites): Hypertrophic scarring or keloids may develop owing to tension on the suture line, infection, or skin type. Meticulous skin closures and the use of Kenalog injections to treat hypertrophic scarring/keloids will improve outcomes.

FIG. 178.11 Pre- and postoperative photograph of nerves XII–VII (3 years postsurgery) and CFNG (8 months postsurgery).

- Infection: This is uncommon in clean cases performed using sterile techniques. Infection may occur in "dirty wounds"—that is, contamination from traumatic injuries. This can be prevented by wound débridement, copious irrigation, and antibiotic therapy using current guidelines. Erythema, edema, and purulent drainage are signs of infection. Infection is treated with culture-directed antibiotic therapy and incision and drainage if necessary.
- Hematoma: Acute changes in the operative sites including fullness, ecchymosis of skin, pain, seepage of blood from suture lines, and rapid filling of drain reservoirs are signs of hematoma. If a hematoma forms over the trachea, it can lead to respiratory distress. Hematoma is treated with evacuation of the hematoma and control of bleeding sites. This can be prevented with meticulous hemostasis, control of blood pressure, and avoiding the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and anticoagulants in the perioperative period. Failure to improve nerve function: Failure of the nerve repair is noted on physical examination. This can be prevented by using good surgical technique with attention to detail and meticulous handling of the tissues and nerve endings. If repair was that of the FN, static

procedures can be employed to improve facial function/esthetics.

- Neuroma: Neuroma formation occurs particularly in the GAN. This typically presents as a trigger point on the lateral neck. Prevention and treatment of GAN neuromas are similar; the cut nerve ends are cauterized or ligated and buried in the SCM.

Harvesting of the Great Auricular Nerve

- Numbness of the outer cheek, occipital scalp, and earlobe may be present but often improves over time.
- Burn to affected areas due to lack of sensation. Patients, particularly women, should be advised to use caution with blow dryers and curling irons.

Harvesting of the Medial Antebrachial Cutaneous Nerve

- Donor-site morbidity is typically very limited.
- Injury to the basilic vein and median nerve may occur.
- A sensory deficit along the medial aspect of the mid-forearm is usually well tolerated.

Grafting of the Sural Nerve

- Intensification of diabetic neuropathy findings and pain may occur.
- Lateral and dorsal foot numbness can impair the ability to discern injury.
- Transient ankle or foot edema may be present.
- Minimal levels of pain, cold sensitivity, and scar discomfort are common.

Grafting of the Cross-Facial Nerve

- Weakness of the donor side of the face is typically not an issue. If it

does occur it is usually not noticeable and, in fact, in some instances may improve symmetry. Any appreciated differences are often temporary, as cross innervation prevails.

- Overall graft failure

Alternative Management Plan

- Static reanimation using a facial sling (Alloderm, fascia lata) plus surgical treatment of the eye
- Treatment of the eye only: gold/platinum weight; lateral tarsal strip/canthopexy; brow lift

Discussion

Evidence-Based Medicine Question

What salvage procedure can be used for failed cross-FN graft (CFNG) with free gracilis muscle transfer in facial paralysis?

Eisenhardt et al. reported a 14% (3/21) failure rate with use of a CFNG and gracilis free muscle transfer for FN paralysis. Although the failure rate of free gracilis muscle transfer in this situation is low, the transferred muscle requires sufficient neural input from the CFNG to be successful. The authors used direct recoaptation of the neural pedicle from the CFNG to the masseteric nerve, leaving the free muscle transplant in place if it was still viable. Because the involved structures are in the same vicinity, another nerve graft was unnecessary. If the procedure is not delayed, the gracilis muscle can be left in place. If the primary reconstructive procedure occurred more than 12 months earlier, a new muscle transfer should be performed. All patients showed muscle contraction after 3 months and a smile with open mouth after 6 months. Symmetrical excursions of the oral commissure and a satisfactory social smile were achieved; however, a spontaneous smile was not.[5]

Editorial Comment

Although this chapter deals mainly with FN reconstruction, the same principles and techniques apply to any nerve reconstruction. Meticulous detail must be paid to patient selection, reconstructive procedure, and technique in order to obtain the best functional result possible and best quality of life. Although primary neurorrhaphy done as soon as possible is the best option, this is not always possible. Following FN repair, weakness and synkinesis are inevitable; House-Brackman grade 3 is the best outcome. FN repair is often supplemented with static procedures such as a platinum (gold) weight for the upper eyelid.

Review Questions

1. FN grafting is contraindicated in

   a. Patients undergoing postoperative radiation therapy

   b. Patients with insulin-dependent diabetes mellitus

   c. Patients above 90 years of age

   d. **Patients whose facial muscles are absent**

2. Sural nerve graft harvest

   a. **Is relatively contraindicated in diabetics**

   b. Is seldom used in facial reanimation

   c. Is most useful when a short graft is required

   d. Can potentially cause foot drop

3. Primary neurorrhaphy is done by suturing the

   a. **Epineurium**

   b. Perineurium

   c. Endoneuriurm

   d. Axons

4. The medial antebranchial cutaneous nerve

   a. Lies between the biceps and triceps of the upper arm

b. Provides a grafting length of 15 to 25 cm

c. Branching pattern and size are similar to the distal FN

d. **All of the above**

5. In a 78-year-old male with skin cancer metastatic to the parotid gland requiring neck dissection, parotidectomy, and sacrifice of the FN, nerve grafting should be

a. Delayed until radiation therapy is complete

b. **Performed immediately**

c. Abandoned due to advanced age

d. Delayed pending final margins

Eyelid Reanimation in Patients With Facial Paralysis

Jason A. Liss, and Morgan R. Godin

Introduction

Prompt attention to the ophthalmic manifestations of facial nerve paralysis is crucial to the care of affected patients. Loss of facial nerve function causes numerous functional and cosmetic deficits in the periocular region. These include poor eyelid closure with an increased palpebral fissure height, lower eyelid ectropion causing limited lacrimal pump function, decreased meibomian gland function and rapid evaporation of tears, decreased lacrimation from loss of parasympathetic tone, and descent of the brow with secondary hooding of the visual axis.[1,2]

Symptoms can range from mild discomfort to severe dryness with corneal ulceration and scarring to corneal perforation with loss of the involved eye. Greater degree and duration of facial nerve dysfunction is the most important risk factor for significant ocular damage, but other features such as concurrent trigeminal nerve involvement, poor Bell phenomenon, and increased age or greater tissue laxity worsen the prognosis for the eye.[2]

We have chosen to include two routinely performed staples of eyelid "reanimation" (upper eyelid weight and lower eyelid lateral tarsal strip) and one procedure that we have found to be of great value in the management of facial nerve paralysis (the tarsoconjunctival onlay flap). The latter can be viewed as a type of tarsorrhaphy, with greater cosmesis and reversibility, with potentially less limitation of peripheral vision.[3]

Other important procedures often performed on patients with facial paralysis, such as brow-lifting procedures, blepharoplasty, tarsorrhaphy,

and lower eyelid spacer graft, are briefly mentioned in the discussion.

Upper Eyelid Weight

Upper eyelid closure is more important than lower eyelid position in preserving corneal lubrication. Two common techniques that are employed to treat a paralyzed upper eyelid are the upper eyelid weight and the palpebral spring. Palpebral springs produce a more rapid closure than a weight, but they typically drop the upper lid margin and have problems with extrusion and migration as well as magnetic resonance imaging (MRI) incompatibility.[4] Therefore, placement of an upper eyelid weight, which allows the paralyzed lid to close with gravity, continues to be commonly performed due to its relative surgical simplicity, high success rate, low complication rate, and cosmetic acceptability. Gold is the most commonly placed weight material; but a cosmetically visible lump, extrusion, inflammation, capsule formation, and gold allergy have led to platinum chains being inserted in many cases.[5] The pretarsal weight implantation technique is described in detail in this chapter.

Key Operative Learning Points

1. Placement of the weight should be as inferior and medial as possible and fixed to the tarsal plate to prevent migration.

2. Dissection through the orbicularis oculi muscle should be straight down from incision to superior tarsal border so that the muscle can be easily and anatomically closed over the implant.

3. Pretarsal placement of the weight will offer the best closure but might be more cosmetically noticeable than other placement techniques.

Preoperative Period

History

Frequent irritation or foreign body sensation?

Prognosis for return of facial nerve function, if known?

Previous eyelid surgery?

Physical Examination

Degree of upper eyelid closure during reflex blink and with forced closure? How much lagophthalmos is present?

Corneal sensation impaired?

Conjunctiva injected?

Corneal surface examination: fluorescein uptake using cobalt blue light, especially inferiorly?

Areas of corneal thinning, stromal haze, neovascularization, or scarring?

Imaging

None necessary

Indications

1. Significant lagophthalmos with signs or symptoms of corneal desiccation

2. Expected duration of facial nerve paralysis of at least several weeks

Contraindications

1. Known gold allergy would indicate placement of an alternate implant material.

2. Restrictive or cicatricial cause of lagophthalmos

Preoperative Preparation

The appropriate weight is chosen by affixing a sizer weight, using double-sided tape or mastisol, to the pretarsal eyelid skin, waiting 10 minutes for the patient to get accustomed to the weight and then observing the eyelid position and movement. Good closure with minimal

lagophthalmos and a maximum of 1 to 2 mm of ptosis indicates the appropriate weight selection.

Operative Period

Anesthesia

Local anesthetic or monitored anesthesia care with local anesthetic

Positioning

Supine

Perioperative Antibiotic Prophylaxis

None

Monitoring

None unless under monitored anesthesia care (MAC)

Instruments and Equipment to Have Available

- Castroviejo needle drivers
- Westcott or spring-loaded iris scissors
- Small toothed forceps for gentle tissue handling
- Small double-skin hooks
- Appropriate suture
- Gold or platinum plate

Key Anatomic Landmarks

1. The superior border of the tarsus is indicated by a vascular arcade often visible beneath the levator fibers and on the surface of Muller muscle.

2. The lash follicles in the skin will indicate the approaching eyelid margin as dissection descends along the tarsus.

3. When dissecting in the pretarsal region of the eyelid, only the skin, orbicularis, and levator aponeurosis fibers are encountered before reaching the tarsal plate.

Prerequisite Skills

1. Basic tissue handling and dissection skills

2. Familiarity with the extraocular anatomy

Operative Risks

1. Dissection superior to the tarsal plate could result in recession of the levator tendon causing ptosis and bleeding from the peripheral eyelid vascular arcade.

2. Placing the implant-fixing sutures full thickness through the eyelid could cause significant corneal damage postoperatively; in addition, failure to lift the tarsal plate off the globe surface when placing these sutures risks entering the cornea with the suture needle.

Surgical Technique

1. The upper eyelid crease is marked across the central and medial upper eyelid. The placement of the weight will be centered over the medial limbus (border of the iris) (Fig. 179.1A). In a case of a concomitant sixth cranial nerve palsy, placement should be as far medial as possible.

2. The upper eyelid is injected with 1% lidocaine with 1:100,000 epinephrine.

3. A 2- to 2.5-cm incision is made with a number 15 blade in the marked crease of the upper eyelid. This incision line is generally 8 to 10 mm from

the margin of the upper lid.

4. Sharp dissection is carried through the orbicularis oculi, straight down to the surface of the tarsal plate. The tarsal plate is contacted near its superior border (see Fig. 179.1B).

5. A pretarsal pocket is then created, which extends inferiorly to the beginning of the lash follicles, and as medial as the tarsus extends (see Figs. 179.1C and 179.2A).

6. The implanted weight is placed into the pocket, ideally centered over the medial limbus and as inferior as possible, with the two suture holes inferior and the single central suture hole superior. The implant is secured using 8-0 nylon sutures, placed partial thickness through the tarsal plate (see Fig. 179.2B). To place these partial-thickness sutures, the lid is elevated off the surface of the globe, and after placement, the underside of the upper eyelid is inspected to ensure that the needle has not been passed full thickness through the conjunctiva.

7. The orbicularis oculi muscle is then closed with buried interrupted 6-0 Vicryl sutures.

8. The skin layer is then closed using 7-0 chromic sutures or similar (see Fig. 179.1D and 179.2C).

Common Errors in Technique

1. Failure to place the weight centered over the medial limbus thereby sacrificing some eyelid closure

2. Failure to properly fix the weight to the tarsal plate

3. Failure to close the orbicularis layer over the weight to prevent extrusion

4. Suturing deeper tissue such as the septum or the levator in the attempt to close orbicularis, thereby shortening the eyelid and creating cicatricial lagophthalmos

Postoperative Period

Postoperative Management

1. Ophthalmic antibiotic ointment is applied 3 to 4 times per day to the suture line.

2. If removable sutures are used, they are removed in 7 to 10 days.

3. Even if dissolvable sutures are used, the patient should be seen within 2 weeks to monitor the condition of the corneal and eyelid closure.

Complications

1. Oversized or undersized weight

2. Implant migration and extrusion

3. Inflammatory reaction or allergy to the implant

4. Pressure-induced astigmatism

Alternative Management

1. In some cases with reasonably good eye closure, lubrication alone or lubrication and lower eyelid surgery might be sufficient.

2. Palpebral springs can be considered.

Lateral Tarsal Strip

Loss of tone in the orbicularis oculi muscle causes laxity and often ectropion in the lower eyelid, distracting the eyelid from the globe, allowing tears to pool in the inferior conjunctival cul de sac, blurring vision, worsening the lacrimal pump function, and allowing rapid evaporation of tears.

In many cases, a lateral tarsal strip procedure to shorten and tighten the lower eyelid can be extremely helpful in reducing lower eyelid laxity and improving lower eyelid apposition to the globe.[6,7] Importantly, this procedure *need not* be reversed in case of facial nerve recovery.

Key Operative Learning Points

1. The structurally sound load-bearing tissues that must be sutured together to tighten the eyelid are the tarsus in the posterior lamella of the eyelid and the periosteum just inside the lateral orbital rim.

2. The eyelid should be shortened horizontally such that after suturing, it can be distracted from the surface of the globe by about 1 to 2 mm.

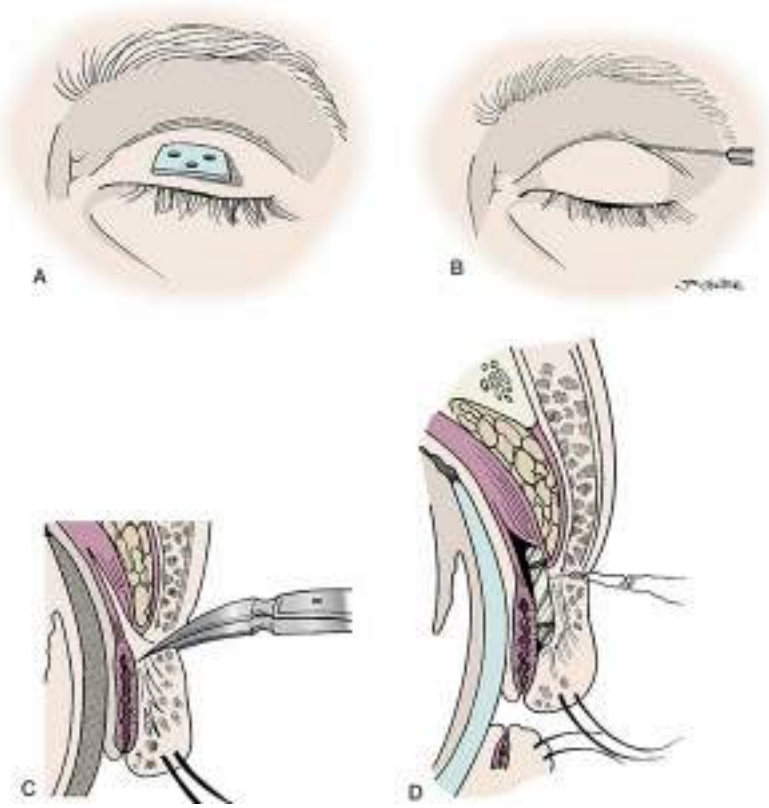

FIG. 179.1 **A,** Gold weights are tried as external lid loads preoperatively. **B,** Double-action scissors are used to sharply dissect a pocket to the tarsal plate noted as a white plane. **C,** Further dissection divides the orbicularis muscle and levator aponeurosis. The lowest point of dissection is 2 mm from the lash line, often noted surgically as the position of the vascular arcade. **D,** The gold weight is centered at the medial and central third of the lid to improve coverage medially. Three-point fixation is necessary to avoid extrusion, and the levator and

orbicularis are closed with 6-0 absorbable suture.

Preoperative Period

History

Frequent irritation or foreign body sensation?

Tears welling up in the cul de sac, intermittent blurred vision, frequent epiphora?

Prognosis for return of facial nerve function, if known? Lower eyelid drops or ectropion?

Previous lower eyelid surgery?

Physical Examination

Significant lower eyelid laxity or ectropion?

Prominent globe compared to the orbital rim? (Simulating a lateral tarsal strip might paradoxically slide the lower eyelid margin beneath the globe rather than anterior to it.)

Impaired corneal sensation?

Conjunctiva injected?

Corneal surface examination, fluorescein uptake, especially inferiorly?

Areas of corneal thinning, stromal haze, neovascularization, or scarring?

Imaging

None necessary

Indications

1. Lower eyelid laxity with a globe that is not very prominent compared to the orbital rim

2. Symptomatic dry eye, tearing, and/or an expected long-term facial nerve dysfunction

Contraindications

1. Prominent globe such that if the lid is tightened, the lid margin will slide under the globe rather than protecting it further

FIG. 179.2 **A,** Pretarsal pocket has been created, which extends inferiorly to the lash follicles and medially to the edge of the tarsus. **B,** Implant (in this case, platinum) is placed into the pretarsal pocket as inferiorly as possible,

centered over the medial limbus and secured with 8-0 nylon sutures, partial-thickness through the tarsus. **C,** Skin closure using 7-0 chromic sutures, after closure of orbicularis over the implant with 6-0 Vicryl.

Preoperative Preparation

None

Operative Period

Anesthesia

Local anesthetic or MAC with local anesthetic

Positioning

Supine

Perioperative Antibiotic Prophylaxis

None

Monitoring

None unless under MAC

Instruments and Equipment Have Available

Similar to gold weight procedure

Key Anatomic Landmarks

1. The tarsus lies in the posterior lamella of the eyelid, is about 3.5- to 4-mm tall in the lower eyelid, and is bordered posteriorly by conjunctiva,

anteriorly by orbicularis, and superiorly by the eyelid margin.

2. The tarsal strip should be attached to the Whitnall tubercle, located 4 to 5 mm posterior to the orbital rim and about 11 mm inferior to the frontozygomatic suture (which is not seen in the surgery)—at about the level of the inferior pupillary margin or such that the lid rides just above the inferior limbus centrally.

Prerequisite Skills

Basic tissue-handling and dissection skills; familiarity with the extraocular anatomy

Operative Risks

1. Use caution not to puncture the globe with a curved suture needle when suturing the tarsal strip.

2. Bleeding can be encountered in the dissection of the lateral canthus or lateral eyelid.

Surgical Technique

1. The area of the lateral canthus and lateral lower and upper lid is injected with 1% lidocaine with 1:100,000 epinephrine.

2. A horizontal or slightly downward-angled lateral canthal incision is made through the lateral commissure and the canthal skin for about 1 cm (see canthotomy/cantholysis picture, Chapter 153).

3. Sharp scissors are used to cut through the orbicularis oculi down to the level of the periosteum of the lateral orbital rim, taking care not to disrupt the periosteum on the rim.

4. The lower eyelid is grasped just lateral to the epithelialized margin and pulled anteriorly and medially, stretching the canthal tendon. The canthal tendon is cut with Stevens tenotomy scissors until the lower eyelid falls freely away from the globe (inferior cantholysis) (Fig. 179.3A).

5. Traction on the lower eyelid toward the lateral orbital rim is used to

determine the desired amount of shortening of the lid. The lid should be distractible by about 1 to 2 mm off the globe once it is shortened.

6. The orbicularis and skin layer are divided off the anterior face of the tarsus for the length of the desired tarsal strip, the marginal epithelium is excised from the margin, and the conjunctiva is scraped off the posterior tarsus with a number 15 blade or lightly cauterized with bipolar cautery (see Fig. 179.3A).

FIG. 179.3 **A,** Lateral tarsal strip (LTS) has been prepared by removing orbicularis and skin from the anterior tarsus, marginal epithelium from the superior

tarsal edge, and conjunctiva off the posterior tarsus. **B,** LTS harnessed with double armed 4-0 Mersilene suture on an S2 needle from posterior to anterior through the strip; one arm is placed 1 mm below the lid margin then the second one 1 to 2 mm below the first. **C,** LTS secured with horizontal mattress suture to the periosteum inside the lateral orbital rim such that the lower eyelid is at the level of the inferior limbus centrally.

7. The lateral tarsal strip is harnessed at its medial-most extent with a double-armed 4-0 Mersilene suture on an S-2 needle, from posterior to anterior through the strip. One arm is placed 1 mm below the lid margin, and the second is placed about 2 mm below the first in the same fashion. These needles should not come through the skin anteriorly (see Fig. 179.3B).

8. The tarsal strip is then sutured to the periosteum over the Whitnall tubercle as follows: Each arm of the 4-0 Mersilene suture is placed through the medial-most extent of the tarsal strip from the posterior (conjunctival) side to the anterior side, and then each needle is sutured to the periosteum inside the lateral orbital rim, at about the height of the inferior pupil, or such that the lower eyelid hits just above the lower limbus centrally, in horizontal mattress fashion (see Fig. 179.3C).

9. Prior to tying the Mersilene, a 6-0 Vicryl suture is used in buried fashion to reestablish the lateral commissure by suturing the new lateral extent of the lower eyelid to the lateral extent of the upper eyelid. The Mersilene is then tied to tighten the eyelid.

10. The skin of the lateral canthus is then trimmed if needed and closed with an interrupted 6-0 plain gut or 7-0 chromic gut suture.

Common Errors in Technique

1. Over- or undertightening of the eyelid

2. Placing the canthus too high or too low

3. Failure to get a solid bite of periosteum at the orbital rim

4. Anterior placement of the lateral tarsal strip causing anterior

distraction of the lower eyelid

Postoperative Period

Postoperative Management

Complications

1. Suture granuloma

2. Eyelid dehiscence

3. Recurrence of ectropion

4. Eyelid rides beneath the globe and fails to provide protection

Alternative Management

1. In some patients with a prominent globe or recessed malar eminence, an eyelid spacer or lower eyelid advancement might be indicated.

2. In more severe cases, a lateral tarsorrhaphy or, in our opinion, a lateral tarsoconjunctival flap from upper lid to lower lid might be very helpful in supporting the lower eyelid and giving good corneal coverage.

Lateral Tarsoconjunctival Onlay Flap Lower Eyelid Suspension

The lateral tarsoconjunctival onlay flap lower eyelid suspension surgery can be beneficial for many patients with facial nerve paralysis. This procedure provides numerous advantages over a tarsorrhaphy, with similar benefits. A tarsorrhaphy can be cosmetically unappealing, limit the peripheral vision, and reversal can cause trichiasis and margin keratinization. The onlay graft provides excellent lower eyelid suspension (and shortening if combined with a lateral tarsal strip), is more aesthetically pleasing than a tarsorrhaphy, provides some upward lower eyelid movement on lid closure, is less peripherally limiting due to the wider palpebral aperture, and is more cleanly reversible (Fig. 179.4).[3]

FIG. 179.4 Lateral tarsoconjunctival onlay flap with lower eyelid suspension; note relatively wide palpebral aperture compared to typical lateral tarsorrhaphy.

Key Operative Learning Points

1. This flap technique is similar in concept to a Hughes tarsoconjunctival flap for eyelid reconstruction.

2. It is important not to extend the tarsoconjunctival flap too loosely from the upper lid, as doing this will sacrifice some of the lower eyelid suspension.

Preoperative Period

History

Similar to the procedures described earlier

Physical Examination

- Significant lagophthalmos
- Poor upper eyelid closure
- Lower eyelid ectropion and laxity

- Corneal staining or more severe corneal dryness
- Loss of corneal sensation

Imaging

None necessary

Indications

Indicated in patients with poor eye closure, lower eyelid ectropion, and dryness, especially if the eyelid weight and lateral tarsal strip have not provided enough benefit. In more severe cases, it can be performed primarily, often along with an eyelid weight, lateral tarsal strip, and lower eyelid retractor recession.

Contraindications

Prior procedures compromising the tarsus of the upper lid or the margin of the lower lid, such as eyelid reconstructions after cancer excisions or significant eyelid trauma

Preoperative Preparation

None

Operative Period

Anesthesia

Local anesthetic or MAC with local anesthetic

Positioning

Supine

Perioperative Antibiotic Prophylaxis

None

Monitoring

None unless under MAC

Instruments and Equipment to Have Available

Similar to the procedures described earlier

Key Anatomic Landmarks

1. The tarsus is located in the posterior lamella of the upper eyelid and measures about 8 to 10 mm in height centrally but tapers at its sides.

2. It is important to leave the inferior 4 mm of tarsus intact to preserve upper eyelid structural integrity.

3. The destination of the flap in this case is the posterior lamella (tarsus) of the lower eyelid margin.

Prerequisite Skills

Basic tissue handling and dissection skills; familiarity with extraocular anatomy

Operative Risks

Minimal

Surgical Technique

1. The lateral upper and lower eyelids are infiltrated with 1% lidocaine

with 1:100,000 epinephrine.

2. A 5-0 silk traction suture is placed in the upper eyelid margin, and the eyelid is everted over a Desmarres retractor.

3. The posterior tarsal surface is dried, and a tarsal segment is marked in the lateral superior tarsus, leaving the marginal 4 mm intact and measuring about 6 mm horizontally.

4. The tarsus is incised along the marked lines with a number 15 blade, and the tarsoconjunctival flap is developed with scissors by dissection superiorly in the plane anterior to tarsus, that is, leaving the tarsus pedicled on the conjunctiva, taking care to advance the tarsal segment enough to reach its destination on the lower eyelid margin but not in excess (Fig. 179.5A).

5. The lateral lower eyelid margin is divided at the gray line for the distance corresponding to the developed tarsoconjunctival flap, and the epithelium of the posterior lamellar margin is excised (see Fig. 179.5B).

6. The tarsoconjunctival flap is sutured to the denuded tarsus of the lower eyelid with interrupted 6-0 Vicryl sutures, in mattress fashion (see Fig. 179.5C and D).

7. If lower eyelid laxity exists that needs to be addressed, a canthotomy/cantholysis and lateral tarsal strip may be performed **prior to** denuding the lower lid margin and suturing the upper lid flap.

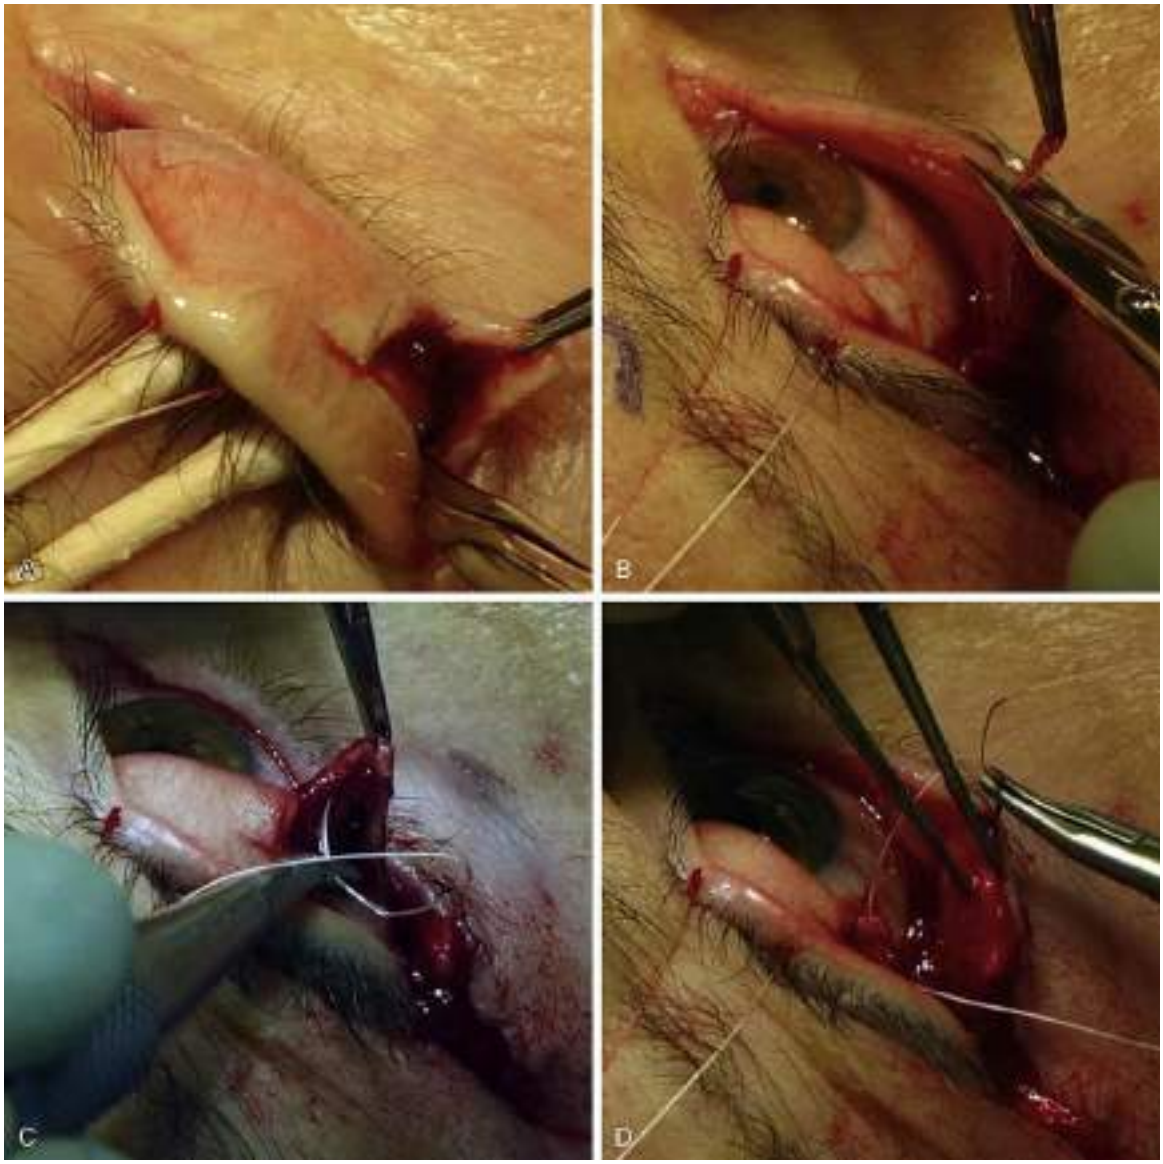

FIG. 179.5 **A,** With the upper eyelid everted, the marginal 4 mm of tarsus is left intact, and the lateral superior tarsus is incised with a number 15 blade, then bluntly recessed downward on a conjunctival pedicle. **B,** The lateral lower eyelid margin is divided into anterior and posterior lamellae, and the posterior marginal epithelium is excised for a distance corresponding to the tarsoconjunctival flap width. **C and D,** The tarsoconjunctival flap is sutured to the denuded tarsus of the lower eyelid with interrupted 6-0 Vicryl sutures.

Common Errors in Technique

1. Advancing the tarsoconjunctival flap too freely from the upper eyelid can reduce the lower eyelid suspension.

Postoperative Period

Postoperative Management

Antibiotic ointment or drops to the involved eye for about 1 week; follow-up within 2 weeks to check on the condition of the cornea

Complications

1. Dehiscence of the graft
2. Peripheral vision limitation
3. Suture granuloma

Alternative Management

To be considered as part of the armamentarium along with the other procedures in this chapter

Discussion

There are many surgical options in the management of the ophthalmic manifestations of facial paralysis, and we have described several here. The majority of patients require a combination of these techniques, and the approach should be tailored for each patient.

Eyelid loading is a standard component in the care of most patients. The success rate is high in most studies, with excellent results for safely reducing lagophthalmos.[8,9] Drawbacks include the slow eye closure achieved by relying on gravity, and complications including weight extrusion, poor cosmesis, inflammation/allergy, and astigmatism. Using platinum chains reduces the incidence of all of these complications except for the slow closure.[5]

Lateral tarsal strip is a well-described and successful procedure for

improving lower eyelid tension and position.[7,8] In patients with lower eyelid laxity and ectropion that do not have overly prominent globes, this is an excellent technique to consider.

In some cases, either because the globe is prominent compared to the orbital rim (Hertel measurement of about 20 mm or more), or there is a recessed malar eminence, or simply due to the tissue laxity and lack of muscle tone, a posterior lamellar eyelid spacer graft is needed to bolster the lower lid against gravity and help bring the lower eyelid margin up to the inferior limbus. This anatomic situation is often referred to as a "negative vector." A tarsal strip alone would potentially pull the eyelid beneath the globe, so the lid needs to be made taller.

Many materials have been used as a spacer graft through the years, with strengths and weaknesses of each material. Some of the choices are autografts (hard palate, ear cartilage, dermis fat graft),[10] cadaveric allografts (acellular human dermis (Alloderm, banked sclera), and xenografts (porcine acellular dermal matrix [Enduragen]; porcine intestinal submucosal collagen matrix [Tarsys]). Hard palate offers an excellent analogue to eyelid posterior lamella because it contains both collagen and mucosal lining, resists gravity well, and does not reabsorb over time. It does require a donor surgical site, though, so many of these procedures are now being done with acellular porcine dermal matrices. These are our favored materials; the technique is outside the scope of this chapter.

The lateral tarsoconjunctival onlay flap lower eyelid suspension surgery can be beneficial for many patients not responsive to eyelid loading and lower lid tightening alone. Advantages over tarsorrhaphy are greater cosmesis, less peripheral vision limitation, lower eyelid elevation on closure, and easy reversal.[3] In severe cases in which these techniques are not working, a lateral tarsorrhaphy must be considered.

Descent of the brow due to loss of frontalis muscle action can cause debilitating obstruction of the visual axis and great cosmetic asymmetry. Chemodenervation above the normal brow can provide improved symmetry. Brow lifting procedures such as pretrichial, endoscopic, mid-forehead and direct brow lifts, as well as transblepharoplasty browpexy procedures, are often a necessary component of care, especially in longer-term cases. In older patients especially, eyelid skin must also be reduced with a concurrent blepharoplasty. The blepharoplasty, however, should

be done conservatively, and care should be taken not to excise descended brow skin rather than true excess eyelid skin. These techniques are outside the scope of this chapter.

Evidence-Based Medicine Question

Is surgical management generally successful in protecting the cornea and restoring comfort in patients with facial nerve paralysis?

Eyelid weights with or without concomitant lower eyelid procedures are very successful in restoring satisfactory closure to the eyelid. Foda,[8] in 1999, reported that 92.5% of patients had complete closure, and Snyder in 2001 showed 89% of patients had satisfactory closure. Jobe,[9] in 1974, had only a 3% extrusion rate for gold weights, although authors have found up to 50% extrusion in some studies. The platinum chains cause less allergy and tissue inflammation, with less extrusion and better cosmetic results.

The lateral tarsal strip is also quite successful, with Marzouk et al.[6] reporting 85% of patients having satisfactory correction of ectropion with similarly good aesthetic and functional results. Kam et al.[7] found 87% functional and 78% anatomic success.

Tao et al.[3] in his report on 110 patients treated with the tarsoconjunctival onlay procedure (with or without canthopexy) found improved lagophthalmos, exposure keratopathy, and eyelid position in all cases.

Golio et al.[1] reported on 72 patients with cancer-related facial paralysis, treated with combinations of gold weight (72 patients), lateral tarsorrhaphy (71), lateral tarsal strip (53), and brow lift (21). All patients reported less dependence on external lubricants, 30 of 39 reported improved foreign body sensation, and 36 of 52 reported less unwanted tearing. They summarize that outcomes in facial nerve paralysis are excellent in general but that most patients require several procedures, which can be performed together.

Editorial Comment

This chapter describes the basic procedures necessary to protect the eye

in case of temporary or permanent facial nerve dysfunction. Whenever possible, it is preferable to start with surgical correction of the lower lid position, because this procedure will not need to be reversed in the event of nerve recovery. The chapter begins with a description of the placement of an upper eyelid load to assist with closure: This improves volitional blink but does not improve the more important reflex blink, so it may be less useful in patients who cannot be taught to intentionally close the eye. There is also a critical question of whether there is loss of corneal sensation, which severely impedes corneal healing. If this is present, tarsorrhaphy should be strongly considered.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Where is the optimal pretarsal placement of a gold weight in the upper eyelid?

   a. Centered over mid-pupil

   b. **Centered over medial limbus**

   c. Centered over lateral limbus

   d. Centered over the orbital septum

2. Potential advantages of a platinum chain over a gold weight include all of the following, except

   a. Improved cosmesis

   b. Lower frequency of allergy

   c. Lower extrusion rate

   d. **Improved speed of closure**

3. The lateral tarsal strip is sutured to which anatomic landmark?

   a. **Periosteum inside the lateral orbital rim**

   b. The orbicularis oculi of the upper eyelid

   c. The inferior crus of the lateral canthal tendon

d. Just outside the lateral orbital rim on the Whitnall ligament

4. A patient has suffered unilateral facial nerve paralysis with resulting lagophthalmos and unclear expected recovery time. What is the single best initial treatment?

   a. Antibiotic ointment

   b. Lateral tarsoconjunctival onlay flap

   c. Gold weight placement

   d. **Artificial tears**

5. All of the following are true regarding the lateral tarsoconjunctival onlay procedure, except

   a. It induces some lower lid elevation on eye closure.

   b. **It is difficult to reverse without complication.**

   c. It narrows the palpebral fissure.

   d. It may limit peripheral vision.

Facial Reanimation

Barry Schaitkin, and Courtney T. Chou

Introduction

- Rehabilitation of the patient with chronic facial paralysis must take into account the loss of form and function. When contemplating facial reanimation, the surgeon should consider all variables that might influence the choice of procedure, including the patient's age, prognosis, pathology, the extent of paralysis and functional deficit, the current status of the nerve and the likelihood of spontaneous recovery, other neural deficits, comorbidities, and patient expectations (Box 180.1).[1,2] Reanimation of the paralyzed eyelid is usually required in addition to the procedures described in this chapter (see Chapter 179).

Key Operative Learning Points

- Surgical principles of nerve repair:
  - Nerve repair, whether by direct anastomosis or graft placement, must be tension-free.
  - The endoneurial surface of each end must match.
  - The ideal graft not only has the proper length but also a similar axon volume.
  - Nerve repair should always be performed using an operating microscope.

Preoperative Period

History

- History of present illness
  - Cause of paralysis
    - One may think of the facial nerve nucleus as the proximal system and the facial nerve musculature as the distal system and classify patients based on which systems are surgically available. The procedures are then dictated by the integrity of those systems for use by the surgeon.
      - Proximal system intact and distal system intact
        - Patients with disruption of the facial nerve in the temporal bone are good examples of the proximal and distal system intact. These patients are ideally suited for having the facial nerve nucleus reconnected to the facial musculature by primary neurorrhaphy or by use of a nerve graft. Reconstituting the nerve should be performed as soon as possible to achieve the best results.
      - Proximal system intact and distal system not available
        - Patients with extensive invasion of the facial nerve by cancer can create a situation without a distal nerve graft site. Ideally, the viable proximal facial nerve can then be used to innervate a microvascular free flap, or alternatively, these patients without a distal system can be helped by muscle transposition.
      - Proximal system not available and distal system intact
        - Patients who have lost the facial nerve as part of acoustic tumor surgery should have the nerve reconstituted immediately, if possible, by a nerve graft. However, this frequently is not possible, and patients are often reluctant to have a craniotomy for reestablishing nerve continuity. These patients are dynamically innervated by nerve substitution with a masseteric nerve graft, hypoglossal jump graft, or by use of a cross-facial nerve graft.
      - Neither system available
        - For those lacking both systems, two dynamic options are available: the temporalis muscle transposition and the innervated free flap based on another cranial nerve (V, the

contralateral cranial nerves VII, XI, and XII have been used). This situation is characteristic of the patient who has undergone radical surgery for cancer of the parotid gland and presents years later for reanimation.

- Duration of paralysis
  - The sooner reinnervation is performed, the better the functional outcome. However, reinnervation should not be performed while recovery is still a possibility. Ideally, primary neurorrhaphy or grafting should be performed within 30 days of injury. If performed after 6 months, the results can be disappointing. Nerve substitution via transposition or jump grafting has been reported to be successful within the first 1 to 2 years after injury. If paralysis has been present for more than 2 years, reanimation methods other than nerve repair or grafting such as muscle transposition, microvascular free flap, or static procedures should be used.
- Patient expectations
  - Facial reanimation requires excellent patient-surgeon communication and rapport. The patient must be educated about the etiology and natural course of his or her facial impairment. When considering a procedure, the risks, benefits, and expected postoperative course and outcome should be discussed.

- Past medical history
  - Age
    - Young patients have increased tissue turgor and elasticity that make muscle transposition more challenging as well as increased fibroblastic activity that can result in hypertrophic facial scars. However, reinnervation in young patients is often more successful due to the greater regenerative potential of their nerves.
  - Life expectancy
    - Life expectancy is an important consideration given the varied recovery times for different reanimation techniques. A patient with a limited life expectancy may benefit from a static procedure or muscle transposition with an immediate result as opposed to a dynamic procedure requiring reinnervation and a prolonged recovery.

- General health
  - Patient comorbidities impact wound healing. Diabetes, malnutrition from chronic disease, and prior radiation increase the risk of delayed healing and wound dehiscence.

BOX 180.1 Facial Reanimation Procedures

Static Procedures

1. Suspension of oral commissure with fascia lata graft
2. Nasal alar lateralization with fascia lata graft or use of Mitek anchor
3. Lower lip wedge resection

Dynamic Procedures

1. Facial nerve repair by primary repair or interposition graft
   a. Primary repair of facial nerve
   b. Repair of facial nerve with great auricular nerve interposition graft
2. Nerve substitution by transposition or graft
   a. Hypoglossal-facial transposition
   b. Hypoglossal-facial graft with great auricular nerve
   c. Masseteric-facial transposition
   d. Cross-facial graft
3. Muscle transposition and free muscle neurovascular anastomosis
   a. Digastric muscle transposition
   b. Gracilis muscle free flap

Physical Examination

- Brow
  - Assess for brow droop and asymmetry.

- Eye
  - Assess for degree of eye closure, presence of Bell's phenomenon (upward movement of the globe with attempted lid closure), tear production, and corneal sensation.
- Nose
  - Assess for shift of ipsilateral upper lip philtrum and collapse of nasal ala, especially with inspiration.
- Mouth
  - Assess for asymmetric smile, inability to expose the lower teeth, and drooling.
- Cranial nerve examination
  - Assess for concomitant cranial nerve deficits, especially in patients who have had an acoustic tumor resected, because this will impact options for dynamic reanimation.
- Imaging
  - None. Although imaging may be required for the evaluation of facial paralysis, it is not required prior to facial reanimation.

Operative Period

Static Procedures

Static procedures can be combined with dynamic procedures or be used independently. Common static procedures to consider when reanimating the middle and lower face are (1) suspension of the oral commissure, (2) nasal alar lateralization, and (3) lower lip wedge resection, which are discussed here *(*Fig. 180.1*)*.[3]

Indications

- Patients with a poor prognosis, in whom dynamic reanimation is not a practical option, as an adjunct to residual function, or in those who have failed dynamic reanimation

- Nasal obstruction as an indication for nasal alar lateralization
  - It is important to perform a complete preoperative nasal analysis to differentiate between paralytic factors and pre-existing structural factors that may also be contributing to the patient's obstructive symptoms.
- Asymmetry of the mouth at rest and with smile as an indication for the suspension of the oral commissure or lower lip wedge resection
  - Major problems encountered around the paralyzed mouth are upper lip droop, corner of mouth droop, and lower lip asymmetry with associated functional deficits such as oral incompetence and speech impediment.

Contraindications

- Medical comorbidities with increased risk for general anesthesia or awake sedation
- Ongoing evaluation or treatment of facial paralysis

Preoperative Preparation

- If performing a static suspension procedure (i.e., suspension of oral commissure or nasal alar lateralization), decide on the material to be used for suspension.
  - Many materials have been used including permanent suture, alloplastic mediums such as Gore-Tex (W.L. Gore & Associates Inc., Flagstaff, Arizona) or AlloDerm (LifeCell Co., Bridgewater, New Jersey) and autologous grafts such as fascia lata and palmaris longus tendon.
  - Although autologous grafts have the disadvantage of donor site morbidity, they are still superior to alloplasts due to decreased risk of infection, rejection, and extrusion.

Operative Period

Anesthesia

- General anesthesia. Although some reanimation procedures, mainly static procedures, can be performed with awake sedation, general anesthesia is preferred for patient comfort.

Positioning

- The patient is placed in the supine position with the head stabilized in a donut pillow for procedures involving the face only and with the addition of a shoulder roll for procedures requiring access to the neck.

Perioperative Antibiotic Prophylaxis

- First-generation cephalosporin

Monitoring

- None

Suspension of oral commissure with a fascia lata graft

Operative Period

Instruments and Equipment to Have Available

- Facial plastics set
- Fascia stripper
- Miniplate set
- Closed suction drain
- Permanent monofilament suture

Key Anatomic Landmarks

- Nasolabial fold (NLF)
- Vermilion border

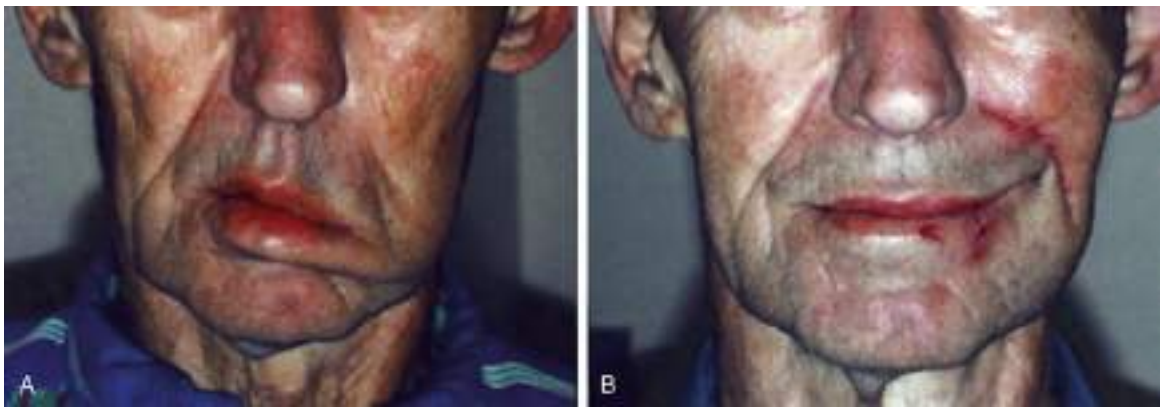

FIG. 180.1 Patient before, **A,** and after, **B,** static suspension of oral commissure and lower lip wedge resection.

- Superficial muscular aponeurotic system (SMAS)
- Modiolus
- Zygomatic arch

Prerequisite Skills

- Facelift
- Open reduction and internal fixation of midface fractures

Operative Risks

- Intraoperative bleeding

Surgical Technique

- Harvest fascia lata graft from lateral thigh.
  - The distance between the zygomatic arch and the modiolus is measured to approximate the required length of fascia lata. One half

of the measured distance is used as the incision length on the lateral thigh. A 2.5-cm-wide strip of fascia lata is harvested through this incision. The distal end of the graft is bisected in preparation for placement superior and inferior to the upper and lower lip.

- Perform perioral and temporal incisions.
  - The perioral incision may be placed within the NLF or the vermilion border. Incisions in the NLF work best in older patients with deep folds on the normal side. The resultant scar will visually resemble an NLF.
  - The temporal incision is placed in the preauricular hairline.
- Develop a tunnel between the two incisions.
  - Blunt dissection is used to develop a plane between the subcutaneous tissue and the SMAS.
- Pass the graft through the tunnel from the perioral incision to the hairline incision using a long clamp.
- Secure the distal ends of the graft.
  - The bisected distal ends of the graft are passed into the upper and lower lip tunnels and secured to the submucosa with permanent monofilament suture. The graft is then secured a third time proximal to the bisected tails to the modiolus.
- Apply superolateral tension to create the desired smile and secure the proximal end of the graft.
  - A tunnel is dissected around the zygomatic arch, and the proximal end of the graft is passed deep to the arch. The graft is pulled superiorly and laterally to create a smile. Preoperative planning determines the vector of pull desired to mimic the contralateral side. Of note, the smile should then be overcorrected.
  - Alternative: The graft may be sutured to the temporalis fascia.
- Irrigate the wounds with antibiotic solution (because the tissue is adjacent to the oral cavity and contamination can occur), place drain, and close incisions.

Common Errors in Technique

- Smile is undercorrected
  - It is important to overcorrect the smile at the time of surgery as the graft will lose some tensile strength. Most changes occur within the first 3 to 6 weeks. The graft material itself, especially alloplastic material, should be stretched on the back table prior to inserting it in the patient to minimize the relaxation of the material over time.
- Circumferential placement of distal ends of the graft
  - This can severely limit the oral aperture and the patient's ability to open the mouth to its full extent.
- Graft placed in the wrong plane
  - If the graft is placed too superficially, it may be visible and result in a "saber sign," which mimics a dueling injury.
  - If the graft is placed too deep, augmented residual function could be lost.

Postoperative Period

Postoperative Management

- Patients require very little specific postoperative care after the majority of these procedures, and most are discharged on the day of surgery. However, there are a few precautions that the surgeon should take.
  - The patient with surgery that abuts the oral cavity should receive perioperative antibiotics.
  - Patients with muscular or facial attachments near the modiolus should be placed on a soft diet to avoid dehiscence.
  - No pressure dressings are used over nerve grafts or muscle flaps.

Complications

- Dehiscence of the suspension material
  - Most of these issues prove easier to remedy through revision surgery because the scar from the first procedure provides a better means of

attachment.

- Granuloma, extrusion, or infection of foreign material used for suspension
  - These issues may affect both the alloplastic material itself as well as the material used to secure the graft (i.e., miniplates).

Alternative Management Plan

- Alternative suspension material may be used.
  - Instead of fascia lata, palmaris longus tendon may be harvested. Gore-Tex, AlloDerm, and suture suspension are also options.
- Dynamic reanimation with a gracilis microvascular free flap may be used if the patient is an appropriate candidate (see "Free muscle neurovascular anastomosis" section).

Nasal alar lateralization with fascia lata graft or use of Mitek anchor

Operative Period

Instruments and Equipment to Have Available

- Facial plastics set
- If using fascia lata graft: fascia stripper and miniplate set
- If not using fascia lata graft: Mitek anchor (Mitek Products Inc., Westwood, Massachusetts)
- Permanent monofilament suture

Key Anatomic Landmarks

- Alar crease
- Lower lateral cartilage
- Anterior face of maxilla

Prerequisite Skills

- Facelift
- Open reduction and internal fixation of midface fractures

Operative Risks

- Intraoperative bleeding
- Injury to infraorbital nerve

Surgical Technique

- If using a fascia lata graft, harvest the graft from the lateral thigh.
- Perform alotomy (Fig. 180.2).
  - The incision at the alar crease may be extended into the NLF for wider exposure.
- Dissect laterally to expose the maxilla.
  - Elevate the periosteum to expose the anterior wall of the maxilla. Dissection should not proceed superior to 1 cm below the orbital rim, where the infraorbital nerve exits its foramen.
- If a fascia lata graft is used, secure the graft to the nasal ala, apply lateral tension, and secure the lateral graft to the anterior wall of the maxilla.
  - The medial aspect of the graft is secured to the fibrocartilage base of the lateral nasal ala with permanent monofilament suture.
  - The lateral aspect of the graft is secured to the maxilla with a miniplate.
- If using the Mitek anchor, drill the anchor into the front face of the maxilla. The device comes preloaded with a permanent suture that can be attached to the nasal ala and tightened.
- Irrigate the wound and close the incision.

Common Errors in Technique

- Alar base and supra-alar widening
  - Due to the oblique vector of suspension, the appearance of the nasal tip can change and become a source of dissatisfaction for patients.

Postoperative Period

Complications

- Dehiscence of suspension material
- Granuloma, extrusion, or infection of foreign material used for suspension

Alternative Management Plan

- Septorhinoplasty
  - Patients with a structural predisposition to valve collapse may benefit from a septorhinoplasty. For instance, alar batten grafting may help in cases of in-bowing during inspiration.
- Alternative suspension material may be used.
  - Gore-Tex, AlloDerm, and permanent suture are other options.

Lower lip wedge excision

Procedure provides horizontal shortening of the lip, improved oral competence and speech, and better symmetry from removal of the area that takes on a "fat lip" appearance.[4]

Operative Period

Instruments and Equipment to Have Available

- Facial plastics set

Key Anatomic Landmarks

- Lateral commissure
- Horizontal chin crease
- Orbicularis oris
- Vermilion border

Prerequisite Skills

- Oral cavity resection for malignancy
  - Although not necessarily required, prior experience with oral cavity resection lends familiarity to handling tissues and identifying structures.

Operative Risks

- Intraoperative bleeding

Surgical Technique

- Outline borders of the wedge resection.
  - The lateral border should not reach the lateral commissure. The inferior border should be superior to the horizontal chin crease. The width of the resection should not exceed one-third of the distance between the junction of the normal and paralyzed side of the lower lip and the lateral commissure on the involved side.
  - A scalpel marking of the vermillion border for later approximation is helpful for accurate approximation of the lip.
- Excise full-thickness wedge.
- Close incision.

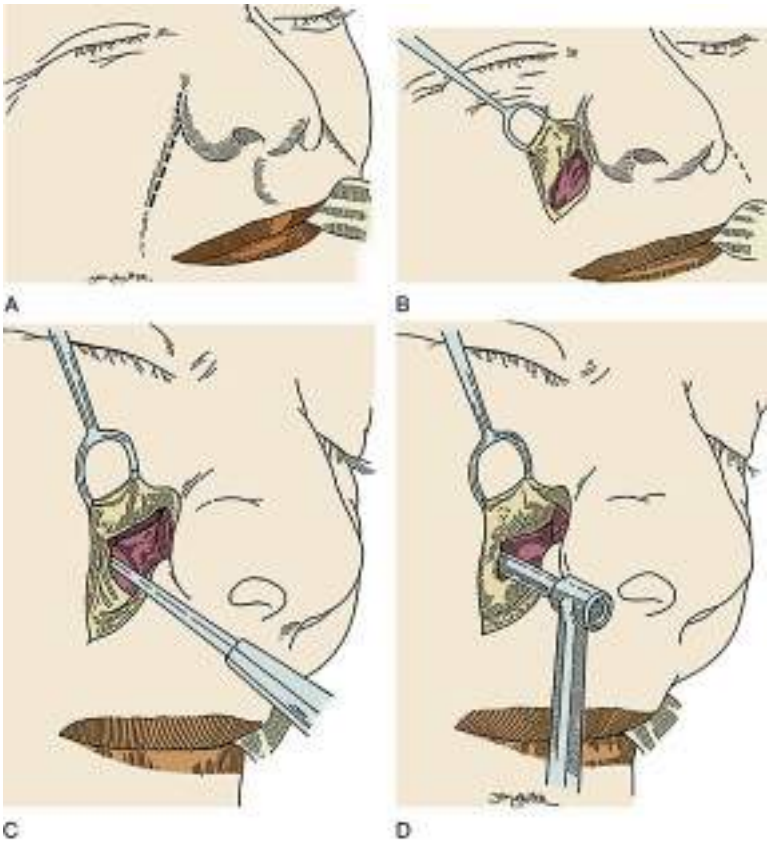

FIG. 180.2 Nasal alar lateralization with Mitek Mini Quick Anchor (Mitek Surgical Products, Inc., Norwood, Massachusetts).

A, Incisions are made in the alar-facial and nasolabial creases. **B,** The deep aspect of the alar base is exposed. **C,** The periosteum is elevated to expose the lateral ascending buttress of the maxilla. **D,** A drill guide is placed perpendicular to the exposed area of maxilla to produce the proper direction and tension for securing fascia from the alar base. From May M: Regional reanimation: nose and mouth. In: May M, Schaitkin BM [eds]. Facial Paralysis: Rehabilitation Techniques. New York, NY: Thieme; 2003, pp 228 [see Fig.7.3], with permission.

- Realignment of the oral mucosa, orbicularis oris, and skin is performed in layers. The vermilion white roll must be realigned meticulously to avoid cosmetic deformity.

Common Errors in Technique

- Microstomia
  - Overresection is avoided by attending to the relative width of the resection as compared to the length of the lower lip.
  - Keep in mind that patients with large dentures will need a space adequate to put them in and take them out.

Postoperative Period

Complications

- Wound dehiscence
- Wound infection

Alternative Management Plan

- Contralateral lower lip weakening with chemodenervation with botulinum toxin or transection of fibers of the contralateral depressor labii inferioris
- Dynamic reanimation with digastric muscle transposition may be used if the patient is an appropriate candidate (see Chapter 168).

Dynamic Procedures

Dynamic procedures can be combined with other reanimation procedures or used independently. (1) Facial nerve repair by primary repair or interposition graft, (2) nerve substitution by transposition or graft, and (3) digastric muscle transposition and gracilis free flap are discussed here.[5,6] Reanimation of the upper and lower face, separately if possible, improves outcomes.

(1) Facial nerve repair by primary repair or interposition graft

Preoperative Period

Indications

- Patients with available proximal and distal facial nerve systems
- Primary nerve repair is indicated when a tensionless closure can be accomplished between the free edges of the nerve.
- Repair with an interposition graft is indicated if a tensionless closure cannot be accomplished due to a gap between the free edges of the nerve.

Contraindications

- Unavailable proximal and/or distal facial systems
- Medical comorbidities with increased risk for general anesthesia
- Ongoing evaluation or treatment of facial paralysis

Preoperative preparation

- Counsel patient on the risks, benefits, and expectations of surgery.
- Determine timing of repair.
  - Ideally, nerve continuity should be reestablished at the time of the ablative operation or within the first 72 hours after injury. During this time period, the distal nerve branches still respond to electrical stimulation, allowing for easier intraoperative identification. However, repair performed up to 30 days after injury may still result in functional improvement.
- If performing an interposition graft, choose a graft nerve.
  - The nerve graft must be long enough to bridge the neural defect without tension and must provide a reasonable match to the endoneurial diameter of the free nerve edges.
  - The great auricular nerve is a good choice for short neural defects. The nerve can yield approximately 7 to 10 cm in length. The use of this nerve results in anesthesia of the ear lobe.
  - The sural nerve is a good choice for patients with neural defects greater than 10 cm. The nerve can yield up to 40 cm in length. The use of this nerve results in anesthesia of the lateral and dorsal

aspects of the foot.

- The medial antebrachial cutaneous nerve is a good choice for total nerve reconstruction as it has multiple branches. The nerve can yield approximately 10 to 15 cm in length. The use of this nerve results in anesthesia of the upper forearm.

Operative Period

Instruments and Equipment to Have Available

- Operating microscope
- Nerve stimulator
- Bipolar Bovie cautery
- Microinstruments set
- Facial plastics set
- Fine permanent monofilament suture
- Closed suction drain

Key Anatomic Landmarks

- To identify the facial nerve (see Chapter 92).
  - Tragal pointer
  - Posterior belly of the digastric muscle
  - Tympanomastoid suture line
  - Styloid process
  - If necessary, the facial nerve may need to be identified proximally within the mastoid (see Chapter 134). The following landmarks are used.
- To identify the great auricular nerve
  - Sternocleidomastoid muscle (SCM)

- Spinal accessory nerve (CN XI)
- External jugular vein (EJV)

Prerequisite Skills

- Parotidectomy
- Prior experience with operative microscope and microinstruments

Operative Risks

- Further injury to distal facial nerve
- Intraoperative bleeding

Surgical Technique

Primary Repair of Facial Nerve

- Perform a modified Blair incision.
- Identify and prepare the ends of the injured facial nerve.
  - Ease of identification depends on the location of, mechanism of, and time since injury.
  - The facial nerve is identified as it exits the stylomastoid foramen using traditional surgical landmarks (see Chapter 92). The nerve is followed distally with gentle dissection and meticulous hemostasis until the site of injury is identified.
    - If attempting to identify the nerve in a previously operated and/or radiated bed, the surgery can be extremely difficult and may require retrograde dissection.
  - The free edges of the nerve are dissected several millimeters proximally and distally.
  - Methylene blue (1%) may be applied with a cotton-tipped applicator to the prepared ends to identify the epineurial (dark blue stain) and endoneurial (lighter blue stain) components of the nerve and to

distinguish them from surrounding structures.

- The epineurium is peeled and trimmed at the proximal and distal ends to expose the endoneurial surface, and the endoneurial surface is trimmed sharply.
- A colored background may be placed under the nerve edges to create a work platform to stabilize the nerve and facilitate visualization.

- Perform suture repair.
  - The best method of nerve coaptation is the subject of controversy. Perineurial, epineurial, endoneurial, and intrafascicular repair have been described, but the data have not demonstrated a significant difference in outcome among these techniques.
  - The current standard is to perform a perineurial repair: Two to three fine (8-0 or 10-0) monofilament sutures are carefully placed through the perineurium, out the endoneurium, through the endoneurium, and out the perineurium to provide adequate approximation.
  - Irrigate the wound, place the drain, and close the incision.

Repair of Facial Nerve With Great Auricular Nerve Interposition Graft

- Perform a modified Blair incision.
- Identify and prepare the ends of the injured facial nerve.
- Harvest and prepare the graft.
  - Note: If using either the sural or medial antebrachial cutaneous nerves, the donor site must be prepped into the field at the beginning of the operation.
  - The great auricular nerve is found by drawing a line between the angle of the jaw and the mastoid. This line is bisected at a right angle by the great auricular nerve as it passes the posterior border of the SCM just posterior to the EJV.
  - The nerve is dissected off the SCM. Additional length may be obtained by dissecting the proximal end of the nerve (posterior and deep to the posterior border of the SCM) and the distal end (within the subcutaneous tissues superficial to the parotid).

- When dissecting the proximal end of the great auricular nerve, care must be taken not to injure the CN XI as it courses from the deep surface of the SCM, parallel and approximately 1 cm superior to the great auricular nerve.

- The great auricular nerve is divided sharply proximally and distally. The length of the graft should be at least 1 to 2 cm longer than the gap to be bridged to allow for trimming of the graft ends.
- The epineurium is peeled and trimmed at the proximal and distal ends to expose the endoneurial surface, and the endoneurial surface may be further trimmed sharply.

- Match the endoneurial diameter of the graft ends to the facial nerve ends.
  - The endoneurial surface of the smaller nerve end may be cut on a bias to increase its surface area and yield a better match to the larger facial nerve end.
- Perform inset of the graft.
  - The graft is placed between the free edges of the facial nerve. The bridge created by the graft should form an S or C shape to ensure a tensionless closure.
    - Rotating the graft so that the distal end is sutured to the proximal end of the facial nerve has been described but has not been shown to result in superior outcomes.
  - Perineurial suture repair is performed as previously described at the two anastomotic sites.
- Irrigate the wound, place the drain, and close the incision.

Common Errors in Technique

- Traumatizing the facial or donor nerve by cutting through intact epineurium
  - Attempting to section a nerve with the epineurium intact may result in crush injury to its fascicular contents.
- Tension at the site of repair

- Due to inadequate length of the facial nerve or interposition graft material. Tension is avoided by noting whether the facial nerve ends meet and hold together without need for suture.

- Mismatch of endoneurial surfaces
  - Mismatch is avoided by careful inspection under magnification and appropriate preparation of the nerve ends.

Postoperative Period

Complications

- Dehiscence of neural repair
- Injury to the CN XI while harvesting the great auricular nerve

Alternative Management Plan

- If patients fail facial nerve repair, either by primary repair or interposition graft, other dynamic reanimation techniques may be utilized (see "Nerve substitution by transposition or graft" and "Muscle transposition and free muscle neurovascular anastomosis" sections). Static procedures may also be considered (see "Static Procedures" section).

(2) Nerve substitution by transposition or graft (hypoglossal-facial transposition or graft, masseteric-facial transposition, cross-facial graft)

Hypoglossal-facial transposition

Hypoglossal-facial transposition and grafting procedures have demonstrated the most consistent results. Thus, they are presented here in the greatest detail, but their general surgical concepts can be applied to masseteric-facial and cross-facial nerve procedures (Fig. 180.3).

Preoperative Period

Indications

- Patients with an unavailable proximal but intact distal facial nerve system
  - For example, patients who have undergone cerebellopontine angle tumor surgery where the nerve is injured but not grafted or have sustained severe temporal bone trauma

Contraindications

- Unavailable distal facial nerve system
  - For example, patients who have undergone a massive resection including extracranial nerves and muscles of expression or gunshot wounds or explosions
- Patients at risk for multiple or bilateral cranial nerve lesions
  - For example, patients with neurofibromatosis type II and adenoid cystic carcinoma
- Medical comorbidities with increased risk for general anesthesia
- Ongoing evaluation or treatment of facial paralysis

Preoperative Preparation

- Counsel the patient on the risks, benefits, and expectations of surgery.
  - Although mimetic movement is not possible, the majority of patients demonstrate voluntary facial movement with tone and symmetry at rest, with improvement seen predominantly in the midface.

FIG. 180.3 Patient before, **A,** and after, **B,** hypoglossal-facial transposition.

- Defects due to donor nerve disruption with both nerve transposition and grafting should be described. Note: Grafting requires only partial disruption of the donor nerve and therefore results in less donor morbidity as compared to nerve transposition, which requires sacrifice of the entire donor nerve.
  - Disruption of the hypoglossal nerve results in hemitongue weakness.
  - Disruption of the masseteric nerve actually results in minimal functional morbidity.

- Determine the timing of the repair.
  - The hypoglossal-facial graft works best if performed in the first year of paralysis.
  - Traditional hypoglossal-facial transposition can be done as long as 2 years after injury with good results.
- Choose the donor nerve.
  - Ipsilateral hypoglossal nerve
  - Ipsilateral masseteric nerve
  - Contralateral facial nerve
- If performing a graft, choose a nerve graft.
  - The three most commonly used nerve grafts are the great auricular, sural, and medial antebrachial cutaneous nerves.

Operative Period

Instruments and Equipment to Have Available

- Operating microscope
- Nerve stimulator
- Bipolar Bovie
- Microinstruments set
- Facial plastics set
- Fine permanent monofilament suture
- Closed suction drain

Key Anatomic Landmarks

- To identify the facial nerve (see Chapter 92).
  - Tragal pointer
  - Posterior belly of the digastric muscle
  - Tympanomastoid suture line
  - Styloid process
  - The facial nerve may need to be identified proximally within the mastoid (see Chapter 134)
- To identify the great auricular nerve
  - SCM
- To identify the hypoglossal nerve
  - Posterior digastric muscle
  - Internal jugular vein (IJV)
  - Internal carotid artery (ICA)
  - External carotid artery (ECA)

- Occipital artery

- To identify the masseteric nerve
  - Zygomatic arch
  - Frontal branch of facial nerve
  - Temporomandibular joint (TMJ)

Prerequisite Skills

- Facial nerve repair by primary repair or interposition graft
- Prior experience with operative microscope and microinstruments

Operative Risks

- Further injury to distal facial nerve
- Intraoperative bleeding

Surgical Technique

Hypoglossal-Facial Transposition

- Perform a modified Blair incision.
- Identify and prepare the facial nerve.
  - The facial nerve is identified as it exits the stylomastoid foramen using traditional surgical landmarks (see Chapter 92). The nerve is followed distally with gentle dissection and meticulous hemostasis to just distal to the pes anserinus.
  - The nerve is divided just proximal to the pes anserinus. The epineurium of the deep/posterior aspect of the nerve is preserved to hold the facial nerve in position and prevent the nerve from retracting into the parotid gland.
- Identify and prepare the hypoglossal nerve.
  - The hypoglossal nerve is identified and isolated as it courses

between the IJV and carotid vessels along the undersurface of the digastric muscle.

- Just distal to the takeoff of the descendens hypoglossi, the epineurium is trimmed to expose the perineurium, and the nerve is sharply divided.
- The proximal nerve ending is then brought medial to the digastric muscle to achieve additional length and allow for a tensionless closure.

- Match the endoneurial diameter of the hypoglossal nerve end to the facial nerve end.
- Perform suture anastomosis.
  - Perineurial suture repair is performed as described previously.
- Irrigate the wound, place the drain, and close the incision.

Hypoglossal-Facial Graft With Great Auricular Nerve

- Perform a modified Blair incision.
- Identify and prepare the facial nerve as described previously for hypoglossal-facial transposition.
- Harvest and prepare the graft.
  - The distance required is usually less than 8 cm, which is easily accomplished with the great auricular, sural, or medial brachial cutaneous nerves. The harvest technique for the great auricular nerve was described previously (see "Facial nerve repair by primary repair or interposition graft" section). The graft is placed in a moist, saline-soaked gauze sponge for later use.
- Identify and prepare the hypoglossal nerve.
  - Once the hypoglossal nerve is identified, it is exposed by placing a Penrose drain under the nerve (but over the descendens hypoglossi nerve) and gently stretching and elevating the Penrose drain with a self-retaining retractor.
  - A beveled incision is made not more than one-third of the way through the hypoglossal nerve, partially transecting the nerve and

exposing a portion of the proximal endoneurial surface.

- The diameter of the hypoglossal nerve is larger than that of the great auricular nerve, and only one-third of the nerve is used for grafting. Kartush has suggested passing an 8-0 monofilament suture through a point representing one-third of the neural diameter to allow the surgeon to know when this limit is reached.
- Sectioning the nerve under visual confirmation of serial stimulation with an electric stimulator also allows the surgeon to work with decreased risk of permanent tongue weakness.

- Match the endoneurial diameter of the graft to the hypoglossal and facial nerves.
- Suture the proximal end of the graft to the proximal hypoglossal nerve.
  - Perineurial suture repair is performed as previously described. The Penrose drain is divided with scissors and gently removed without disrupting the graft.
- Suture the distal end of the graft to the distal facial nerve.
  - Perineurial suture repair is performed and tensionless closure ensured by S- or C-shaped graft placement as previously described.
- Irrigate the wound, place a drain, and close the incision.

Masseteric-Facial Transposition

- Masseteric-facial nerve transposition is performed with principles similar to those described for hypoglossal-facial transposition.
- The masseteric nerve is a branch of the mandibular branch of the trigeminal nerve (V3). When adequately dissected, it has sufficient length for tensionless, direct coaptation with the facial nerve.

  The nerve may be identified within the “subzygomatic triangle.”

Common Errors in Technique

- Traumatizing the facial or donor nerve by cutting through intact epineurium

- Tension at the site of repair
- Mismatch of endoneurial surfaces

Postoperative Period

Complications

- Dehiscence of neural repair
- Injury to the CN XI when harvesting the great auricular nerve

Alternative Management Plan

- If patients fail nerve substitution, either by primary transposition or graft, other dynamic reanimation techniques may be used (see "Muscle transposition and free muscle neurovascular anastomosis" section). Static procedures may also be considered (see "Static Procedures" section).
- When these procedures are successful, eye reanimation is often still insufficient and it may be necessary to employ eye reanimation procedures.

(3) Muscle transposition and free muscle neurovascular anastomosis

Digastric Muscle and Gracilis Muscle transposition

The digastric muscle transposition and gracilis muscle neurovascular free flap are discussed here *(Fig. 180.4)*.[7] Use of the temporalis muscle for transposition is discussed elsewhere (see chapter 168).

Preoperative Period

Indications

- Patients with neither proximal nor distal facial nerve system available
  - The digastric muscle works best in those with isolated lower lip

paralysis. Combining this lip depressor with procedures on the lip elevators runs the risk of causing oral incompetence.

- The gracilis muscle is harvested as a free flap from the thigh to allow for active re-creation of smile function.

Contraindications

- Lack of suitable motor input
  - The anterior belly of the digastric is innervated by the third division of the trigeminal nerve (V3).
  - The gracilis is usually innervated as a single-stage procedure with the masseteric branch of V3.
    - A single-stage jump graft from the hypoglossal nerve is a second option.
    - A two-stage cross-facial nerve graft is a third option.
- Medical comorbidities with increased risk for general anesthesia
- Ongoing evaluation or treatment of facial paralysis

Preoperative Preparation

- Counsel the patient on the risks, benefits, and expectations of surgery.
  - It is important to review the accomplishments of any previous reanimation procedures.
- Determine the duration and extent of current facial function.
- The patient is marked preoperatively with the vector and extent of movement desired.

Operative Period

Instruments and Equipment to Have Available

- For digastric transposition:
  - Facial plastics set

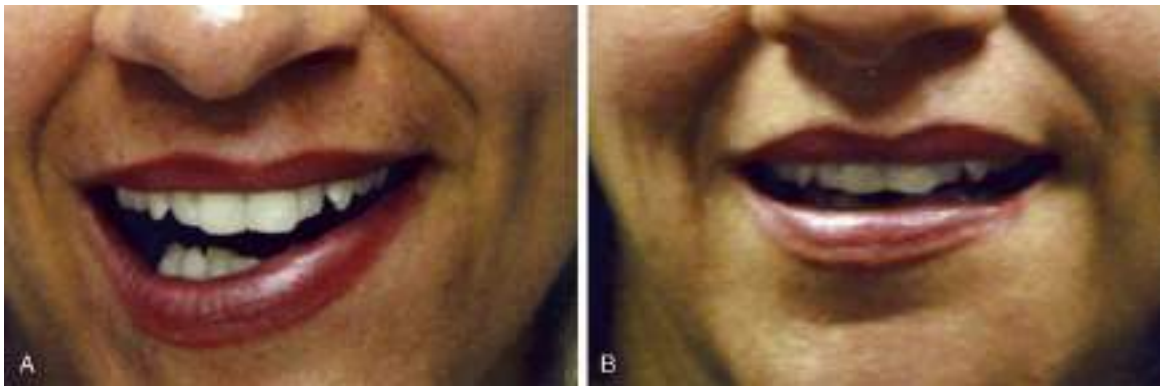

FIG. 180.4 Patient before, **A,** and after, **B,** digastric muscle transposition after ramus mandibularis paralysis during parotidectomy.

  - Anchoring sutures of 4-0 Vicryl
  - 6-0 nylon suture
  - Closed suction drain
- For gracilis free flap:
  - Operating microscope
  - Nerve stimulator
  - Bipolar Bovie cautery
  - Microinstruments set
  - Anchoring sutures of 3-0 Ti-Cron (Syneture, US Surgical Covidien, Mansfield, Massachusetts)
  - Fine permanent monofilament suture
  - Closed suction drain

Key Anatomic Landmarks

- To identify the digastric muscle:
  - Vermilion border

- Greater cornu of the hyoid

- To identify the gracilis muscle:
  - Temporalis fascia
  - SMAS
  - Modiolus

Prerequisite Skills

- Facelift
- Soft tissue techniques

Operative Risks

- Intraoperative bleeding
- Loss of any current facial function if dissection is deep to the SMAS

Surgical Technique

Digastric Muscle Transposition

- Select a horizontal neck crease for an incision at least 2 cm inferior to the mandibular border.
- Isolate the digastric muscle, and release the posterior tendon.
- Dissect and create a tunnel to the submental incision.
- Release the digastric muscle from the hyoid bone.
- Tunnel to the vermillion incision, preserving the nerve to the anterior belly of the digastric muscle.
  - In older patients, a lower-lip wedge resection to remove nonfunctional bulky lip can be performed (see "Static Procedures" section).
- Set tension on the rotated digastric to provide some initial static support.

- Attach the digastric with a 4-0 Vicryl suture to the orbicularis oris along its inferior ipsilateral border, and close the deep layer similarly.
- Irrigate the wounds, place the drains, and close the incisions.
  - Use 6-0 nylon suture for lip closure. Marking the vermillion border preoperatively assists in accurate reapproximation of the lip.

Gracilis Muscle Free Flap

- Mark the patient's smile based on the contralateral smile preoperatively.
- Harvest the gracilis muscle.
  - Measure the required length from the proposed new oral commissure to the temporalis fascia.
  - Anchoring sutures can be placed while the muscle is still in situ.
  - Preserve the neurovascular pedicle.
  - Less than one-half of the gracilis is required.
- Facelift incision dissected to the oral commissure or connected to the vermillion incision to pass muscle
- Anchoring sutures of 3-0 Ti-Cron set and tested for smile vector
- Microscopic repair of vein, artery, and then nerve
- Attach the adjusted length of the gracilis to the temporalis fascia.
- Irrigate the wounds with antibiotic irrigation because the tissue is adjacent to the oral cavity and contamination can occur, place the drain, and close the incisions.

Common Errors in Technique

- Anchor detachment
- Smile is undercorrected, overcorrected, or placed in an incorrect vector
- Thin skin flap reveals muscle
- Free flap vascular incident that results in loss of the flap

- Too much bulk

Postoperative Period

Complications

- Infection
- Hematoma
- Partial dehiscence
- Failure or underpowering of neural input

Alternative Management Plan

- If the reanimation procedures fail, static procedures may be considered (see section "Static Procedures").

Discussion

Evidence-Based Medicine Question

When should facial nerve reinnervation, via primary neurorrhaphy or interposition grafting, be performed following nerve injury?

- Many studies have looked at this question and their results have been variable. In general, when the nerve is repaired within 30 days of injury, results have been excellent. Functional results decrease as the time from injury increases. Although there is evidence of recovery in patients grafted more than 1 year after injury, it is our opinion that repair after 1 year should not be performed given disappointing functional results. In these cases, nerve transpositions, muscle transpositions, or free flaps may be considered.

Editorial Comment

The degree of facial movement following gracilis muscle transfer

depends on the donor motor nerve density. The masseter nerve provides a more robust innervation source than the cross-facial nerve. Reconstruction with either innervation source provides an improvement in oral commissure excursion. Patients with masseteric innervation will likely have an increased range of excursion, whereas patients with cross-facial innervation may be better able to generate a spontaneous smile.

Review Questions

1. Patients with facial paralysis after acoustic tumor surgery are an example of:

   a. Proximal system intact and distal system intact

   b. Proximal system intact and distal system not available

   c. **Proximal system not available and distal system intact**

   d. Neither system available

2. Which of the following suspension materials has the lowest risk of extrusion?

   a. Permanent suture

   b. Gore-Tex

   c. AlloDerm

   d. **Fascia lata**

3. Although the best method of nerve coaptation is controversial, the current standard method is which of the following?

   a. **Perineurial repair**

   b. Epineurial repair

   c. Endoneurial repair

   d. Intrafascicular repair

Marginal Mandibulectomy

Melonie Nance

Introduction

1. The goal of surgical management of any cancer of the head and neck is to remove the cancer in its entirety and preserve form and function. Marginal mandibulectomy (MM) evolved as a surgical technique to obtain the margin around the tumor yet avoiding the cosmetic and functional complications of segmental mandibulectomy (SM). Crile first described the MM in 1923 as an incision that is "carried down to the underlying bone, and thence into the bone by a sharp chisel or saw, so that a slice of bone can be split off in one piece, bearing the undisturbed cancer off as on a bone platter."[1] The three most common locations of cancer of the oral cavity in which MM plays a role include the floor of the mouth, the gingival ridge, and the retromolar trigone, where carcinoma abuts the mandible.

2. It was once believed that the oral cancers invade the mandible by draining through the lymphatic channels in the mandibular periosteum on their way to the cervical lymphatics. Hence, segmental mandibulectomies and composite resections were performed for oncologic completeness. Reconstructive surgery was still in rudimentary stages so that resections resulted in suboptimal cosmetic and functional outcomes, including malocclusion, temporomandibular joint dysfunction, *Andy Gump* deformity, tracheostomy, and gastrostomy tube dependence. Marchetta et al. later demonstrated that mandibular involvement occurs predominantly via direct invasion of the periosteum.[2] This finding eliminated the mandate for SM. Furthermore, Barttelbort et al. proposed a theory of tumor invasion of the mandible. The cancer initially quickly invades the broad plane of the mandible superior to the mylohyoid muscle attachment. Involvement of the

inferior lingual cortical plate occurs infrequently and late.[3] Because of this theory, MM became a feasible procedure for removal of the cancer without compromising the mandibular arch.

3. The local recurrence and survival rates after segmental and MM were shown to be comparable (though one must be aware of the patient selection bias: Patients with gross bone involvement require a more extensive procedure). MM became an oncologically sound procedure in the management of oral cavity cancers and securing the margin around the cancer. The adverse cosmetic and functional outcomes are limited by preservation of the architecture of the mandibular arch and native muscular attachments. In addition, dental rehabilitation is a viable option in the form of a removable dental plate or dental implants. A major and legitimate concern with this procedure is the inability to obtain reliable intraoperative bone margins. Hence, careful preoperative planning must be executed.

Key Operative Learning Points

1. The goal of MM is to secure the margin around the cancer.

2. Proper patient selection is the key: Meticulous preoperative clinical and radiologic evaluation should be performed to rule out bone involvement.

3. Osteotomies must be planned before the surgery.

4. Osteotomies should be placed with assurance of preservation of healthy residual teeth and allowing for dental rehabilitation.

5. Most recurrences occur in the soft tissues, not the bone. Hence, careful intraoperative frozen section analysis should be used to avoid recurrence in the soft tissues.

6. Most MM defects can be successfully reconstructed with the split-thickness skin graft.

Preoperative Period

History

Physical Examination

1. Despite invention and advancement of many sophisticated diagnostic imaging techniques, physical examination remains the mainstay in decision making. Invasion of the mandible should be suspected and assessed in any patient with an ulcerative lesion within the vicinity of oral or lingual cortices, as up to one-third of cases of histologically proven mandible invasion do not show clinical signs of bone invasion preoperatively.[4] Tsue et al. and Werning et al. independently observed that the location of the primary cancer was predictive of mandibular invasion: Bone invasion was more likely to be present in cancers of the floor of the mouth, retromolar trigone, and inferior alveolar ridge.[5,6] The presence of dentition was shown to influence perineural invasion. The inferior alveolar nerve was four times more likely to be involved by the cancer in the edentulous mandible than in the partially dentate mandible.[7] The resorption of the alveolar ridge appears to be greater in the edentulous mandible, which places the nerve in a more superficial position, making it more susceptible to invasion of the cancer. Bimanual palpation allows the surgeon to determine whether the tumor is fixed to the bone, signifying bone invasion. The examination may be limited by pain and might require topical or even a general anesthetic (Fig. 181.1).

Imaging

1. Werning et al. demonstrated that clinical evaluation of mandibular bone invasion was more sensitive than radiologic assessment (a mixture of Panorex, occlusal views, routine radiographs, and computed tomography [CT]) (sensitivity of 73%), while radiologic evaluation was more specific (specificity of 82%) and had a higher reliability index (0.29 vs. 0.19). They concluded that the combination of clinical and radiologic evaluations is more accurate than either one alone.[6] A newer tomographic modality, single positron emission CT (SPECT), was shown to have 87% overall accuracy in predicting bone invasion, as compared to 71% for clinical examination, CT scanning, and Panorex.[8] SPECT sensitivity approached 95%, as compared to 55% for conventional CT and 50% for Panorex. Another tomographic evaluation named Dentascan was found useful in evaluation of the buccal and lingual mandibular cortices. The Dentascan images consist of panelliptical and parasaggital views

derived from the reformatting of the regular axial CT images. Brockenbrough et al. demonstrated sensitivity of 95%, specificity of 79%, positive predictive value of 87%, and negative predictive value of 92% for Dentascan.[9] One of the immediately obvious limitations of CT scanning in the oral cavity is dental artifact. Magnetic resonance imaging (MRI) does not have this shortcoming and may be more useful in the evaluation of medullary bone. It also produced promising results: Sensitivity of MRI in detecting mandibular invasion was 93% with 93% accuracy.[10]

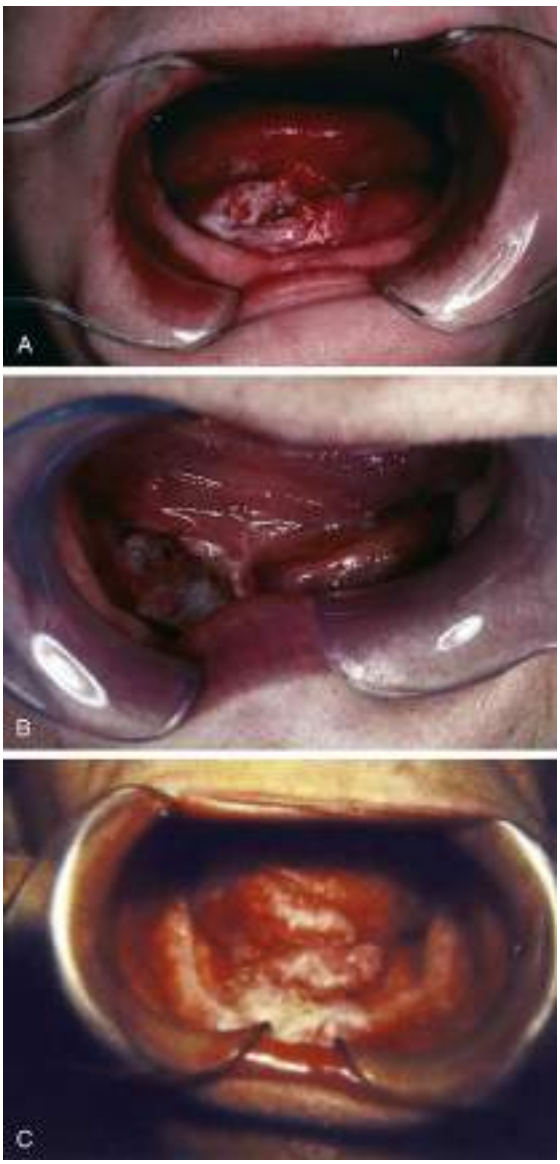

FIG. 181.1 **A,** Cancer of the floor of the mouth too close to the mandible to resect without marginal mandibulectomy. **B,** A tumor adherent to the mandibular

periosteum. **C,** A tumor crossing but not invading the mandible.

Indications

1. Tumor so close to the mandible that it is not feasible to obtain an adequate margin of resection without removing the alveolar process of the mandible

2. Abutment of the lesion to the lingual aspect of the periosteum of the mandible

3. Tumor that crosses the alveolus and into the gingivobuccal sulcus

Contraindications

1. Absolute

   a. Gross destruction of the bone

   b. Invasion by cancer of the mandibular canal

2. Relative

   a. Edentulous mandible with reduced vertical height

      1) The concern in question is sacrifice of the endostial blood supply, placing the remaining bone at risk of avascular necrosis and a pathologic fracture.

   b. Previously radiated mandible

      1) While there is usually a single port of cancer entry into the bone in radiation-naïve mandible, histologic analysis of previously radiated bone demonstrates multiple tumor loci. This finding suggests that the radiation alters bone resistance to tumor spread, likely by impairing the periosteal blood supply and weakening it, making the pattern of spread less predictable and posing a real risk of leaving cancer behind by performing subtotal resection.[7]

Preoperative Preparation

1. While clinical assessment in combination with radiographic evaluation is of paramount importance, direct examination of the bone under the periosteum remains the gold standard for identifying mandibular invasion.

2. In addition to the informed consent, preoperative patient counseling must also encompass discussions of postoperative airway and nutrition management, which may include temporary tracheostomy and placement of a nasogastric tube. In addition, various reconstructive options should be reviewed.

Operative Period

Anesthesia

1. General anesthesia
   a. Orotracheal intubation with endotracheal (ET) tube placed on contralateral side from tumor is sufficient.
   b. Nasotracheal intubation may be considered, since it provides greater exposure.
   c. If the patient is to have a tracheostomy, it should be done prior to the surgery and an endotracheal tube placed in the tracheostoma to deliver the anesthetic.

Positioning

1. The patient is placed in the supine position.

2. Shoulder roll is not necessary for tumor resection but may be placed preoperatively if a neck dissection is planned.

Perioperative Antibiotic Prophylaxis

1. Standard oral cavity perioperative antibiotics are recommended such as Unasyn or similar.

Monitoring

Usual monitoring for general anesthesia

Instruments and Equipment to Have Available

1. Standard head and neck and dental surgical instrument set

2. Multiple types of cheek and tongue retractors should be available.

3. Both a sagittal and reciprocating saw should be available. The surgeon must determine the most appropriate one depending on the position of the tumor, exposure, retraction, and degree of mouth opening.

Key Anatomic Landmarks

1. The mandible is a horseshoe-shaped facial bone of paramount importance for maintaining an aesthetically pleasing appearance and supporting the attachment of muscles critical for proper oral competence, speech, mastication, and swallowing. It is derived from the first branchial arch. It consists of medullary and cortical bone. The cortical bone is thinner at the occlusal surface. The inferior alveolar nerve, the third division of the trigeminal nerve, enters the mandibular canal at the mandibular foramen. It travels through the mandibular canal to exit the mental foramen to provide sensation to the lower teeth (incisive nerve) and lip (mental nerve). The blood supply to the mandible is derived through the periosteum via facial arteries. Important aspects to be considered in MM are as follows:

   a. Mandibular height—With atrophy of the edentulous mandible, the vertical height is reduced and (1) the alveolar canal may lie very close to the surface and (2) the remaining mandible may be too thin and therefore at risk of a pathologic fracture.

   b. Location of the mental foramina—Ideally, the osteotomies should be placed at least 7 mm away to protect the nerve bundle.

   c. Position of the mylohyoid line—It is the attachment of the mylohyoid muscles, which are considered the "deep margin" of the

floor of mouth.

Prerequisite Skills

1. Familiarity with oral cavity structure
2. Familiarity with neck dissections
3. Experienced with skin grating techniques

Operative Risks

1. Cosmetic dissatisfaction
    a. This can be mitigated by properly managing expectations with the patient in an honest preoperative discussion.
2. Postoperative pathologic fracture
3. Dental malalignment
4. Injury to the inferior alveolar nerve

Surgical Technique

1. Surgical planning
    a. MM involves two vertical and one horizontal osteotomies in continuity with the excised cancer, preserving the inferior rim of the mandible.
        1) There are two variations on the technique:
            a) Rim mandibulectomy involves resection of the full thickness of the upper mandible.
            b) Sagittal mandibulectomy involves resection of the partial thickness of the lingual cortex of the mandible.
2. Technique
3. After achievement of adequate general anesthesia, perioperative antibiotics are administered intravenously, and the head and neck area and the appropriate reconstructive option donor site are prepped and

draped. Direct laryngoscopy should be performed first to confirm preoperative evaluation findings. If the findings remain favorable for proceeding with the surgery, a tracheostomy is placed if needed. A bite block is used to prop the mouth open, and various cheek retractors are available to facilitate exposure. A silk suture is placed in the midline of the tongue approximately 1 cm posterior to the tip for traction purposes. The lesion is identified, the mucosa is dried with gauze, and the extent of the resection is marked with methylene blue, marking pen, or needle tip monopolar cautery (on cut mode). Following the oncologic principle of en bloc resection, the MM always remains in continuity with the soft-tissue specimen.

4. Incisions are made with the needle tip monopolar cautery (Fig. 181.2). A marking suture is placed on the known margin of the specimen before removing it to orient the pathologist who will be examining the specimen with frozen sections. Ideally, the pathologist should be present in the operating room for proper in situ orientation. The incision is carried through periosteum down to the bone. A broad, sharp periosteal elevator is used to elevate the mucoperiosteum off the mandible, thereby exposing the alveolar process. Dental extractions are performed if the tooth is within the planned osteotomy site. The osteotomy should be made in the middle of the tooth socket to preserve healthy bone adjacent to the remaining tooth.

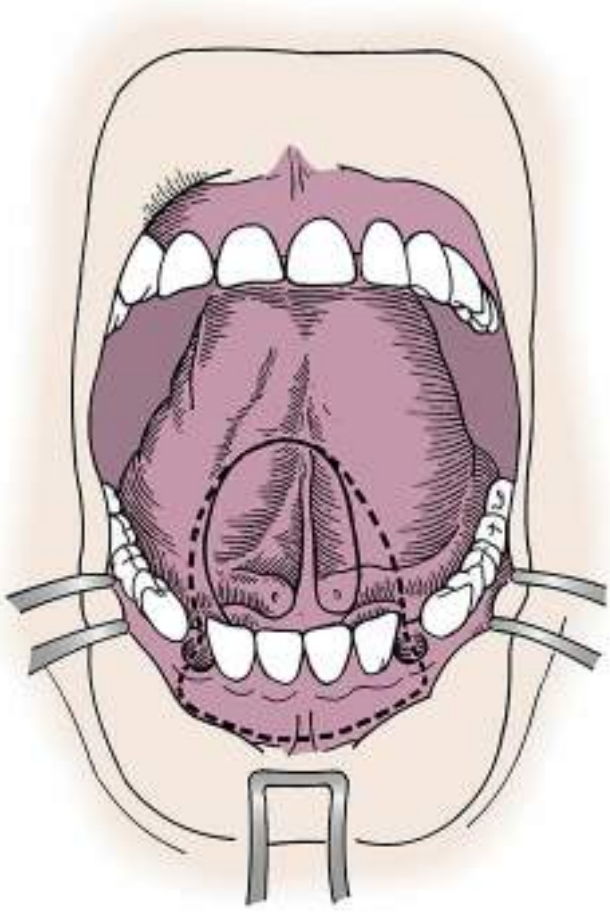

FIG. 181.2 An incision in soft tissue with dissection of the periosteum off the bone.

5. Originally, it was thought that since there is a chance that the inferior alveolar nerve can be invaded by the cancer, it should be removed along with the mandibular canal en bloc with the MM. However, Brown and Brown et al. did not find evidence supporting the significant spread of the cancer along the nerve or through the medullary space. They concluded that the excision of the mental canal with the nerve within it is not a required part of the MM.

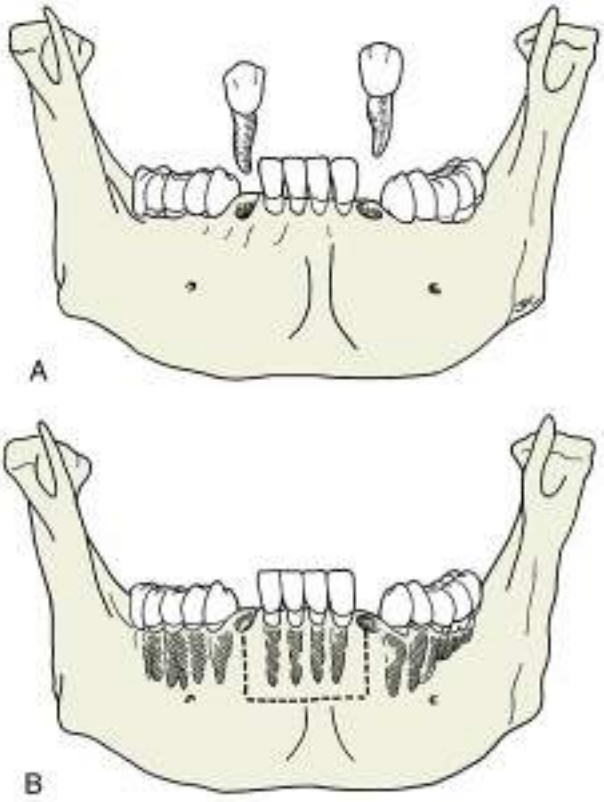

FIG. 181.3 **A,** Teeth are extracted and osteotomies are placed in the tooth sockets to avoid eventual loss of support to the remaining teeth. **B,** Vertical and horizontal osteotomies are made with an oscillating saw.

6. While the tumor size dictates the amount of bone to be excised, it is advised to leave at least 1 cm of the bone to reduce the chance of postoperative fracture. An oscillating saw is used for both vertical transverse osteotomies. It is important to perform complete osteotomies, as trying to remove the bone forcefully with a suboptimal osteotomy may lead to mandibular fracture. The osteotomies in rim mandibulectomy can be placed at 90-degree angles to each other (Fig. 181.3).

7. Once free of the mandible, the bone fragment is left attached to the soft tissue part of the tumor, and the specimen is delivered en bloc.

8. While the soft tissue margins are assessed by frozen section analysis, hemostasis is achieved with cautery and bone wax, and osteotomy sites are smoothed with a pineapple drill bit.

9. Closure/reconstruction

a. The wound is closed primarily or with a split- or full- thickness skin

graft in radiation-naïve patients. Free tissue transfer is employed when additional soft tissue coverage is needed (in cases of partial glossectomy or maxillectomy) or in radiation failure cases. The skin grafts heal well, because most of the cut bony surface is cancellous rather than cortical bone and provides adequate recipient bed vascularity for the graft survival. However, in the update by Deleyiannis et al., one-fifth of the patients reconstructed with split-thickness skin grafts that received adjuvant radiation developed osteoradionecrosis. Hence, free tissue transfer should be considered in cases of sizeable tumors, which may warrant postoperative radiation (Figs. 181.4 and 181.5).

Common Errors in Technique

1. Invasion of bone may be underestimated in up to one-third of the cases.

2. Improperly placed or executed osteotomies may compromise dental health and future dental rehabilitation and mandibular strength.

3. Failure of the proper intraoperative frozen section analysis may lead to positive margin, compromising local control.

Postoperative Period

Postoperative Management

1. Postoperative care is similar to the patients with floor of mouth soft tissue cancer resection. Antibiotic prophylaxis is given for the length of time accustomed to a particular institution. Routine tracheostomy care is advised in cases where preoperative tracheostomy was placed. In patients whom split-thickness skin-graft reconstruction was employed, liquid diet is started as soon as cleared by speech and language pathology evaluation. The bolster holding the graft in place can be removed in 5 to 7 postoperative days. The patient does not need to remain in the hospital for that long and can be discharged once the calorie counts confirm adequate nutritional intake (exceptions are patients with newly placed tracheostomy—they need to remain in the

hospital until the first tracheostomy change). In cases with free tissue transfer, postoperative protocols specific to that institution should be followed.

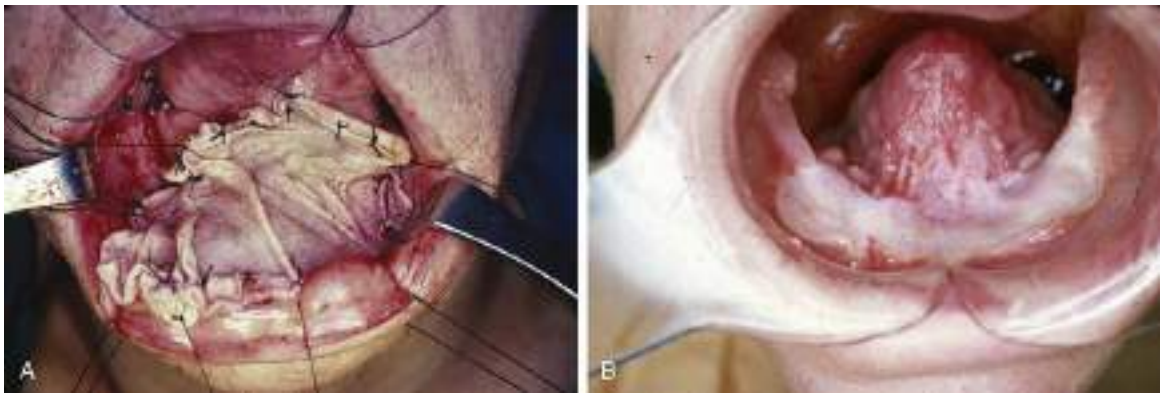

FIG. 181.4 **A,** A split-thickness skin graft is sewn into place over the defect. **B,** The healed skin graft overlying soft tissue and bone.

Complications

1. The major complication of MM is intraoperative or postoperative fracture of the mandible. Fracture can take place intraoperatively in two situations. First occurs when a vertical osteotomy is extended deeper than necessary. Mandibles with decreased vertical height (such as an edentulous mandible) are particularly vulnerable to this type of incident. Second happens when the osteotomies are not complete and the surgeon is trying to remove the bone forcefully by fracturing the alveolar process or the cortex of the bone. In both settings, the fracture must be repaired intraoperatively with a compression plate. The reported postoperative fracture rate ranges between 2% and 16%. The risks associated with this complication included concurrent osteoradionecrosis, prior radiation, facial artery ligation, and periosteal stripping.

2. In the review of 43 patients by Chen et al., the rate of osteoradionecrosis was 17.4% in patients who received adjuvant radiation after undergoing MM. It developed between 2 and 6 months after completion of radiation. All patients recovered without surgical interventions. Four of 137 (2.5%) MM patients presented by Pathak et al.

developed osteoradionecrosis postoperatively. All four were managed with SM and free tissue transfer.

Discussion

Evidence-Based Medicine Question

Does the use of an MM decrease the survival rate in cancer of the oral cavity?

1. Survival
    a. Several authors found that the type of mandibular resection (segmental vs. marginal) did not affect the 5-year survival, supporting the MM as the oncologically sound alternative to a more extensive segmental resection. Munoz et al. report a 5-year survival rate of 60.35% for patients who underwent marginal or SM. The type of resection did not affect the survival. It was the positive soft tissue margin and bone invasion that correlated with the poor 5-year survival (Figs. 181.6 and 181.7). O'Brien et al. similarly emphasized clear soft tissue margin status as the predictor of survival. In their 11-year experience with MM, Pathak et al. report 5-year disease-free survival of 62.9% and cause-specific survival of 72.2%. Cause-specific survival was significantly better in patients with gingival buccal than floor of mouth cancer. Age, tumor stage, margin status, bone involvement, and adjuvant radiation did not affect 5-year cause-specific survival. In their 13-year experience, Muscatello et al. reported similar 5-year disease-free survival of 77.3% and overall survival of 60.7%.

2. Recurrence
    a. The reported rates of recurrence in patients who underwent MM range between 4% and 20%. Most recurrences are reported to occur within the first year. Munoz Guerra et al. compared an MM group (50 patients) with an SM group (56 patients). They failed to show that bone invasion affected local recurrence in either group and identified tumor stage as the only factor predictive of local recurrence. Similar findings of no statistically significant correlation between the bone invasion and recurrence were reported by other

groups. Several research groups demonstrated that the recurrences predominantly occur within the soft tissue. In the review of 43 MM patients by Chen et al., two-thirds of patients with local recurrence underwent salvage surgery, and 83.3% were controlled oncologically, bringing the total local control after salvage surgery to 90.7%. Similar numbers for salvage treatment and total local control were reported by Pathak et al.

3. Quality of life

Rogers et al. administered the university of Washington quality of life questionnaire (UQ-QOL) to 44 patients undergoing an MM and 57 patients undergoing SM preoperatively and postoperatively at 6, 12, and 18 months. The SM group had more pain, problems with chewing, and lower overall UW-QOL scores. The SM group also scored worse at all postoperative time points, specifically, in areas of appearance, swallowing, recreation, and chewing. The difference between groups diminished in patients with large tumors and those who underwent adjuvant radiation. Wolff et al. assessed quality of life by assigning the eastern cooperative oncology group (ECOG) performance status to their 82 SM and 54 MM patients. While there were no statistically significant differences in survival, number of recurrences, second primaries, metastases, and postoperative complications between the groups, over 50% of MM group were able to carry normal unrestricted activity compared with preoperative status, where only 35% of SM group were able to achieve the same.

Editorial Comment

MM is one of the first and best examples of modifying a surgery (i.e., SM) to preserve function and cosmesis, while following sound oncologic principles to attain a complete resection of the tumor. This chapter presents a scholarly review of the procedure, including its historical background and addressing oncologic and surgical principles.

As for any organ-sparing surgery, adequate patient selection is a requisite to obtain superior outcomes. A high resolution CT scan with bone algorithm or Dentascan helps to identify the presence of bone erosion and estimate the height of the mandible in edentulous patients (an atrophic mandible will not tolerate an MM irrespective of oncologic feasibility). A dual-energy CT eliminates much of the dental amalgam artifact; thus, its need should be identified during the oral examination. Nonetheless, bimanual palpation and the ability to glide the lesion and

surrounding soft tissues over the bone are superior to imaging in those patients without gross involvement by CT. Unfortunately, an adequate examination is often limited by pain, therefore requiring general anesthesia. In any case, these two techniques are complementary; thus, using them in combination is best.

Technically, MM has not changed significantly since its inception. However, the additional use of titanium reconstruction plates has extended the indications in patients with mild to moderate atrophy of the mandible and decreased the incidence of postoperative pathologic fractures. In addition, the use of thin and pliable flaps such as the platysma, submental, and radial forearm microvascular flaps can accelerate healing and preserve function.

Review Questions

1. Marginal mandibulectomy is appropriate for patients presenting with which symptoms?

   a. Erosion of the bony cortex of the mandible

   b. Involvement of the mandibular canal by cancer

   c. **Abutment of the lesion onto the periosteum**

   d. Circumferential encasement of the mandible without bone invasion

2. Complications of marginal mandibulectomy include all of the following except:

   a. **Oral fistula**

   b. Pathologic fracture of the mandible

   c. Malocclusion

   d. External cosmetic deformity

Segmental Mandibulectomy

Steven Parnes, and Kristina Piastro

Introduction

Segmental mandibulectomy involves the removal of a full-thickness segment of the mandible, often secondary to a malignant or benign tumor, trauma, or osteoradionecrosis. Segmental mandibulectomy may be performed in the setting of a *composite resection*, a term coined by Ward and Robben in 1951. It was thought that cancer of the oral cavity had a propensity to spread via periosteal lymphatics to the mandible; thus resection of a segment of mandible in continuity with a cancer of the oral cavity, oropharynx, or a primary cancer of the alveolar ridge was recommended regardless of whether the bone was actually invaded. Marchetta and colleagues disproved the theory of lymphatic invasion; thus mandibulectomy (Table 182.1) is reserved for those with advanced cancer of the oral cavity or oropharynx where invasion of the mandible is clinically evident or cannot be ruled out. Fundamental concepts of extirpation have not changed in the interval. However, methods of reconstruction continue to evolve with the development of microsurgical techniques and reliable free flaps.

Key Operative Learning Points

- Most patients must undergo a tracheostomy, because postoperative oral disability could otherwise result in aspiration, and edema may lead to airway obstruction.
- Mandibulectomy results in significant cosmetic and functional compromise and should be undertaken only if the operating surgeon feels that negative margins can be obtained.
- The periosteum and mandible serve as barriers to invasion; however,

patients who have undergone radiation, have had surgery that resulted in periosteal stripping/resection, or have poor peridontal health are at greater risk.

  - Cancers generally arise at the occlusal surfaces, but they can also invade at the muscular attachments or through invasion of the mental/inferior alveolar nerve.

- Defects after segmental resection of the mandible can be divided into anterior and lateral defects in reference to the mental foramen.
  - An anterior defect results in loss of function of the oral cavity, including mastication, oral competence, drooling, swallowing ability, and airway compromise.
  - A lateral defect results in less morbidity; however, they include imbalance of mastication forces and altered contour of the posterior lower third of the face. The mandible will deviate toward the resected side due to the pull of the suprahyoid muscles on the residual fragment, causing inferior displacement and rotation around the remaining condyle.
- Free flap reconstruction offers a high degree of reliability and good aesthetic outcomes.
- Decisions regarding reconstruction should be based on the patient's age, dentition, and expectations as well as on the anticipated soft tissue defect.
  - Plans for reconstruction of the mandible must be finalized before the mandibulectomy procedure. Various techniques are listed in Table 182.2.
  - A simulated virtual surgical plan may be helpful.

Preoperative Period

History

- Comorbidities and lifestyle habits that would affect the healing process
- Postoperative swallow, speech, and dental rehabilitation

- Approximately 25% of all head and neck cancers and 60% of all oropharyngeal cancers are positive for human papillomavirus (HPV), a finding that may alter postoperative treatment.[1]
- We have found varying association of mandibular invasion with inferior alveolar nerve paresthesia, loose teeth, gender, age, habits (alcohol, tobacco chewing), clinical type of lesion, skin fixation by the tumor, dental status, and patients with recurrent cancers who have received prior radiotherapy.

Physical Examination

- Routine preoperative examination of the head and neck with attention to the relationship of the primary cancer to the mandible using bimanual palpation to evaluate for adherence of the cancer to the periosteum or bone invasion.
- Preoperative determination of the presence or extent of invasion of the mandible is challenging.
- Testing for numbness of the lower lip to ascertain whether the cancer has involved the mental nerve

TABLE 182.1

Definitions of Mandibulectomy

Mandibulotomy	Osteotomy of the mandible to permit exposure, no bone resected; bone is reapproximated at the completion of the procedure
Marginal mandibulectomy	A portion of the mandible, typically the alveolus or lingual plate, is resected while leaving the continuity of the mandible intact
Segmental mandibulectomy	A portion of the mandible is resected, with disruption of condyle-to-condyle continuity. IE resection of the Ramus Angle Body Parasymphysis

Skin graft

Reconstruction plate
Plate and screw with a regional pedicle flap
Plate and bone-anchored post with a titanium hollow screw reconstruction plate (THORP)
Microvascular free flaps with bone (preferred option)
Radius
Fibula
Scapula
Iliac crest

Imaging

- Clinical examination has been found to be a sensitive way to identify bone invasion; however, the best results can be obtained by combining it with a radiologic study.
- No imaging technique is 100% accurate in identifying invasion of the mandible.
- More than 60% to 70% of bone mineral must be lost before radiographic changes become evident.
- Computed tomography (CT) scans, magnetic resonance imaging (MRI), and bone scintigraphy have been reported to have sensitivity and specificity ranging from 85% to 95%.[1]
  - CT findings of osseous involvement include cortical erosion adjacent to the primary lesion (Fig.182.1A), aggressive periosteal reaction, abnormal attenuation in bone marrow, and pathologic fractures. Image quality around the alveolar crest may be hampered by severe dental artifacts and image noise.
  - MRI may be more sensitive for marrow and the inferior alveolar canal; however, it also results in more false positives and frequently overestimates the extent of tumor invasion. This is due to the high intensity of the edematous or inflammatory changes at the soft tissues adjacent to the tumor.

- Positron-emission tomography (PET) with fluorine 18 fluorodeoxyglucose (FDG) is also expected to be useful for assessing bone invasion because FDG accumulates well at the malignant tumor.

- For patients undergoing free flap reconstruction, conventional angiography or MR angiography is recommended for patients over 50 years of age and those with comorbidities such as diabetes mellitus (DM), hypertension, trauma, arteriopathy, or equivocal pulses.
- Three-dimensional (3-D) imaging for reconstruction plans and 3-D modeling have greatly improved preoperative surgical planning (see Fig. 182.1).

Indications

- Malignant tumor invasion of the medullary space of the mandible by either a primary tumor of the alveolar ridge or from an adjacent site such as the floor of the mouth
- A hypoplastic, edentulous, or previously radiated mandible that precludes safe performance of a marginal mandibulectomy
- Benign tumor of the jaw, such that extirpation would result in instability and possible pathologic fracture
- Advanced osteonecrosis related to radiation or bisphosphonate use or osteomyelitis
- Severe mandibular trauma with unstable or devitalized bone

Contraindications

- Comorbidities for general anesthesia; cardiac, hemodynamic, nonreversible coagulopathic disorder
- Extensive tumor that precludes complete resection
- Distant metastases (a palliative mandibulectomy may be indicated in highly selected patients)

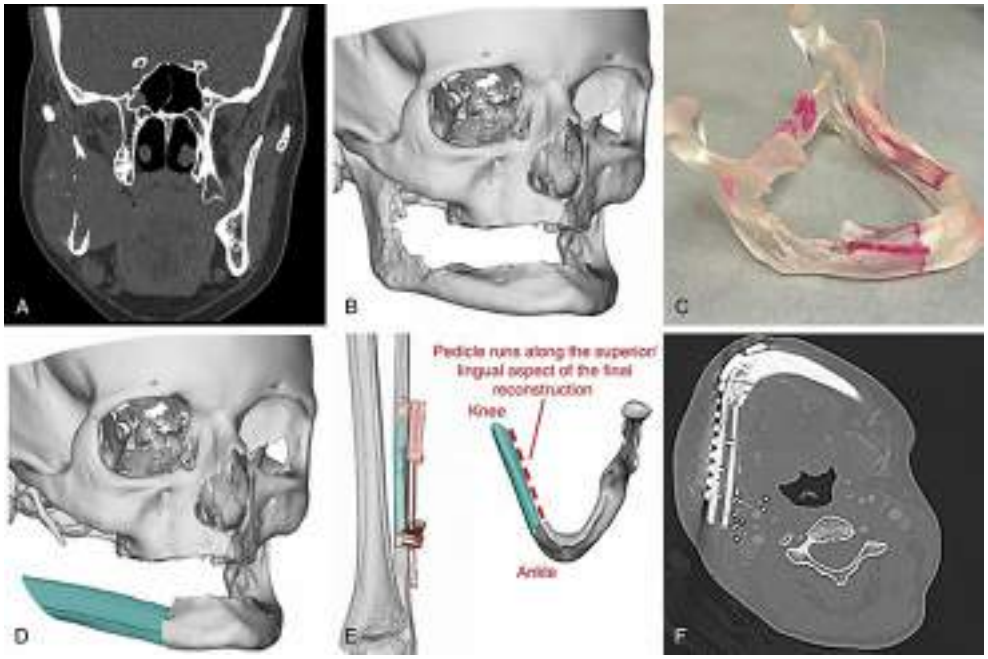

FIG. 182.1 **A,** A computed tomography (CT) scan of a patient demonstrating carcinoma that eroded the ramus of the mandible. **B,**Three-dimensional reconstruction for virtual surgical planning. **C,** Three-dimensional model of mandible preoperatively. **D,** Virtual plan with fibular reconstruction. **E,** Fibular resection planning. **F,** CT scan of postoperative view after osseocutaneous fibular free flap reconstruction.

Preoperative Preparation

- Discussion of patient expectations and possible outcomes, including expected sequelae and unexpected complications
  - Functional and cosmetic outcomes, especially in those patients who have had prior radiation therapy
  - Planned incision sites, tracheostomy for airway management, possible gastrostomy tube for alimentation
- Multispecialty approach, as patient will likely require postoperative therapy
  - Dental, radiation, and medical oncology, speech/swallow
- Coordination with teams involved

- Reconstructive team: appropriate preparation, setup, instrument availability, reconstructive plan, and possible grafts or pedicle flaps
- Dental/Oromaxillofacial Surgery: extractions, primary osseointegrated fixation devices
- General surgery: gastrostomy tube placement for postoperative alimentation

Operative Period

Anesthesia

- General, with oral endotracheal intubation and conversion to tracheostomy
  - Nasal intubation for lesions confined to the mandible that are not felt to warrant tracheostomy
- May initiate paralysis after identification of marginal branch of CN VII and XI

Positioning

- Head is positioned 180 degrees away from the anesthesia circuit.
  - Allows for multiteam approach if there is a free flap plan
  - Reverse Trendelenburg position (approximately 20 degrees)

Perioperative Antibiotic Prophylaxis

- A postoperative infection rate of 24% to 87% has been reported in clean-contaminated cases without the use of prophylactic antibiotics.[2]
- Higher risk with DM, advanced stage of disease/extent of surgery, tracheostomy, flap reconstruction, previous external radiation therapy (XRT).
- A variety of single and combination antibiotics have been evaluated and recommended for prophylaxis for major head and neck surgery.

- Prophylactic perioperative antibiotics should be started prior to skin incision for maximal benefit.
  - Academy of health-systems pharmacists (ASHP) guidelines recommend administration of prophylactic antibiotics within 60 minutes of start of procedure and redosing after two half-lives of the drug.
  - Coverage should include skin flora as well as aerobic and anaerobic bacteria.
  - A variety of single and combination antibiotics have been evaluated and recommended for prophylaxis for major head and neck surgery involving the upper aerodigestive tract. Examples include
    - Clindamycin: 600 mg IV with 4 additional doses q6h
    - Ampicillin/sulbactam: 1.5 g (1 g ampicillin and 0.5 g sulbactam) or 3 g (2 g ampicillin and 1 g sulbactam) IV/IM every 6 hours
    - Cefazolin: 2.0 g IV with 3 postoperative doses q8h
- Continuation of perioperative antibiotics beyond 24 to 48 hours postoperatively has not demonstrated decreased rates of infection.

Monitoring

- Standard general anesthetic monitoring
- Arterial line for free flap cases, hemodynamic and blood loss monitoring
- Communication with anesthesia team regarding fluid management and use of vasopressors, which may negatively affect free flap survival
- Acoustic Doppler ultrasonography postoperatively for free flap monitoring
  - A suture placed to mark the site of the pedicle to ensure that both the medical and nursing teams can properly assess free flap viability

Instruments and Equipment to Have Available

- Soft tissue and head and neck set
- Orthognathic/oral surgery/dental extraction set
- Nerve monitor if indicated, bipolar electrocautery, saw set with both wedge-shaped reciprocating and oscillating saw or Gigli manual saw if powered unavailable, drill to smooth bony free edges
- Reconstructive team: microscope, microvascular set, mandibular reconstruction plating set

Key Anatomic Landmarks

- The mandible contributes to the peripheral boundaries of the floor of mouth: the lower third of the facial form, speech, swallowing, mastication, and respiration.[4]
  - Disruption of the mandible can significantly affect any of these functions.
- Mandibulectomy is divided into lateral and anterior defects by the mental foramen.
  - When intraoral incisions are being extended to improve exposure, ensure dissection and preservation of the contralateral mental nerve.
- The farther anterior the defect, the more disfiguring and functionally debilitating the outcome. This is related to loss of key muscular attachments located anteriorly (genioglossus, geniohyoid) and loss of tongue mobility and control.
- Defects of the symphyseal region are most debilitating, and surgical reconstruction is mandatory for segmental stabilization.
- Lateral defects are more forgiving if muscular attachments are preserved; in these cases the result is often near normal appearance and function.
- Choice of incisions varies with the site of the cancer and planned reconstruction.
  - If tumor invades the mandible, an ipsilateral neck dissection is usually warranted and may be incorporated with a lip-splitting, half-H incision that is at least 2 cm below the angle of the mandible

to avoid injury to the mental nerve (Fig. 182.2).

- More than 30% of patients with squamous cell carcinoma of the oral cavity have lymph node metastases, and histologic confirmation of metastatic disease is the most important prognostic factor.
- The neck dissection specimen may be kept in continuity with the tumor or dissected separately.
- Cancers involving the base of the tongue, approaching midline, or major lymph adenopathy of the ipsilateral side should be treated with a bilateral neck dissection.
- When a lip-splitting incision is used, it is important to ensure close realignment of the vermillion border prior to making the incision.

- Degloving with a visor flap compromises the contralateral mental nerve.

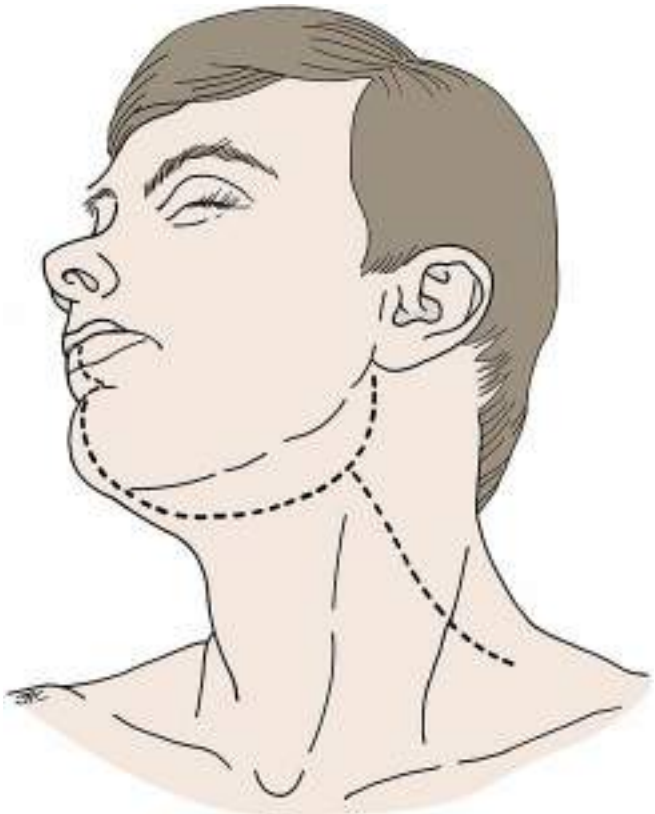

FIG. 182.2 Among the incisions used for composite resection is the lip-splitting modified half H. This incision

provides excellent visibility of lesions in the posterior oral cavity. It can be used for bilateral neck dissection by the formation of a submental trifurcation.

Prerequisite Skills

- Soft tissue handling
- Neurovascular dissection, microvascular surgery team expertise
- Familiarity with surgical and Gigli saws
- Dental extraction technique and instruments

Operative Risks

- Risks associated with anesthesia
- Injury to lingual and hypoglossal nerves, resulting in dysphagia and dysarthria
- Significant blood loss from various branches of the external carotid and internal maxillary arteries
- Segmental mandibulectomy results in transection of the inferior alveolar nerve and will cause permanent anesthesia of the affected lower lip postoperatively.
  - There has been variable success with a segmental nerve graft using donor nerve (sural nerve or lateral femoral cutaneous nerve); preservation of the contralateral mental nerve is recommended.

Surgical Technique

- The technique of mandibulectomy has not changed significantly over the past several decades except that a nondiseased mandible is no longer removed, and a mandibulotomy is the preferred approach in these cases, as discussed in Chapter 181, "Marginal Mandibulectomy." What has changed are the methods of reconstruction, which range from primary closure; healing with secondary intention; reconstruction with split-thickness skin grafts, local, or regional flaps to microvascular

reconstruction with free tissue transfer. These methods are beyond the scope of this chapter. Here we describe the method of segmental mandibulectomy and associated procedures as performed at our institution.

- Tracheostomy is generally indicated for maximal intraoperative exposure and postoperative airway management; however, for lesions requiring minimal soft tissue resection and reconstructive plans, a nasal intubation may be sufficient.
- Tumor is reexamined under general anesthesia and the resection and reconstructive plans are confirmed; margins are marked usually between 1 and 2 cm from the edge of the cancer.
- We prefer a lip-splitting incision, which is carried out inferiorly to about the level of the hyoid and posteriorly to the mastoid tip, providing excellent exposure of the mandible and neck while preserving the contralateral mental nerve (see Fig.182.2).
  - If the incision for neck dissection is incorporated, care must be taken to avoid communication with the tracheostomy incision and injury of the marginal nerve, with placement of the incision at least 2 fingerbreadths below the border of the mandible.
  - A visor flap may also be used with initial intraoral gingivobuccal incisions (Fig. 182.3C and D) and may be more cosmetically appealing; however, this tends to compromise the contralateral mental nerve and does not allow for visualization of tumors at the posterior to middle third of the tongue and retromolar trigone.
- The intraoral incisions along the antero-lateral gingivo-labial and buccal sulcus allow mobilization of the lip (Fig. 182.4) as it is dissected the mental nerve is sacrificed, this does not add to morbidity as the inferior alveolar canal needs to be transected with the specimen (Fig. 182.5)
- Dissection is carried over the periosteum of the buccal plate of the mandible anterior to the masseter muscle. The marginal branch is identified and elevated with the skin flap. Should there be evidence of tumor invading lateral to the mandible, the facial artery and mandibular branch may have to be sacrificed (Fig. 182.6).
- When adequate exposure of planned mandibular and tumor resection

has been identified, the reconstructive team may wish to preplate the mandible prior to resection. The reconstructive plate is prebent, and screw holes are placed at either end on the residual bone. The plate is then removed and sterilized prior to implantation.

- The position of the osteotomy is then marked; it should encompass a margin of at least 2 cm and extend anteriorly to include the mental foramen. Should there be teeth at the planned osteotomy sites, dental extractions are performed at this point.
- A reciprocating saw is used to perform the anterior osteotomy, with care taken not to injure the neurovascular structures at the floor of mouth; appropriate soft tissue retraction prevents excessive injury. Since postoperative extraction may prove difficult, additional extractions should be carried out if the patient has poor remaining dentition or not enough remnant mandible to support surrounding teeth.
- Posteriorly an oscillating saw may be used to section the ramus. Should the extent of disease require an osteotomy above the notch of the mandible, the coronoid will be removed with the specimen. This will require section of the tendon of the temporalis muscle (Fig. 182.7). The placement of this osteotomy will decrease bleeding risk from the inferior alveolar artery.
- Once both osteotomies have been performed, additional mucosal incisions can be carried out in the oral cavity and may be aided by suture traction on the tongue or soft palate (Fig. 182.8).

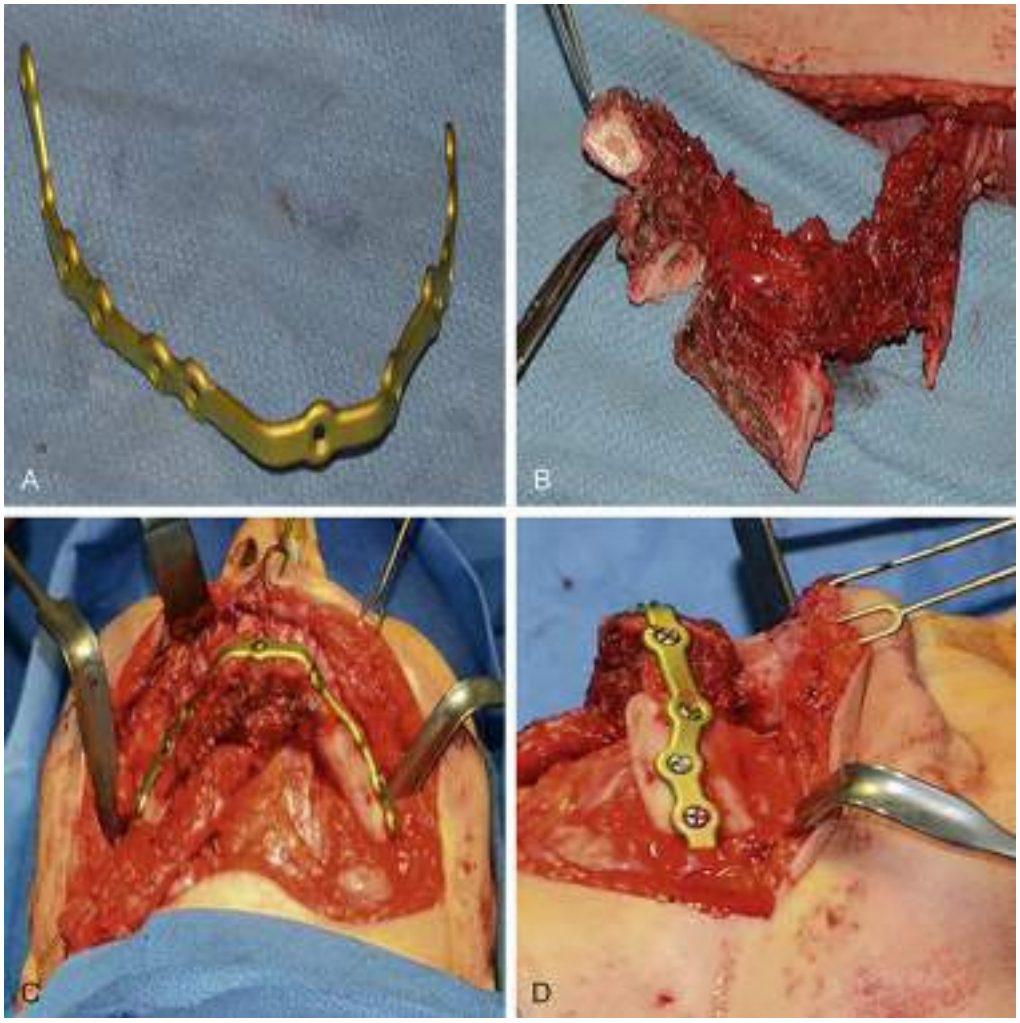

FIG. 182.3 **A,** Precontured mandibular reconstruction plate. **B,** Harvesting of the free fibular osseocutaneous graft. **C,** Visor incision with inset of the free fibular graft (FFG). **D,** Sagittal view of inset FFG with adequate projection.

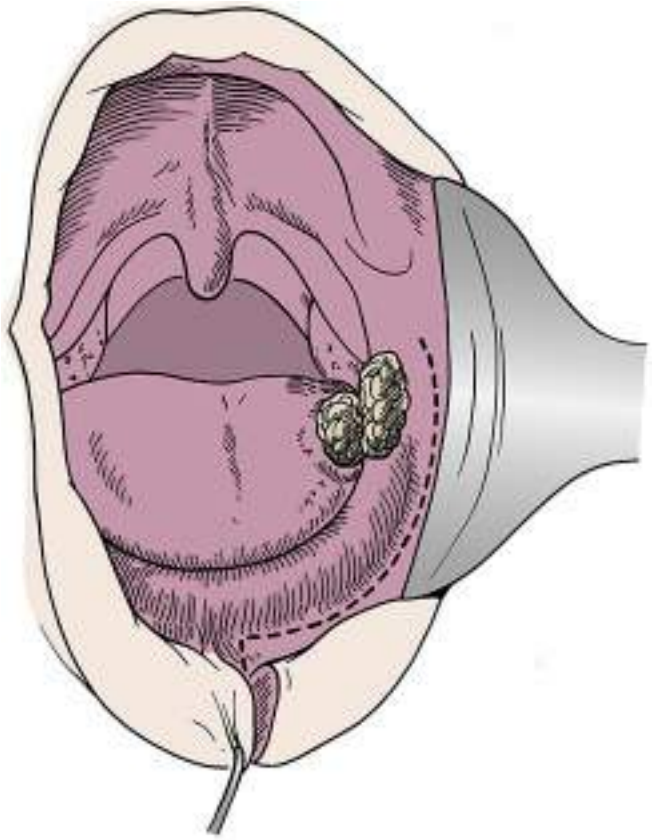

FIG. 182.4 A lip-splitting incision with extension along the buccogingival sulcus to permit retraction of the cheek flap. Care must be taken to avoid compromising the tumor margin of the resection laterally.

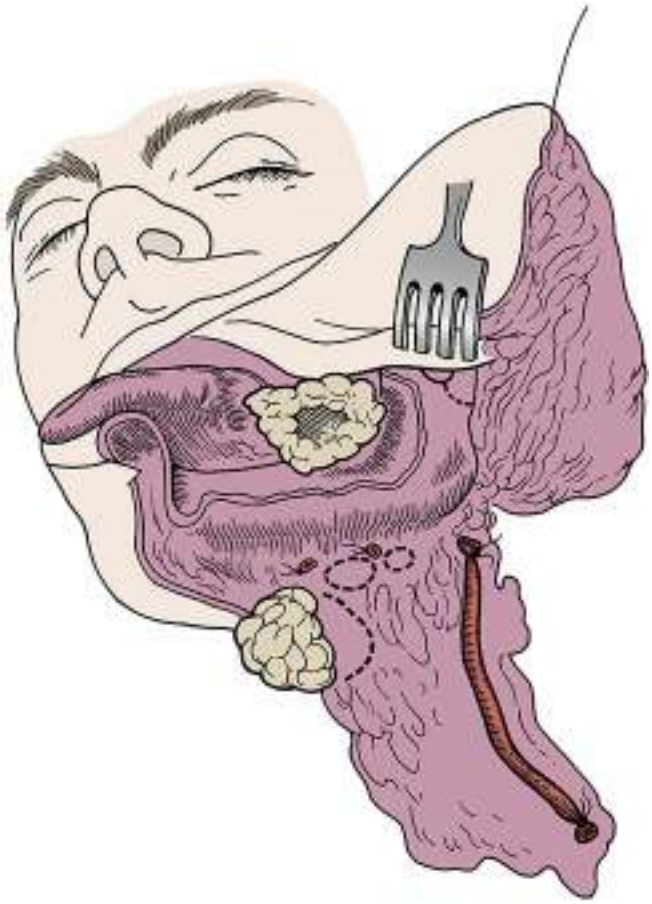

FIG. 182.5 Reflection of the cheek flap provides excellent visualization of the cancer.

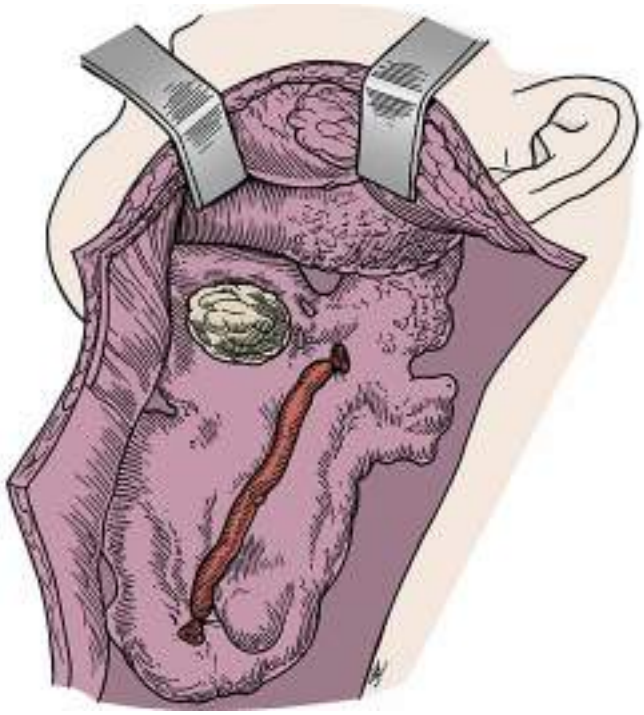

FIG. 182.6 Dissection of the mandibular periosteum and masseter muscle lateral to the mandible. Care must be taken to avoid exposing the cancer by excessive dissection superiorly.

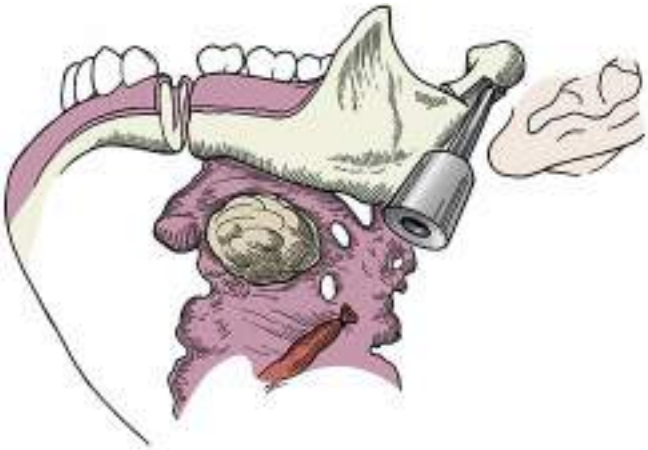

FIG. 182.7 An oscillating saw is used for osteotomy of the neck of the mandibular condyle. The osteotomy could also be made through the midramus. If oncologically feasible and reconstruction is planned, a vertical osteotomy will provide more bone, thereby improving fixation of the graft.

- Once the tumor is fully excised, hemostasis is achieved with cautery and/or a ligature, and the edges of the bone resection may be smoothed with a drill.
- The composite resection is sent for review of frozen sections to include the neurovascular pedicle of the mental/inferior alveolar nerve. Often we will obtain an intraoperative consult with the pathologist to discuss the case and the specimen, making sure that it is accurately labeled and assessed. Bone margins cannot be assessed as they require decalcification; therefore biopsy of the proximal and distal neurovascular structures may serve as the surrogate.
- We often choose to perform the neck dissection with a separate specimen if there is no frank lateral extension of the tumor to the basin of the pre-and postfacial nodes. The surgical steps are discussed in Chapter 181, "Neck Dissection."

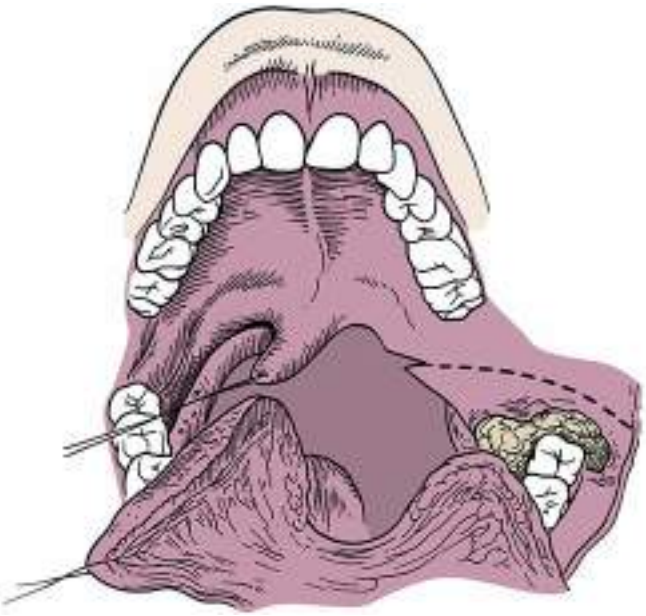

FIG. 182.8 Retraction of the soft palate with a suture placed in the uvula will help to make precise incisions through the mucosa of the soft palate. It is also advisable to place a suture through the specimen to facilitate orientation by the pathologist.

- A supraomohyoid (levels Ia, Ib, II, and III) is performed; elective removal of level IV is still under debate.

- Bilateral neck dissection is carried out with advanced tumors of the oral tongue, floor of mouth, lip, and mandible that violate the midline of these regions.

- Reconstruction options for oral and mandibular defects are varied (see Table 182.2) and include primary closure, skin grafts, local and regional flaps, and free tissue transfer with microvascular anastomosis. The most frequently used flap at our institution is the fibula osteocutaneous free flap, which has demonstrated excellent survival and viability (see Fig. 182.3B).

- Goals of reconstruction:
  - Reestablish the contour of the lower third of the face.
  - Restore tongue volume and floor of mouth to preserve mobility and allow for optimal speech and swallow functions.
  - Restore mandibular continuity while maintaining appropriate occlusal surfaces, and provide a structure for future dental implantation.

- The reconstructive methods are beyond the scope of this chapter; they are discussed elsewhere in this text (see Chapters 161 to 169).

Common Errors in Technique

- Obtaining surgical access for mandibulectomy is one of the surgeon's greatest challenges; direct visualization of the osteotomy and protected tissues is vital.

- Misalignment of the reciprocating saw may cause damage to surrounding structures.

- The inferior alveolar and lingual nerves are put at risk because the cheek interferes with the saw and causes it to point posteriorly; this can be avoided by performing the posterior cut through an open approach.

- The submandibular duct is often put at risk; if the gland won't be excised, the duct should undergo a sialodochoplasty and be sutured to the floor of the mouth.

- Transection of the lingual, buccal, and facial vessels can result in

significant bleeding; awareness of anatomy and preparation to encounter and control bleeds mitigates this concern.

- If the neck dissection is performed in conjunction with a composite resection, the vessels should already be identified more proximally, with access to control should bleeding be encountered.

Postoperative Period

Postoperative Management

- Monitoring in the intensive care unit (ICU) for 24 to 48 hours
  - Flap assessment with acoustic Doppler ultrasonography, capillary refill, color, and turgor
  - Fluid balance and shifts
  - Tracheal suctioning, drain management
- If a bolster was placed, with antibiotic coverage while in place, it is removed approximately 1 week after surgery.
  - Oral care, oral rinses
  - Consideration of removal of the tracheostomy occurs after bolster removal.
- Nutrition/Gastrointestinal access: Usually via nasogastric tube, generally at least until bolster removal and decannulation
  - Gastroesophageal reflux precautions with a proton pump inhibitor

Complications

- Infection and fistula formation, the need to remove fixation hardware, and possible flap failure, osteomyelitis, temporomandibular joint (TMJ) pain, chronic pain
- Dental malocclusion in the dentate patient undergoing segmental resection
- Nonunion of the bony reconstruction

- Positive margins, necessitating a return to the operating room for additional resection
- Dysphagia, dysarthria
- Aspiration

Alternative Management Plan

- Definitive radiation therapy, concurrent chemoradiation, and induction therapy are alternative options for patients who are not candidates for surgery.
- Chemotherapy is given concurrently with radiation therapy; definitive radiation doses used are 66 to 74 Gy (2.0 Gy/fraction; daily Monday to Friday over 7 weeks).
- Chemotherapy may be given as an induction in order to decrease tumor size and make it amenable to either resection or radiation therapy.
- For recurrent or distant metastatic cancers, a platinum-based chemotherapy regimen is preferred.

Discussion

Evidence-Based Medicine Question

Are radiation and chemotherapy indicated in the treatment of advanced cancer of the oral cavity that has invaded the mandible?

Cancer of the oral cavity that has invaded the mandible requires resection with segmental mandibulectomy with sufficient oncologic margins. Patients with bone involvement are staged T4, and many of these patients will be found to have cervical adenopathy on pathologic review of neck dissection specimens. Recent reports suggest that adjuvant chemotherapy and radiation are beneficial in this group.[4]

The updated meta-analysis by Bourhis et al. (2009) looked at chemotherapy in head and neck cancer (MACH-NC)using individual patient data from 93 randomized trials (level 1A evidence) and showed

that concomitant chemoradiotherapy is the standard of care in locally advanced head and neck squamous cancer. At 5 years, these investigators found that, relative to radiotherapy alone, the addition of concomitant chemotherapy to radiotherapy was associated with an increase in survival of 6.5%—representing a 12% to 13% improvement in locoregional control and about a 3% decrease in distant metastases.

Editorial Comment

Segmental mandibulectomy has been a reliable procedure for the resection of advanced oral cancers for over a century. Despite its multiple sequelae, the extirpative technique has undergone only trivial changes. Reconstruction of the mandible, however, has leapt forward with the use of microvascular tissue transfer. This has proven to be a reliable reconstructive technique for both the soft tissue and bone, thus helping to restore cosmesis and function.

Review Questions

1. What is an indication for segmental mandibulectomy?

   a. Oral cavity tumor adjacent to mandible with evidence of invasion into superficial lingual cortex

   b. Access to resection of a malignant tumor of the oropharynx

   c. **Malignant tumor invading the medullary space or neurovascular structures of the mandible, either a primary alveolar ridge tumor or from an adjacent site such as the floor of mouth**

   d. All of the above

2. What is the difference between lateral and anterior segmental mandibulectomy?

   a. All lateral mandibulectomy defects require osteocutaneous reconstruction.

   b. **Anterior defects result in significant functional and airway**

compromise and therefore require reconstruction and stabilization.

c. The aesthetic and functional outcomes in lateral and anterior defects are similar.

d. The more posterior a mandibular defect, the greater the functional and aesthetic deficits.

3. Which imaging modality has 100% accuracy in the detection of mandibular invasion?

a. CT

b. MRI

c. PET-CT

d. **None of the above**

Mandibular Osteotomy Approaches

Carlos D. Pinheiro-Neto, and Lisa Galati

Introduction

The mandibulotomy approach was first described by Roux in 1836.[1] Dubner and Spiro, in 1959, developed the technique with paralingual extension, which is the origin of the modern mandibulotomy. Since then, several modifications to the technique have been described.[2] However, the basic principle of the mandibulotomy still remains, which is to provide exposure and a surgical corridor to the oral cavity and oropharynx. The approach may also be used to access the parapharyngeal space and skull base. The modifications are usually intended to minimize postoperative complications. The two principal types of anterior mandibulotomy are the median and the paramedian.

The median mandibulotomy is performed between the central incisors and may require the extraction of a tooth, owing to the narrow space, with the osteotomy placed in the middle of the tooth socket. This preserves the bone of the adjacent sockets, maintaining the stability of the adjacent teeth. The paramedian mandibulotomy is performed between the lateral incisor and canine and usually does not require tooth extraction.

Key Operative Learning Points

1. The osteotomy is performed anterior to the mental foramen to maximize blood flow to the bone and facilitate postoperative healing.

2. Accurate reapproximation of the lip is the key to superior cosmesis. The lip should be closed in three layers: the mucosa, the orbicularis oris muscle, and the skin.

3. Bone realignment and fixation are enhanced by preplating (placing the plate and drill holes) before proceeding to the mandibulotomy. Use of a stair-step osteotomy facilitates fixation.

4. Postoperative application of a bulky supportive dressing tends to reduce facial edema and support immobilization, which enhances rapid healing and good cosmesis.

5. A tracheostomy is necessary to provide an airway during the early postoperative phase. The cannula can be removed as soon as edema resolves and oropharyngeal function has resumed.

Preoperative Period

History

1. History of present illness

   a. Questions about the site of the tumor: tongue, tonsil, gingiva, soft palate

   b. Tumor size and growth: how long ago was the lesion noticed?

   c. Assessment of function: dysphagia, trismus, dyspnea, dysphonia, aspiration, and weight loss

   d. Has a mass in the neck been noted? When? The presence of metastasis of the neck is a major prognostic factor and also important for surgical planning. Often a mandibulotomy is performed in association with neck dissection.

2. Past medical history

   a. History of cancer

Important to ask about cancer affecting other anatomic sites. Carcinomas of the oral cavity and oropharynx share similar risk factors with carcinomas of lung and esophagus.

   b. Dental disease

Poor dentition increases the risk of wound infection and consequent malunion or nonunion of the mandible. Teeth in poor condition may require extraction prior to or at the time of the osteotomy. Consultation

with an oral/maxillofacial surgeon is mandatory. Poor dentition and periodontal disease are important considerations for radiation therapy, as these are major risk factors for osteoradionecrosis (ORN) of the mandible; they should be treated prior to mandibulotomy.

c. Craniofacial anomalies

d. Prior radiation therapy to the head and neck area

e. Diabetes mellitus

It is well known that diabetes is a risk factor for poor and delayed healing as well as wound infection.

3. Past surgical history

a. History of craniofacial trauma or orthognathic surgery

The presence of plates and screws in the mandible can change the osteotomy plan.

b. Facial lacerations, especially in the inferior lip, vermilion, and chin

Any preoperative scars should be well documented in order to avoid confusion with cosmetic sequelae resulting from the surgical approach

c. History of tracheostomy or tracheal surgery

The surgeon should anticipate difficulties during the tracheostomy owing to scar from previous surgery. Was it an emergent tracheostomy or a planned one? Was it a percutaneous endoscopic or classical tracheostomy?

d. History of any head and neck surgery

4. Social history

a. Tobacco and alcohol use

Both are well-established risk factors for oral cavity and oropharyngeal squamous cell carcinoma.

Physical Examination

1. Careful inspection of the head and neck is important to search for scars that might suggest previous facial trauma or surgery. Scar in the anterior neck may represent a prior tracheostomy. The skin should also be

assessed, especially in patients with a history of radiation therapy.

2. Information about the size of the tumor, location, infiltration, and cranial nerve involvement can be assessed with a thorough physical examination, including inspection and palpation.

3. In case of severe trismus, intraoral palpation is compromised and further assessment of the lesion can be done with complementary examinations.

4. Flexible transnasal laryngoscopy is a good option to evaluate extension of the tumor to the hypopharynx and larynx, especially in patients with severe trismus.

5. Palpation of the neck is important for the diagnosis of metastasis to the cervicallymph nodes.

6. Careful inspection of the teeth and gingiva is important. Swelling and hyperemia of the gingiva in the presence of tenderness to palpation are suggestive of periodontal disease. A dental consultation should be ordered accordingly.

Imaging

1. Panoramic radiography: Important in order to study the site of the osteotomy. Information regarding the angulation and distance between the tooth roots can be obtained. If a stair-step osteotomy is planned, the distance between the apices of the teeth and the border of the mandible at the osteotomy site should be measured.

2. Computed tomography (CT): Important in order to detect bone involvement. Invasion of the mandibular cortex is often best studied with CT scans.[3] The presence of bone involvement is a contraindication to the mandibulotomy approach.

3. Magnetic resonance imaging (MRI): Possible spread through the medullary space may be better identified with MRI.

Unfortunately, imaging techniques may miss subtle involvement of bone by tumor. If there is a rim of normal tissue between the tumor and bone, the mandible may be spared. There is no substitute for good clinical judgment.

Indications

1. Tumors located in the posterior aspect of the oral cavity and oropharynx may be best suited for a mandible-sparing procedure if the periosteum of the mandible is not infiltrated by the cancer.

2. The mandibulotomy approach should be considered if the transoral approach fails to provide good enough exposure to ensure clear margins for lesions involving the soft palate, tonsil, base of the tongue, and/or retromolar trigone.

3. With the advent of transoral robotic surgery (TORS), the regions that can be resected transorally with clear margins have increased. Some cancers that previously would have required an osteotomy of the mandible for approach and resection are currently being successfully treated with TORS. (See Chapter 99, Transoral Robotic Surgery.)

4. Larger and more infiltrative cancers still require a mandibulotomy approach to provide enough exposure for complete resection. Additionally, reconstruction is greatly facilitated and healing enhanced if the repair is performed with a comfortable surgical exposure.

5. Intact dentition and severe trismus interfere with the transoral approach.

6. In resecting cancers involving the base of the tongue, tonsillar fossa, soft palate, and/or retromolar trigone, the choice between using the mandibulotomy approach and TORS usually depends on the surgeon's preference and/or experience. Both techniques have been effective in the treatment of oropharyngeal cancer.[4,5]

7. If the cancer is fixed to the periosteum but does not invade the cortex, a marginal mandibulectomy is preferred. (See Chapter 181).

8. A combination of marginal mandibulectomy and anterior mandibulotomy is to be avoided because it is frequently associated with a pathologic fracture postoperatively.

9. Exposure in patients requiring a marginal mandibulectomy may be improved by using a midline lip- and chin-splitting incision and elevation of the facial flap. This technique is appropriate in patients in whom the transoral approach would be inadequate for a marginal

mandibulectomy and excision of the cancer.

10. If the mandible is grossly invaded, a segmental mandibulectomy is essential. The area of bone to be removed is determined preoperatively, and osteotomies are created during surgery to facilitate exposure and complete resection of the cancer.

Contraindications

1. If the cancer has invaded the mandible, mandibulotomy is not appropriate. Such patients require a segmental mandibulectomy to achieve clear margins.[6,7]

2. When the periosteum is involved but the cortex is intact, a marginal or rim mandibulectomy should be considered.

3. Segmental mandibulectomy is recommended if the cortex of the mandible or marrow space is involved by cancer. The space obtained after segmental mandibulectomy is used to gain access to the oral cavity and/or oropharynx for complete resection of the cancer. In this case the reconstruction is performed with free flaps; fibular free flaps are commonly used.

Preoperative Preparation

1. After the preoperative evaluation, the surgeon should be able to decide on the best surgical approach to the cancer: transoral, mandibulotomy, or mandibulectomy.

2. In some cases the preoperative plan can change, but that would be an exception. In challenging situations, any possibility of modification of the surgical plan should be anticipated by the team and explained to the patient.

3. Physical examination is critical to detect invasiveness of the cancer; when this is associated with radiologic findings, accuracy is increased.

4. The best clinical examination is performed with the patient under general anesthesia.

5. In the imaging studies, it is sometimes difficult to distinguish a

subperiosteal reaction from invasion. These studies are also important to evaluate the cervical lymphatics. MRI enhances the soft tissue interfaces, whereas CT better delineates the interface between bone and soft tissue. Neither imaging technique, however, can detect subtle degrees of bone involvement.

6. Where tumor is in close proximity to the mandible, intraoperative frozen section pathology is important for evaluation of the periosteum.

Operative Period

Anesthesia

- General anesthesia is established and—if there is no contraindication, such as severe trismus—orotracheal intubation is performed.
- Where orotracheal intubation is impossible, fiberoptic nasal intubation is performed. It is imperative for the surgeon to be in the room, helping the anesthesiologist, during the intubation of patients with oral cavity/oropharynx tumors.
- After the airway has been secured, a tracheostomy should be carried out and the endotracheal tube removed from the oral cavity, thereby improving the exposure.
- Primary awake tracheostomy is indicated in cases of severe compromise of the airway.

Positioning

The patient is placed in the supine position. A shoulder roll is used to extend the neck and improve exposure of the mandible.

Perioperative Antibiotic Prophylaxis

- A variety of single and combination antibiotics have been evaluated and recommended for prophylaxis in major head and neck surgery involving the upper aerodigestive tract. Examples include

- Clindamycin: 600 mg IV with 4 additional doses q6h
- Ampicillin/sulbactam: 1.5 g IV with 8 additional doses q6h
- Cefazolin: 2.0 g IV with 3 postoperative doses q8h

Monitoring

None necessary

Instruments and Equipment to Have Available

- Standard head and neck set
- Extra-thin reciprocating and oscillating saw
- Mandible plate system
- Screws
- High-speed drill

Key Anatomic Landmarks

Profound anatomic knowledge and understanding of the mandibular mechanics and physiology are paramount for surgeons who intend to split a normal, functional anatomic structure to approach deeper areas in the neck. The lower lip is the first structure to be divided before osteotomy of the mandible. The lip is a composite tissue formed by skin, muscle, and mucosa. The vermilion is the most apparent feature of the lip and is a modified mucosa adapted to external exposure. To prevent deformities of the lip, the surgeon should be aware of two important vermilion lines for the inferior lip reconstruction. The anterior vermilion line or mucocutaneous junction is the transition between the vermilion and the skin. The posterior vermilion line (or "wet-dry" line) marks the boundary between the vermilion and the mucosa of the lip, the innermost line of contact between the upper and lower lips when the mouth is closed. The orbicularis oris muscle forms most of the body of the lip. The inferior labial artery, a branch of the facial artery, supplies

the inferior lip. This artery crosses the lip horizontally in a plane between the muscle and the mucosa approximately at the level of the anterior vermilion line (Fig. 183.1).[8]

An important anatomic consideration for a mandibular osteotomy is the course of the inferior alveolar nerve, which enters the medial aspect of the ramus through the mandibular foramen and courses through the mandibular canal. The course of the nerve through the ramus is oblique downward and forward until it reaches the body of the mandible, where it runs horizontally and forward until it exits through the mental foramen, located at the external cortex of the mandible. A vertical line through the mental foramen usually crosses between the first and second premolars.[9] The inferior alveolar nerve provides the sensory supply to the lower teeth. After exiting the mental foramen, the nerve is called the mental nerve and gives sensory supply to the inferior lip and chin. The inferior alveolar artery is a branch of the maxillary artery and also runs through the mandibular canal until it exits as the mental artery through the mental foramen (Fig. 183.2).

FIG. 183.1 Cadaver dissection showing **A,** demarcation of the incisions in the lip and chin. **B,** Mandible split showing the normal anatomy of the floor of the mouth.

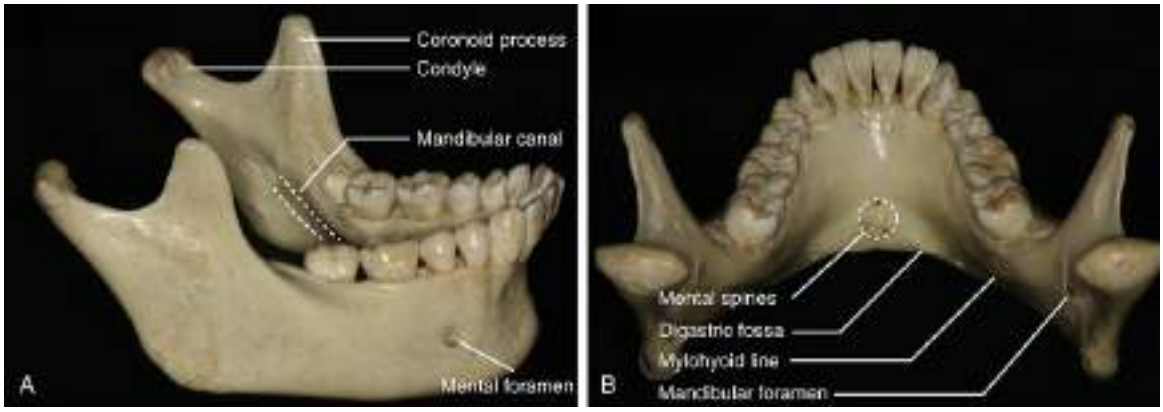

FIG. 183.2 Anatomy of the mandible. **A,** Lateral view. **B,** Posterior view.

Muscles originating in the mandible represent an additional functional consideration. The most superficial anterior belly of the digastric muscle arises from the inner lower border of the symphysis of the mandible. The mylohyoid muscle is the main muscle of the floor of the mouth and originates at the mylohyoid line, which extends from the symphysis of the mandible to the third molar. Deeper to the mylohyoid, the geniohyoid muscle arises from the inferior mental spine, also located at the inner cortex of the mandibular symphysis, and the genioglossus muscle originates at the superior mental spine. All these muscles play important roles in mastication, swallowing, and speech.

If no tooth extraction is planned for the mandibular osteotomy, the space between the teeth should also be considered. The interdental space between the lateral incisor and the canine (paramedian approach) is significantly larger than the distance between the central incisors (median approach).[10]

The ideal site for osteotomy of the mandible should combine maximum exposure of the operative site with maximum preservation of the uninvolved anatomic structures. The exact location of the osteotomy is tailored accordingly to the lesion; however, the anatomic foundations should be respected so as to minimize complications. Lateral mandibulotomy, performed through the body of the mandible, has largely been abandoned owing to the risk of injury to the inferior alveolar nerve. The mandibulotomy performed anterior to the mental foramen is preferable.

Prerequisite Skills

1. Lip reconstruction (See Chapter 25, Lip Surgery.)

2. Open reduction and internal fixation of mandible fractures (See Chapter 121, Facial Fractures.)

3. Oncologic principles for resection of cancers of the oral cavity and oropharynx (See Chapters 29 and 46, Oral Cavity and Oropharyngeal Tumors.)

Operative Risks

1. Injury to the dental roots: Preoperative panoramic radiography to study the angulation and length of the dental roots at the osteotomy site is important to avoid injury to the roots. A straight vertical osteotomy between the teeth is usually preferred.

2. Injury to the mental nerve: If exposure of the nerve is needed, careful dissection of the mental nerve and its release from the periosteal layer of the mandible are important to prevent injury of the nerve during the lateral elevation of the lip-chin flap.

3. Bleeding at the osteotomy site from branches of the inferior alveolar artery can be controlled using bone wax or cautery.

4. Bleeding from the lingual artery can be life threatening in the postoperative period; thus this artery should be dissected out and ligated.

Surgical Technique

Marking Lip and Chin Landmarks

- The cutaneous incision is marked in the midline and oriented vertically.
- The anterior vermilion line (mucocutaneous junction) and the posterior vermilion line (wet-dry line) are marked to facilitate reapproximation of the lip at the completion of the case.

- For the anterior vermilion line, the back of the tip of the surgical blade is used to mark the transition between the vermilion and the skin.
- A needle and methylene blue dye are used to temporarily tattoo the wet-dry line, and the marked line is preserved until the end of the procedure.

Lip and Chin Incisions

- The lip is split through the skin, orbicularis oris muscle, and mucosa.
- Terminal branches of the inferior labial artery are cauterized.
- The incision is extended vertically along the chin and submental area down to the level of the hyoid bone.
- An incision is made in the midline down to the periosteum of the mandible.
- Intraoral incisions are then carried laterally in the gingivobuccal sulcus, and a 5- to 8-mm cuff of vestibular mucosa is left attached to the bone to facilitate closure at the completion of the procedure.
- The periosteum is incised sharply, then carefully elevated for about 2 cm on both sides of the osteotomy site.
- The elevation of this cheek flap should be enough to provide good exposure of the anterior aspect of the mandible where the mandibulotomy will take place.
- The inferior border of the mandible is well exposed.
- The origin of the anterior belly of the digastric muscle is identified in the inferior border of the mandible.
- If possible, exposure of the mental foramen and nerve is avoided to decrease the risk of injury to the nerve and postoperative numbness. If the nerve is exposed, meticulous dissection around it should be performed using sharp instruments (surgical blade) to release the nerve from the periosteum of the mandible.

Osteotomy of the Mandible

- The mandibulotomy is performed anterior to the mental foramen.
- The osteotomies are marked in a stair-step fashion starting between the lateral incisor and canine teeth.
- The fixation plates are bent to exactly match the external surface of the mandible and screw holes are drilled to ensure proper alignment of the bone fragments during the reconstruction phase. Two plates with four holes are used, two holes for each side of the osteotomy. Monocortical screws are used for the superior plate and bicortical screws for the inferior plate close to the border of the mandible. The bicortical screws are measured with a depth gauge.
- A surgical blade is used to incise the gingiva between the lateral incisor and the canine tooth.
- The incision is carried vertically down to the periosteum.
- An extra-thin oscillating saw perpendicular to the bone is used to perform the vertical alveolar osteotomy between the teeth.
- After passing the level of the tooth roots, the osteotomy is turned laterally at a 90-degree angle.
- Measurements—using panoramic radiography and/or sagittal CT scan cuts—can be made preoperatively to check the length of the dental roots at the mandibulotomy site.
- Panoramic radiography is also helpful in assessing the angulation of the dental roots.
- The horizontal osteotomy progresses laterally for about 0.5 to 1 cm and is then curved inferiorly at a 90-degree angle toward the border of the mandible.
- After the osteotomy is completed, the mucosa of the floor of the mouth is incised and the mandible retracted laterally (Fig. 183.3A).
- Exposure of cancer in the posterior oral cavity and oropharynx is improved when the mylohyoid muscle is divided while the submandibular gland and its associated duct are retracted medially with the tongue.

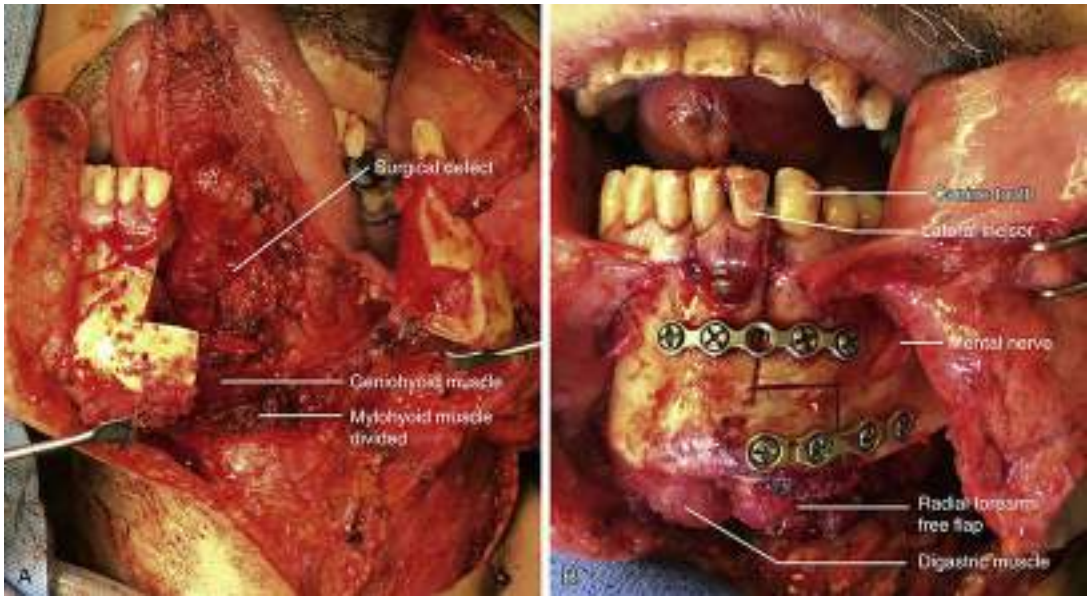

FIG. 183.3 Intraoperative photos from a patient with a T3 squamous cell carcinoma of the left floor of the mouth. A paramedian stair-step mandibulotomy was used to provide exposure, enabling approach and resection of the cancer. A left selective neck dissection, levels 1 to 4, was performed. A radial forearm free flap was used for reconstruction. **A,** Photo after resection of the tumor. The inferior aspect of the incision was extended laterally to provide good exposure for the neck dissection. **B,** After the reconstruction. The fixation plates were bent prior to the mandibulotomy to exactly match the external surface of the mandible; the screw holes were drilled to ensure proper alignment of the bone fragments during the reconstruction phase. The left surgical defect were completely filled with the radial forearm free flap. The mandible segments and teeth are well aligned.

- If exposure of the parapharyngeal space or skull base is intended, the posterior osteotomy can be extended to the anterior tonsillar pillar and soft palate.

Reconstruction (Fig. 183.3B)

- After excision of the cancer, the mandible is once again brought into anatomic position.

- Suturing of mucosa at the floor of the mouth is carried from posterior to anterior using absorbable sutures.
- The mylohyoid muscle is approximated and finally the two segments of the mandible are fixed with plate and screws using the previously drilled holes.
- The soft tissues and skin are approximated, respecting the marked vermilion lines, and the wound is drained as needed.
- In case of a large surgical defect, free flaps are used for reconstruction.

Common Errors in Technique

1. Failure to mark the anterior and posterior vermilion line

The repair is more challenging and there is a higher risk of cosmetic complications if the vermilion is approximated as marked.

2. The cuff of vestibular mucosa left attached to the bone in the gingivolabial sulcus is inadequate. A cuff of 5 to 8 mm is usually enough to facilitate closure and decrease the risk of wound dehiscence.

3. Inappropriate preosteotomy bending of the titanium plates

Time should be taken to achieve a perfect match of the plate to the surface of the mandible. A poorly bent plate can cause complications in fixation. Failure to achieve complete stabilization of the mandibulotomy site can result in painful nonunion. In the event of instability, the patient should be returned to the operating room for appropriate fixation. In patients who have been previously treated with radiation therapy, nonunion may result in osteoradionecrosis and sequestration. Bone débridement with bone grafting and fixation may be required to achieve an appropriate union.

4. Use of a thick saw blade for the osteotomy

A thick saw blade would leave a larger gap between the mandible segments, thus increasing the risk of malunion, nonunion, or delayed union.

5. Failure to complete the osteotomies exclusively with the saw blade

Undesirable fracture of the mandible may occur. This can cause problems

with fixation and ultimately lead to malunion or nonunion of the segments.

6. Besides injury to the inferior alveolar nerve, an osteotomy posterior to the mental foramen may be associated with ischemic necrosis of the mandible, especially in patients who have previously undergone radiation therapy or in those who require postoperative adjuvant radiation therapy.

7. Angled osteotomy cut of the alveolar bone

This can cause an inadvertent lesion of the dental root and loss of the tooth. Preoperative panoramic radiography to study the angulation of the dental roots at the osteotomy site is important. Usually a straight vertical osteotomy between the dental roots is preferred.

8. Failure to provide adequate soft tissue coverage and watertight closure at the completion of the procedure may result in contamination of the osteotomy by saliva, and contaminated hardware may have to be removed. If drainage persists beyond 2 months postoperatively, the surgeon may recommend a minor procedure to open the labial sulcus and remove the plate.

9. If marginal resection of the mandible is combined with mandibulotomy, a weak, devascularized segment and subsequent pathologic fracture may result.

Postoperative Period

Postoperative Management

1. The patient may return to a liquid or soft diet as soon as healing of the soft tissue has taken place.

2. Intermaxillary fixation is not necessary.

3. The patient should not attempt to chew solid food until approximately the sixth postoperative week.

4. The integrity of the healing mandibulotomy can be ascertained clinically by direct inspection and evaluation of the mandibulotomy site.

5. The decision to use postoperative radiation therapy in patients undergoing resection of malignant tumors is based on established criteria and protocol. Mandibulotomy is to be considered a surgical approach that facilitates resection of the cancer and appropriate reconstruction. When radiation therapy is deemed necessary, it may be undertaken without undue risk. Various investigators have indicated that a mandible-stabilizing plate has minimal effect on the tissue dose of radiation. The plate may minimally reduce the dose in some areas and also cause some "hot spots." Neither of these, however, significantly affects the efficacy or safety of postoperative radiation therapy, and dose adjustments are not required. Patients who have previously undergone radiation therapy may be at increased risk for postoperative osteonecrosis.

Complications

- Recent studies of mandibulotomy have shown a decrease from 30% to 10% in overall postoperative complication rates.
- The complications are related to the soft tissues of the lip, gums, and/or mandible. They can be minor, with no major repercussion in the overall oncologic treatment, but complications can also be severe enough to delay radiation therapy and cause impairment of function.
- Surgeons must recognize any complication promptly and address it in order to prevent any significant delay in treatment.
- Cosmetic deformities and functional issues related to the lip include notching of the lower lip, stenosis of the labial sulcus, fistula, loss of the contour of the chin pad, lip numbness, decreased lip mobility, and so on.
- Dental injuries can culminate in the loss of one or both teeth. Fortunately such injuries are relatively uncommon.
- More severe complications are related to failure of fixation and include malunion, nonunion, malocclusion, and delayed union. With the evolution of the fixation and surgical techniques, complications related to the failure of fixation have decreased to less than 3%.

Alternative Management Plan

1. Transoral robotic surgery, or TORS

If the cancer can be completely resected with clear margins via a transoral approach, TORS would be preferable to a mandibular osteotomy. Not having to split the lip and mandible avoids the fixation and cosmetic complications that can occur with the latter approach.

2. Advanced cancer

In cases of inoperable cancer, surgery may be avoided and the treatment based on radiation and chemotherapy.

Discussion

Evidence-Based Medicine Question

What is the best type of osteotomy for the mandible?

In an edentulous patient, the exact site of the osteotomy is not critical. In patients with intact dentition, a tooth can be extracted and the osteotomy performed through the middle of the tooth socket. This preserves the alveolar bone forming the sockets of the adjacent teeth. Currently there is a tendency to avoid dental extraction despite the risk of injury to both teeth during the osteotomy. It is suggested that preservation of the teeth improves the stability of the dental occlusion in the postoperative period.[2] In addition, difficulties with healing of the gingiva over the extracted socket area may result in bone exposure, increasing the risk of complications related to fixation (e.g., malunion or nonunion, osteomyelitis, or osteoradionecrosis). Several studies have shown that dental complications are relatively uncommon following mandibulotomy without tooth extraction. Extra-thin oscillating and reciprocating saws (0.5 mm) are used to minimize the bone gap and decrease the risk of dental injuries. Considering the interdental space, the paramedian osteotomy performed between the lateral incisor and the canine tooth is preferred to the median osteotomy, which is performed in the midline immediately between the central incisors.[10] The stair-step osteotomy has shown considerable advantages, greater resistance to

vertical loads, and less bone gap movement compared with the straight vertical mandibulotomy.

Thin osteotomes can be used to finish the osteotomy in the inner cortex of the mandible. Some studies suggest that bone contact and healing will be enhanced if the inner cortex is fractured instead of cut with the saw. The stair-step osteotomy also avoids disrupting the origin of the geniohyoid and genioglossus muscles in the midline. There is concern that trauma to those muscles could increase the postoperative dead space and thus interfere with the swallowing function after surgery.

Editorial Comment

The midline mandibulotomy provides a wide exposure of the oropharynx and infratemporal fossa while allowing control of the great vessels of the neck and pertinent cranial nerves. However, indications for midline mandibulotomy have diminished owing in great part to the advent of TORS and other techniques that can provide exposure of the infratemporal fossa. Nevertheless, the technique of mandibulotomy remains useful and should be part of the armamentarium of every head and neck surgeon.

Review Questions

1. A patient with a T3 carcinoma of the oropharynx presents with severe trismus but no invasion of the periosteum of the mandible. Which is the most suitable surgical approach?

   a. Transoral robotic surgery

   b. **Mandibulotomy approach**

   c. Marginal mandibulectomy

   d. Segmental mandibulectomy

2. The mandibulotomy approach is performed between the

   a. Central incisors

b. Central and lateral incisors

c. **Lateral incisor and canine tooth**

d. Canine and first premolar tooth

3. Mark the true sentence about the straight vertical and stair-step mandible osteotomies:

a. The vertical osteotomy is preferred because it offers better support for the vertical loads.

b. **The stair-step osteotomy is preferred because it offers better support for the vertical loads.**

c. The vertical osteotomy is preferred because it offers better support anteroposterior forces.

d. The stair-step osteotomy is preferred because it offers better support of anteroposterior forces.

4. Why can the injury to the mandibular canal cause necrosis of the mandible?

a. Neurogenic atrophy due to injury of the inferior alveolar nerve

b. Neurogenic atrophy due to injury of the mental nerve

c. Chronic trauma due to numbness from injury of the inferior alveolar nerve

d. Ischemia due to injury of the mental artery

e. **Ischemia due to injury of the inferior alveolar artery**

Nasal Fracture

Kenneth D. Rodriguez

Introduction

- The prominent, central position of the nose on the face makes it highly vulnerable to facial trauma.
- The nasal bones are the most commonly fractured facial bone and the third most common fracture in the human body.[1]
- The most common cause of a nasal fracture is blunt trauma.
- When not promptly identified and treated, resultant nasal deformity and/or nasal airway obstruction may persist.
- Most fractures occur between the thicker proximal segment of the nasal bone and the thinner distal segment and generally result in depression at the point of impact.
- Depending on the severity of the trauma there can be lateral displacement of the contralateral nasal bone, or the fracture may be comminuted (Fig. 184.1).

Key Operative Learning Points

- Nasal fractures should be reduced within 2 weeks of the original injury.
- Not all nasal fractures need to be repaired.
- Careful evaluation of the nasal septum should be performed during the evaluation of a nasal fracture.
- A closed reduction of a nasal fracture can be done under local or general anesthesia (GA).

- The reduction of complex nasal fractures may require an open approach.

Preoperative Period

History

- Key points include time frame, mechanism of injury, and consideration of whether or not additional injuries may be present.
- It can take several days for the edema associated with nasal trauma to subside. If immediate evaluation is not possible (within hours of the injury), an accurate assessment of cosmetic change may not be possible until the edema subsides in several days.
- Inquire about a history of prior facial trauma and facial fractures, nasal deformity, or nasal airway obstruction.
  - Pre-existing conditions that are not the result of acute injury cannot be repaired using closed techniques.
  - Preinjury photographs can assist in determining a particular area of concern or determining a baseline, but often the quality is not adequate to assess for subtle changes.
  - Patients may not have a clear idea of what their baseline appearance was. Subtle changes to their nose can be perceived as changes when in fact they were present prior to the injury.

Physical Examination

- Externally, the nose should be viewed in all orientations and gentle palpation can identify areas of step-off. However, in the acute phase, soft tissue edema may obscure the fracture site.

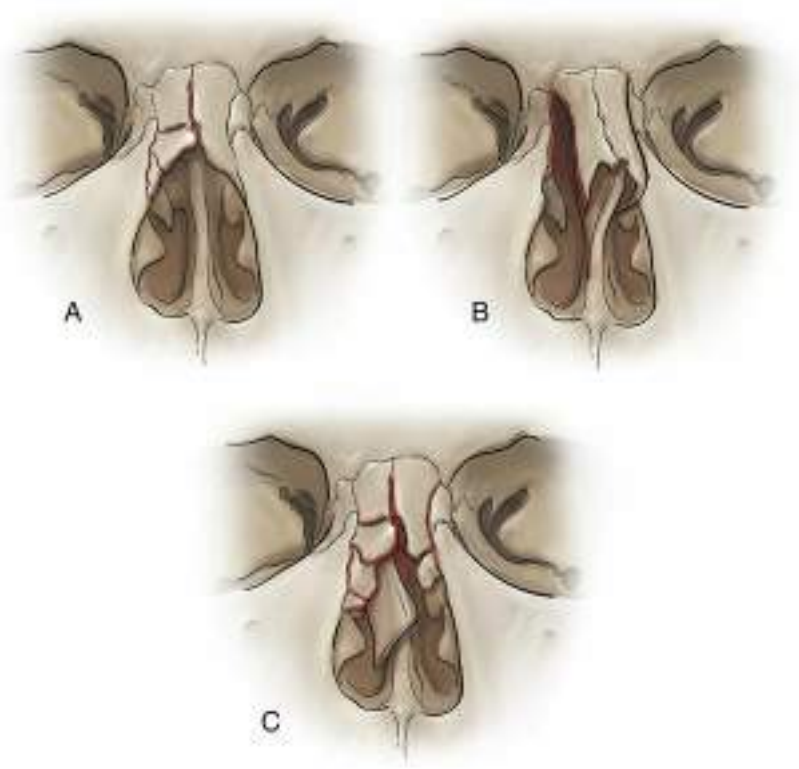

FIG. 184.1 Nasal fracture patterns. **A,** Isolated right nondisplaced nasal bone fracture. **B,** Right and left displaced nasal bone fracture with sepal fracture. **C,** Comminuted fracture of nasal bones with septal fracture.

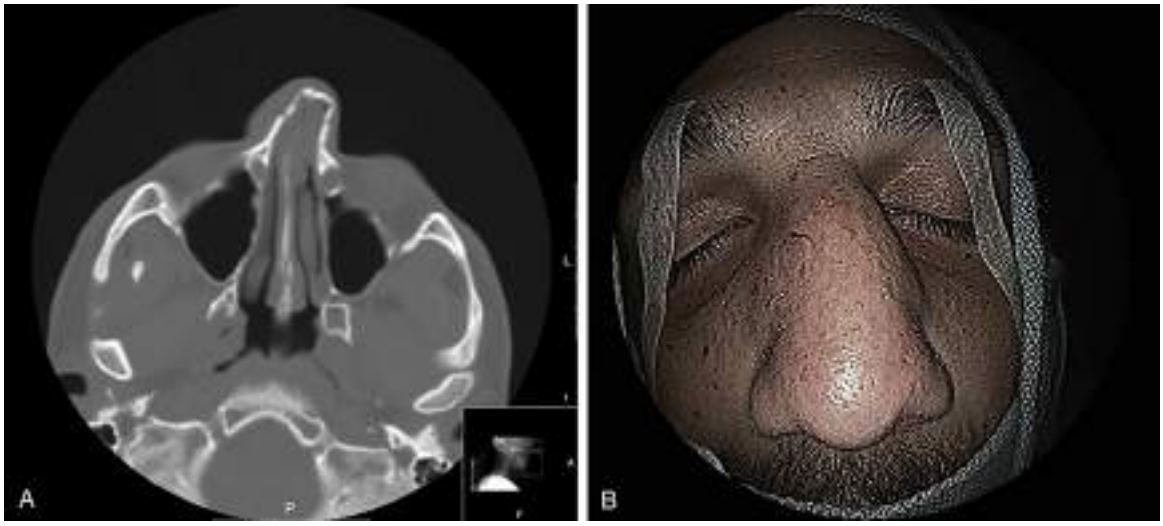

FIG. 184.2 **A,** Axial noncontrast computed tomography (CT) of a patient struck on the right side of his nose with resultant depression of the right nasal bone and lateral

shift of the left nasal bone. **B,** Intraoperative photograph of same patient depicted in the CT demonstrating depression of the right nasal bone and resultant shift to the left side.

- Patient feedback and explanation of the site of injury can aid with the assessment.
- The septum should be evaluated for fracture or hematoma.
  - Septal hematomas should be addressed immediately if present.
- Nasal endoscopy can be used to allow for complete evaluation of the septum.[2]
  - Unrecognized septal trauma is a common indication for need of revision surgery.
- Damage to the upper/lower lateral cartilages are often overlooked and should be carefully examined for.

Imaging

- Nasal fracture is a clinical diagnosis, and imaging is not required to confirm a fracture, although patients often present with imaging obtained through the emergency department (ER) (Fig. 184.2).[3]
- Generally speaking, nasal fracture does not occur without epistaxis. If other facial fractures are suspected, noncontrast high-resolution computed tomography (CT) scan through the facial bones with coronal and sagittal reconstructions is indicated (Fig. 184.3).

Indications

- If the patient is comfortable with his or her external appearance and nasal breathing, the patient can be observed.
- Reduction of nasal fractures can be performed in any age group.
  - Closed reduction:
    - Unilateral or bilateral nasal bone fracture(s) without significant dislocation

- Open reduction:
  - Extensive fractures of the nasal bones with major dislocation with or without fracture of the caudal septum
  - Open septal fracture or persistent deviation following prior closed reduction[4]

Contraindications

- Isolated nasal fracture repair in the context of a severe nasoethmoid complex fracture. This can result in cerebrospinal fluid leak or worsen a pre-existing leak.[5] Concurrent repair of the nasal fracture as part of the larger midface repair is indicated.

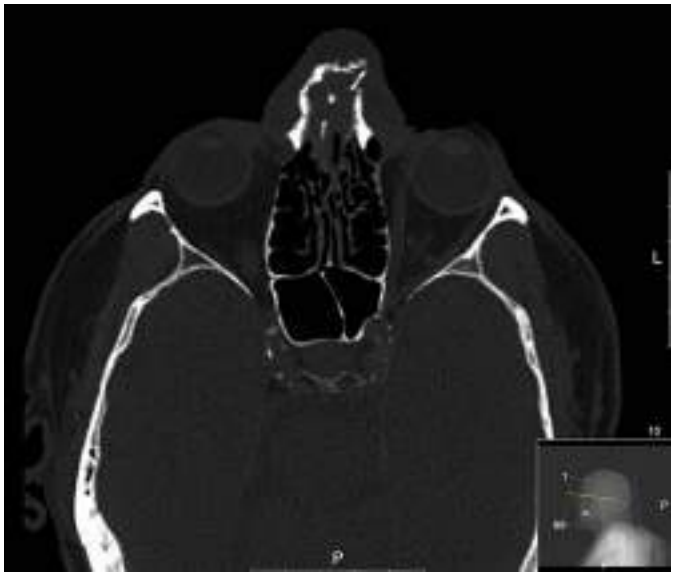

FIG. 184.3 Axial noncontrast computed tomography of a patient who fell striking his nose in direct fashion with the ground resulting in severe comminuted bilateral nasal bone fractures. This imaging was obtained secondary to concern for additional orbital fractures. P, posterior. L, left.

Preoperative Preparation

- There is no specific preoperative preparation of the patient for nasal

reduction. Patients may wish to place ice on their face to further decrease edema.

- If GA is indicated, standard medical risk assessment should be performed.
- In children, it is suggested that the reduction of the fracture be performed within 7 to 10 days to provide for more rapid healing.[6]
- In adults, the general guideline is within 10 to 14 days.[7]

Operative Period

Anesthesia

- Can be performed under local or GA
- There are data to support the use of local anesthesia for closed nasal reduction, but consideration must be given to patient tolerance, risk of bleeding, and access to proper equipment if the procedure is performed outside of the operating room setting.
  - Local:
    - Topical anesthesia (4% lidocaine) along with a vasoconstrictive agent (oxymetazoline or phenylephrine) is applied to the nasal mucosa on pledgets and left in place for at least 10 to 15 minutes.
    - The position of the pledgets should include the undersurface of the nasal bones, lateral nasal wall in the region of the sphenopalatine artery foramen, floor of the nose, and mid septum.
    - One percent lidocaine with 1:100,000 epinephrine is then injected.
      - Injections should be performed in the region of the nasal dorsum (rhinion to the supratip) for the nasociliary nerve distribution from V1, around each infraorbital foramen (can be performed intra or extra nasal) for the infraorbital nerves, and at the base of the columella and nasal floor (nasopalatine nerve).
      - External injections, when possible, are often better tolerated.
  - General:

- Following securing of the airway, a topical decongestant as listed above can be used on pledgets to decongest the nasal mucosa. Four percent cocaine is also a reasonable choice if available but is more expensive.
- Injections can be used to decrease blood loss but are not critical in this setting for closed reductions and can delay the procedure while waiting for the vasoconstrictive effect.

Positioning

- Supine
- The patient should be draped with the nose widely exposed. The face is generally not prepped with betadine for closed reductions.
- It is critical not to distort the facial skin around the nose.

Perioperative Antibiotic Prophylaxis

- Need for perioperative or postoperative antibiotics is unclear for closed nasal reduction
- Recent data on septoplasty with packing and spontaneous epistaxis that requires packing indicate that the routine use of antibiotics (perioperative or post-packing) is not necessary.[8,9]

Monitoring

- No special monitoring is necessary.

Instruments and Equipment to Have Available

- Walsham forceps
- Asch forceps
- Langenbeck elevator

- Back of a knife handle (can be wrapped in gauze)
- Boies elevator ("butter knife")
- Suction
- Topical/injectable products as listed in anesthesia section

Key Anatomic Landmarks

- The nasal bones are paired projections that articulate with the frontal bone superiorly, lacrimal bone laterally, and ascending process of the maxilla inferiorly.
- The nasal bones become thinner and wider in the caudal direction.
- There is significant variability to the size of the nasal bones between men and women, as well as among different races.
- There are also differences in the thickness of the skin and subcutaneous tissue overlying the nasal bones from individual to individual that can serve to mask subtle fractures.
- The caudal aspect of the septum articulates with the maxillary crest. The fibrous connections at that level as well as the intrinsic flexibility of the septal cartilage allow mobility, decreasing the risk of septal fracture.

Prerequisite Skills

- Closed nasal reduction represents a basic skill for the resident in training.
- Open techniques require expertise in rhinoplasty and/or septoplasty and represent a far more advanced skill set that in some cases requires fellowship-level training.

Surgical Technique

- Closed reduction:
  - Palpation of the nasal bones should be performed to determine

mobility and to feel for step-offs with the midface articulations.

- Endonasal examination should be performed if there are concerns for septal injury that could not be fully evaluated in the clinical setting.
- It is good practice to externally measure the distance between the superior aspect of the nasal bones and the external nasal valve and use that distance as the deepest point of entry into the nose with any instruments.
- It is often helpful to address the side of most significant deformity first.
- Using controlled pressure, the fracture fragments can be reduced into improved alignment.
  - Palpation on the bones externally while they are being reduced internally can allow for more precise placement as step-offs can be corrected with visual and tactile feedback (Video 184.1).
    - There is often resultant epistaxis that can be controlled with additional topical decongestant.
- If there is a concurrent septal fracture, closed reduction can be attempted following the same basic technique as with a closed nasal bone fracture. This can be performed endoscopically or via a speculum.
- In patients with a comminuted nasal bone fracture, there can be need for internal splinting to keep the fragments in place.
  - Both absorbable and nonabsorbable products can be used for this depending on the patient need.
  - External splints are often employed and include Denver splints or thermoplastic splints. Care must be taken when applying any external splint onto a freshly reduced nasal bone as slight pressure can cause loss of reduction.
- Open reduction:
- Septal fractures can be accessed through a hemitransfixion incision, and the nasal bones can be approached via rhinoplasty techniques (both techniques covered elsewhere in this textbook; see Chapter 95).
- Other approaches include the use of a pre-existing laceration, an

incision across the glabellar region (open sky incision), or lateral rhinotomy (to access a unilateral fracture).

- Unfortunately, these incisions create prominent scars as a trade-off for simple access and excellent exposure.
- A coronal incision can be used without the need of facial incisions to access injuries to the frontal/nasal bone junction. Plating, if indicated by the fracture pattern, can be performed via these open approaches.

- There are multiple current procedural terminology (CPT) codes involving nasal fracture reduction (Table 184.1).

Common Errors in Technique

- It may take significant pressure to reduce a fracture, and it is critical to stay as steady as possible during reduction as slipping off the base of the nasal bones into the soft tissue at that level can cause significant trauma.
- Care should be taken deep to the origin of the nasal bones off the frontal bone as fractures there are uncommon and mucosal trauma caused by pressure underneath nonmobile bone can easily lacerate and cause bleeding.
- It is often helpful to keep an elevator internally holding the reduced fragments in alignment while external pressure is placed to secure the external dressing to prevent depression of fragments.

Postoperative Period

Postoperative Management

- Follow-up in 1 week allows for resolution of perioperative swelling.
- External and internal nasal packing are generally removed at the initial visit, although packing can be left for longer if indicated.
- Activities that predispose to nasal trauma should be avoided for at least 1 month.

- Athletes may benefit from the use of a face mask.

Complications

- Early
  - Septal hematoma, epistaxis, infection, or excessive facial edema or bruising
  - Cerebrospinal fluid (CSF) rhinorrhea may result from disruption of the skull base or worsening of skull base/posterior table fractures during reduction.
- Late
  - Subperichondrial fibrosis from untreated septal hematoma, intranasal scarring, persistent nasal breathing issues, or unfavorable cosmetic appearance

Alternative Management Plan

- If the reduction was challenging, and complete symmetry was not attained, it is often in the best interest of the patient to allow the nasal bones to completely heal and consider rhinoplasty at a later time.
  - Complete healing can take months, and subtle changes can improve or worsen over this time.
  - Patients may be resistant to further operations despite persistent symptoms following closed nasal reduction.
- Outcomes from nasal fracture reduction are variable. Several series of closed nasal fracture results were reviewed and demonstrated an average of 79% patient satisfaction and 37% surgeon satisfaction.[7]

TABLE 184.1

Current Procedural Terminology

21310	Closed treatment of nasal bone fracture without manipulation
21315	Closed treatment of nasal bone fracture without stabilization
21320	Closed treatment of nasal bone fracture with stabilization
21325	Open treatment of nasal bone fracture; uncomplicated
21330	Open treatment of nasal bone fracture; complicated, with internal or external skeletal fixation
21335	Open treatment of nasal bone fracture; with concomitant open treatment of fractured septum

- Some authors advocate initial septorhinoplasty as the best option, and data would suggest less patient dissatisfaction with that approach, but clearly this is not indicated for all individuals.[2] We as surgeons must understand the scope of procedures available to us and appreciate our own limitations. Individually evaluating patients and tailoring procedures to meet their specific needs and expectations will maximize outcomes.

Discussion

Evidence-Based Medicine Question

What is the preferred anesthesia technique to perform closed reduction of a nasal fracture in regard to patient satisfaction with their postoperative appearance?

a. Intranasal pledgets without local injected anesthesia

b. Intranasal pledgets with local injected anesthesia

c. Intranasal pledgets with local injected anesthesia with oral benzodiazepine

d. **General anesthesia**

A meta-analysis of local versus GA for management of nasal bone fractures supported the use of a general anesthetic. There was a statistically significant difference in favor of patients treated under GA with regard to improvement in the appearance of the nose after treatment (P = .006).[10]

Editorial Comments

Nasal fractures are extremely common; nonetheless, the difficulty of their management is grossly underestimated. Although the mechanics of a closed reduction are relatively simple, it requires extreme attention to detail and a thorough assessment of every component of the external and internal nose. The septum and upper lateral cartilages are often undervalued during the assessment, and ignoring their luxation often results in suboptimal outcomes. The idea that a nasal fracture is easily

corrected under local anesthesia (and sometimes attempted under topical) in the clinic or ER setting should be dispelled except for highly selected patients or when limited resources dictate the circumstances. The surgeon should be skilled in both closed and open techniques and best apply them according to the severity of the fracture. A universally accepted algorithm is yet to be defined.

Review Questions

1. Imaging is required under what circumstances during evaluation of a nasal fracture?

   a. No external changes or breathing issues

   b. Nasal breathing issues without external change

   c. Nasal breathing issues with external change

   d. **None of the above**

2. If closed nasal reduction under local anesthesia was planned, which of the following nerves would not need to be anesthetized?

   a. Nasopalatine

   b. **Supraorbital nerve**

   c. Infraorbital

   d. Nasociliary

3. In adults, nasal fractures are best repaired in what time frame?

   a. <1 day

   b. <2 weeks

   c. <3 weeks

   d. All of the above

   e. **A and B**

Fractures of the Mandible

William Chung, and Gaurav A. Shah

Introduction

There are numerous causes of mandibular fractures including assault, motor vehicle accidents, projectile missiles, and pathologic fractures. Multiple studies have shown motor vehicle accidents and interpersonal assaults as the leading causes for mandibular fractures.[1–3] When a mandible fracture is suspected, careful evaluation of other injuries must be ruled out. A recent study reported a 64.8% association with life-threatening injury such as closed head injury, skull fracture, and body cavity trauma.[1] In the setting of isolated fractures to the maxillofacial skeleton, cervical spine injury ranged from 4.9% to 8.0%.[4]

The mechanism of trauma can provide valuable information to the clinician on the potential injury patterns and locations to the mandible (Fig. 185.1). An anterior impact typically causes a symphyseal fracture with or without condylar involvement, whereas lateral impacts typically result in body or angle fractures.[1] Interpersonal assaults have a high predilection for mandibular angle fractures.[1] The majority of mandibular fractures occur in males in the 25- to 34-year-old age group.[1] Nearly 25% of mandible fractures in women are due to falls, and the practitioner should be wary of and evaluate for non-accidental trauma.[1]

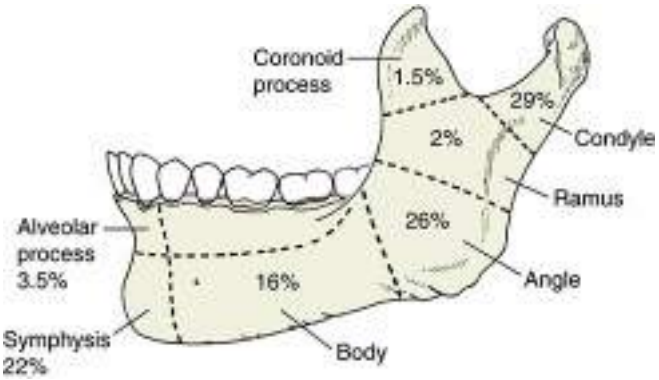

FIG. 185.1 Anatomic classification and percent distribution of mandibular fractures in dentate adult patient.

The classification of fractures by location can be further described by the fracture pattern as open (compound), closed (simple), comminuted, green stick, complex, and/or multiple. Open/compound fractures communicate through the skin or mucosa with the external environment. Comminuted fractures include multiple segments of bone that are crushed or splintered. Complex fractures are either an open or closed fracture that are associated with significant soft tissue injury.

Key Operative Learning Points

- Understanding the basic principles of dental occlusion is necessary to ensure optimal fracture repair.
- Displacement of fracture segments is defined as either favorable (stable) or unfavorable (unstable) given the biomechanics exerted on the fragments by muscle pull (Fig. 185.2).
- Understanding the interaction of these forces is essential during reduction of fractures as excessive interfragmentary motion during fracture healing interrupts proper bone formation at the histologic level.
- Temporary reduction of significantly displaced fracture segments that include the dentition can be achieved by placement of a bridal wire, which assists in control of flail segment(s) or hemorrhage (Fig. 185.3).

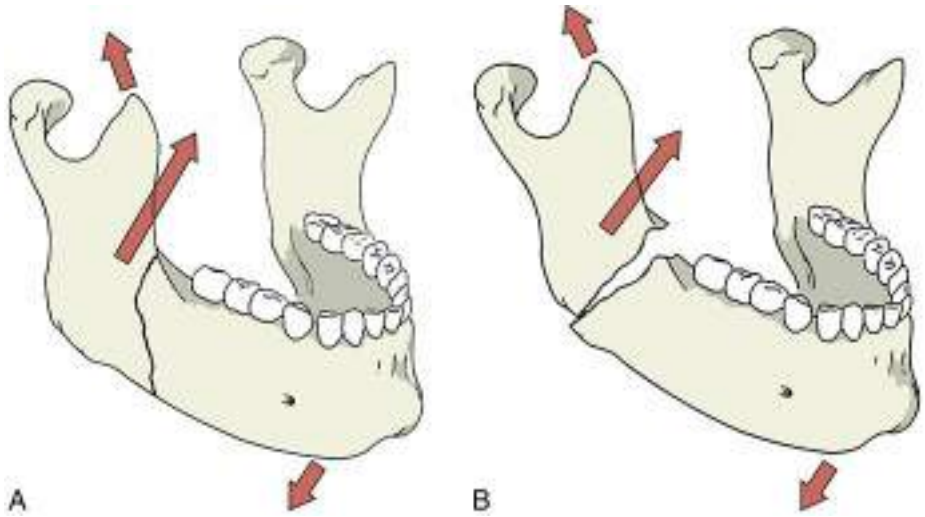

FIG. 185.2 **A,** Favorable mandibular angle fracture. With the muscular pull of the temporalis and masseteric and the minor influence of the digastrics and suprahyoid musculature, there is a tendency toward further fracture reduction or stabilization. **B,** Unfavorable mandibular angle fracture. With these same muscular forces, there is a tendency toward gapping at the superior border and rotation of the proximal or angle segment upward. This bony step can also be palpated intraorally.

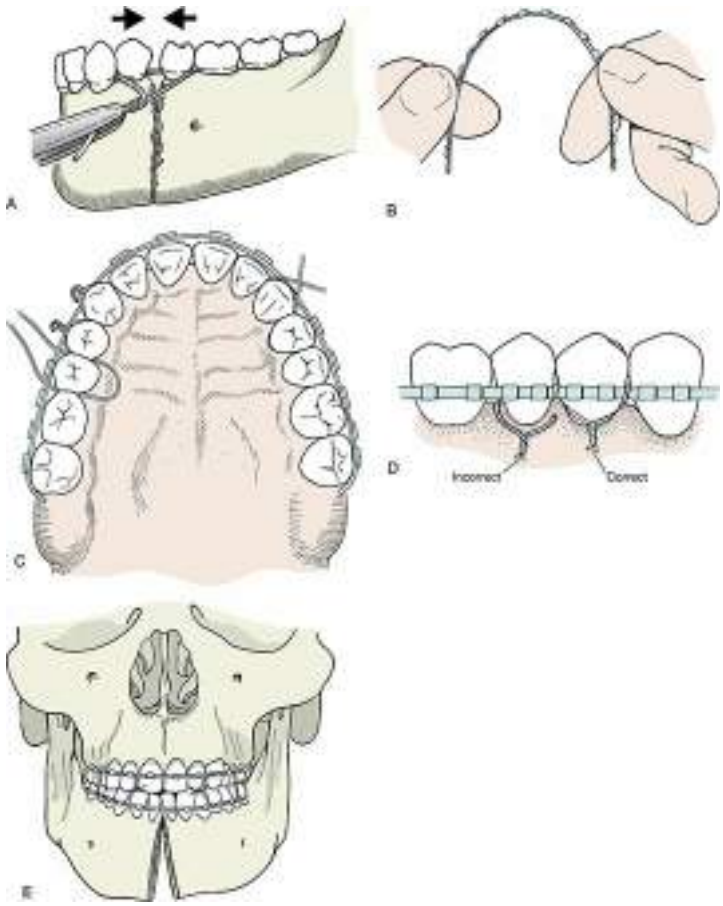

FIG. 185.3 **A,** A bridal wire is passed around the first and second bicuspids in a left mandibular body fracture to aid in reduction and stabilization. This is performed before fixation of the arch bar and allows the arch bar to be secured to the mandible in an already reduced position. **B,** Arch bar is cut and bent to appropriate length and shape of dentition for fixation. **C,** Arch bar is fixed to posterior teeth with 24-gauge circumdental wires and to anterior teeth with 26-gauge circumdental wires. The wires pass above the bar on the one side of the tooth and below the bar on the other side then twisted in a clockwise fashion. **D,** Wires should pass between tooth and gingival papilla to avoid strangulation of these structures. **E,** Overtightening the maxillomandibular fixation wires in the presence of a symphysis fracture will cause the inferior border of the fracture to splay apart and the occlusion will lean lingually, preventing adequate fracture reduction.

- Intubation is made challenging in cases of flail mandible fractures.
- A prospective cohort study found that inferior alveolar nerve injury was four times more likely in posterior mandibular fractures (56.2%) than in anterior mandibular fractures.[5]
- A unilateral subcondylar fracture often presents with a contralateral open bite with deviation of the mandible to the ipsilateral side upon opening. Bilateral condylar fractures may present as an anterior open bite with premature contact of any posterior teeth.[1]
- In contrast to bicortical fractures, greenstick fractures of the mandible are often difficult to identify by physical exam ination alone. Careful history with focus on mechanism of injury and force of impact are critical for further workup and evaluation in those with a high suspicion for mandibular trauma.
- In mandibular body fractures, masticatory forces create strain or tension above the mandibular canal. Below the canal, compression forces along the inferior border promote bony contact under an occlusal load. Fixation is necessary to neutralize this force.[6]
- Angle fractures are shown to have the highest rate of complication compared with other mandibular fractures partly due to its proximity to the inferior alveolar nerve and masseteric and facial vessels.[7]
- Regardless if a transoral or extraoral approach is used, rigid internal fixation for an angle fracture is necessary to neutralize the tension, compression, and torsional forces encountered at the angle due to the opposing forces of mandibular elevators and depressors in the region.[8]
- A third molar in the line of fracture may be left in place if it does not interfere with reduction, while its removal at time of repair has been shown to increase the risk of infection.[8]
- The marginal mandibular nerve and cervical nerve are 2 cm below the inferior border of the mandible 80% of the time.[9]
- Condylar fractures account for 11% to 16% of all facial fractures and nearly a third of mandibular fractures.[10] Management of these fractures remains highly controversial; many surgeons favor nonsurgical treatment because it results in satisfactory function and esthetics.

- Al-Moraissi and Ellis determined open reduction and rigid internal fixation (ORIF) for subcondylar fractures provided superior functional clinical outcomes compared to maxillomandibular fixation (MMF) when considering maximal incisal opening, laterotrusive movement, protrusive movement, malocclusion, pain, and chin deviation.
- Absolute indications for ORIF of condyle fractures: (1) displacement into the middle cranial fossa; (2) difficulty establishing dental occlusion with closed treatment alone; (3) lateral extracapsular displacement of the condyle; (4) presence of a foreign body; and (5) open fracture with potential for fibrosis[3]
- Coronoid fractures occur in less than 2% of all mandible fractures and are typically due to lateral impact at the level of the zygomatic-maxillary complex. Treatment for coronoid fracture is typically unnecessary.
- Some have recommended that open treatment of atrophic mandible fractures be avoided due to the risk of compromised blood supply over the fracture.
- Atrophic fractures can be classified by the following: Class I—15 to 20 mm of bone height; Class II—10 to 15 mm; and Class III—<10 mm of bone height.
- More rigid fixation is necessary in mandibles with <15 mm of bone height. Fixation must be rigid enough to allow for load-bearing and ideally load-sharing under function.
- When multiple mandible fractures exist, rigid fixation on at least one side is necessary to decrease the chance of a complication.

Preoperative Period

History

1. History of present illness
    a. Determine patient's level of consciousness and ability to communicate; may need to rely on family or friend(s) in the obtunded patient.

b. Inquire about pretrauma status of patient's dentition/occlusion.

c. Determine level of pain and presence of trismus.

d. Investigate mechanism of trauma.

2. Past medical history

a. Cardiac disease

b. Pulmonary disease

c. Endocrine disorders (e.g., diabetes and adrenal disorders)

d. Coagulopathies

e. Immune disorders

3. Past surgical history

a. Previous facial/mandibular fracture repair; consider use of previous incisions

b. Be aware of extent of scar tissue from previous surgical procedures.

4. Medications

a. Anticoagulants, antiplatelet agents

b. Antihypertensive medications

c. Diabetic medications

d. Immune suppression medications

e. Antibiotics

5. Allergies

6. Social history

a. Tobacco history

b. Alcohol use/abuse

c. Illicit drug use/abuse

Physical Examination

The evaluation of mandibular trauma begins with a systematic assessment and evaluation of the patient during the primary and

secondary trauma surveys. Protection of the airway and cervical spine *must* be considered during every exam for mandibular trauma. Bilateral mandibular body or parasymphyseal fractures can cause a flail segment that is pulled back by the genial musculature resulting in airway restriction, making a typical chin lift or jaw thrust maneuver complicated.[4]

Extraoral

1. Symmetry and height of lower third of face
2. Edema and ecchymosis overlying mandible or neck
3. Palpable step-offs at inferior border of mandible
4. Jaw opening pattern and maximum interincisal opening
5. Crepitus in anterior/lateral neck.
6. Lacerations (adjacent to critical structures—nerves, vessels) over mandible or neck
7. Soft tissue loss/avulsions
8. Foreign bodies, tooth fragments within soft tissue wounds
9. Altered sensation along distribution of trigeminal nerve (third division)

Intraoral

1. Integrity of mucosa
2. Edema or ecchymosis in vestibules/floor of mouth
3. Lacerations of mucosa, gingiva, or tongue
4. Missing/fractured teeth, particularly within adjacent lacerations
5. Occlusion
6. Range of motion of the mandible
7. Altered sensation of trigeminal nerve (third division)

Imaging

Imaging is optimally obtained in at least two planes as single plane images may either prohibit a clinician from accurately identifying every fracture or underestimate the technical difficulty required for proper fracture reduction.[8] Plain film radiography combinations that are used for mandibular fracture evaluation include a panoramic radiograph with a posterior-anterior radiograph of the mandible. A horizontally unfavorable fracture can be visualized on a panoramic radiograph, while a vertically unfavorable fracture can be determined on an anteroposterior radiograph.

1. Panorex—most diagnostic plain film image to diagnose mandibular fractures. Overlap of cervical spine may obstruct identification of posterior fractures.

2. PA skull radiograph—Evaluate symphyseal fractures.

3. Open mouth Townes—Evaluate subcondylar fractures.

4. Lateral oblique(s)—are useful for identifying mandibular body and angle fractures

5. Computed tomography (CT) scan—Multiple studies determined that a CT was 100% sensitive in diagnosing mandibular fractures compared to 86% sensitivity noted by panoramic radiograph.[3]

   a. 3-dimensional images helpful in cases of severely comminuted mandible fractures or in conjunction with pan-facial fractures

Indications

1. Restore facial form and function.

2. Restore occlusion.

3. Restore mandibular range of motion.

4. Reduce fracture(s) to stop hemorrhage.

Contraindications

1. Neurologically unstable
2. Hemodynamically unstable
3. Acute infection

Preoperative Preparation

Surgical intervention for mandibular fractures should not be delayed to minimize the risk of postoperative infection, improve patient comfort, and facilitate oral nutrition. However, urgent surgical intervention may be delayed due to severe neurologic injuries, hemodynamic instability, or pre-existing unstable comorbidities. One study found no increase in complication rates when definitive repair was performed within three days compared with those after 3 days.[3]

When teeth are present on only one side of the fracture, an open technique with rigid fixation is preferred. The requirement for either load-bearing or load-sharing fixation is dependent on the whether or not enough bone stock exists that can bear the load of mastication across the fracture site. Load-sharing fixation requires that the fragments transfer forces across the area, which can be accomplished with mini-plates, compression plates, or lag screws. Load-bearing fixation is a plate that must bear all forces and is used in area of severe comminution or continuity defects.

Occlusion

- Multiple formal classification systems exist to describe occlusal relationships. The Angle system is most widely used.
- In a normal Class I pattern, the mesiobuccal cusp of the maxillary first molar is aligned with the buccal groove of the mandibular first molar.
- In a Class II relationship, the buccal groove of the mandibular first molar is distal to the mesiobuccal cusp of the maxillary first molar when in occlusion.
- In a Class III pattern, the buccal groove of the mandibular first molar is mesial to the mesiobuccal cusp of the maxillary first molar when in occlusion.

- Patients with a pre-existing malocclusion may have molar relationships that are normal in the anterior-posterior plane as described by the Angle system. However, discrepancies in the transverse plane may exist such as dental crowding, misalignment, or cross-bites.
- Obtaining a photograph of the patient smiling before the injury assists the clinician in determining an optimal dental-occlusal relationship.

Operative Period

Anesthesia

1. Nasal endotracheal intubation is required to allow for intraoperative MMF, unless a concomitant severe nasal fracture is present.

2. Tracheostomy may be required if nasal endotracheal intubation is not possible due to injury.

Positioning

1. Supine

2. Prepare and drape lower third of the face and neck in standard fashion. Prepare oral cavity with chlorhexidine rinse *or* clindamycin-infused normal saline.

Perioperative Antibiotic Prophylaxis

Preoperative antibiotic administration is imperative.[8] This practice is supported by a landmark prospective study from the *New England Journal of Medicine* in 1992 that determined prophylactic antibiotic use, specifically 2 hours before surgery, for clean-contaminated procedures reduced the risk of postoperative wound infection.

1. Choices:

   a. Cefazolin

   b. Ampicillin/sulbactam

   c. Clindamycin is preferred for penicillin-allergic patients.

Monitoring

1. Routine

2. Request the anesthesiologist to HOLD any paralytic agents after induction/intubation to facilitate testing of the facial nerve, when appropriate.

Instruments and Equipment to Have Available

1. Hardware for MMF (surgeon's preference and dependent on status of existing dentition and occlusion)

2. Fixation hardware, when necessary (surgeon's preference)

3. Wire driver and cutter

4. Surgical retractors

5. Hemostats

6. Periosteal elevators

7. Curettes

8. Bone clamps

9. Nerve stimulator

10. Sutures

Key Anatomic Landmarks

1. Dental root(s)

2. Mental nerve and foramen

3. Inferior alveolar nerve and canal

4. Superficial layer of the deep cervical fascia—facilitate location of the marginal mandibular nerve

5. Facial artery and vein

6. Tail of parotid gland

7. Attachment site of genioglossus muscle

8. Platysma muscle layer, especially in submental region. Re-suspension critical to avoid chin ptosis

Prerequisite Skills

- Application of Erich arch bars/wires or bone fixation screws for MMF techniques
- Surgical dissection of the mental nerve/foramen
- Surgical dissection of the submandibular region

Surgical Technique

The goals of reconstructing the mandible are to reestablish the lower third of the face in all three dimensions to ensure adequate form and function.

Dentoalveolar Fractures

- Avulsion of deciduous teeth should not be reimplanted as it may cause further damage to permanent tooth.
- Adult teeth should be reimplanted within 1 hour for most favorable prognosis.
- Avoid desiccation of tooth; store tooth in saliva, saline, or Hank's Balanced Salt Solution.
- Gentle assessment of alveolar socket performed to be certain no foreign bodies or lacerations are present while avoiding dislodgment of a developing blood clot
- Initial consideration is given to gently irrigating the socket, followed by referral to a dental practitioner for space maintenance.
- The tooth roots should not be manipulated to avoid harm to the periodontal ligament; the tooth should be replanted into the socket by

holding onto only the crown of the tooth. This should be followed by using finger pressure to compress the buccal and lingual/palatal alveolar plates.

- Reduce fracture to proper occlusion when possible with splinting for 2 to 3 weeks.
- Soft diet and vigilant oral hygiene are imperative.

Symphysis/Parasymphysis Fractures

The mandibular symphysis is demarcated by the region anterior to an imaginary vertical line distal to the lower canine teeth.[6] These fractures can be treated closed with MMF or ORIF.

Closed treatment is indicated when the fracture line is appropriately reduced when muscle pull is applied. Erich arch bars or self-tapping bone screws in conjunction with a 24 or 25 gauge wire can be used to place the patient in MMF.[6]

- Symphysis fractures are typically approached through a vestibular incision 8 to 10 mm below the mucogingival junction for ORIF
- Once symphysis is exposed and the fracture reduced, a tension plate is fixated with monocortical screws 2 to 2.5 cm below the incisal edges of the mandibular incisors. This roughly corresponds to the region where the alveolar bone merges with the basal bone forming a depression in the anterior mandible.
- Use of lag screws for an oblique fracture is a well-established technique that can be used to counteract torsion.[6]

Mandibular Body Fractures

- The optimal occlusion is determined, and the patient is then placed into MMF. Nondisplaced body fractures can be treated with 6 weeks of MMF.
- If ORIF is required, a transoral incision 8 to 10 mm below the mucogingival junction is used with attention to identifying and skeletonizing the mental nerve branches during dissection.

- Eversion of the lip mucosa facilitates identification of the peripheral branches of the mental nerve during dissection. Once located, fine-tipped mosquitoes carefully follow and skeletonize the branches down to the foramen.[9]
- A tension band is adapted and fixated with two monocortical screws on either side of the fracture. Placement is typically above the mental foramen and below the root apices.
- A fracture plate is adapted and fixated just above the inferior border, with a minimum of two bicortical screws on either side of the fracture. In complex cases, three screws on either side of the fracture are required.

Angle Fractures

- The decision to open an angle fracture depends on the degree of displacement, presence of dentition, favorability of the fracture, and the surgeon's experience with the anatomy of this region.
- If an extraoral approach is used, an incision is made 2 to 2.5 cm below the inferior border of the mandible within a resting line of tension to minimize postoperative scarring.
- Layered dissection with use of a nerve stimulator minimizes injury to the marginal mandibular and cervical branches of the facial nerve.
- A tension band is placed superiorly and fixated with two monocortical screws on either side of the fracture. A fracture plate is fixated at the inferior border with 2 to 3 bicortical screws on either side of the fracture.
- A layered closure is required.

Condylar/Subcondylar Fractures

- Intracapsular (condylar) fractures can be treated with a 3-week course of MMF, unless the condylar head is dislocated.
- Access for subcondylar fractures is possible through a submandibular incision alone but can be maximized by making both submandibular and preauricular incisions, the latter allows direct visualization of

repositioning of the condylar head within the glenoid fossa.

- Fixation of such fractures requires smaller hardware due to the anatomy of the bone, but efforts should be made to place at least two screws on either side of the fracture, when possible.
- Layered closure is required.

Ramus Fractures

Ramus fractures can be treated with MMF for 4 weeks. ORIF is required if a significant malocclusion or facial asymmetry is present. A submandibular or retromandibular incision is ideal for access.

Atrophic Mandible Fractures

- An extraoral or transoral incision can be used to fixate atrophic fractures. The latter incision is associated with a lesser chance of facial nerve injury. However, the inferior alveolar nerve can be closer to the superior aspect of the alveolar crest of an atrophic mandible and can become distorted during fracture manipulation.
- An atrophic mandible fracture is often rigidly fixated with a 2.0-mm plate or compression plate.
- Wound dehiscence is a common complication due to the irritation of the mucosal tissue from the underlying hardware when a functional load is brought against the tissues.

Multiple Fractures

- Establishment of a stable occlusion with MMF before fixation (Fig. 185.4)
- Fixation in the case of multiple fractures should occur starting with the two most stable, largest segments. The combination of fixation and reestablishment of the occlusion decreases the chances of gonial flaring and malocclusion postoperatively.[8]
- The use of locking plates and screws are often useful when added stability is desired and distraction of fracture segments is a concern.

FIG. 185.4 **A,** Patient presented with deviation of mandible to the left and premature occlusal contact on right posterior teeth. An open mouth reverse Towne view, **B,** and panorex view, **C,** reveal left subcondylar fracture with overlap and displaced right body fracture. **D,** Patient underwent maxillomandibular fixation (MMF) with transoral approach to right body fracture with placement of a fracture plate at the inferior border. The left subcondylar fracture was treated closed with a 2-week period of MMF. **E,** Postoperative occlusion at 6 weeks. Guiding elastics were placed between weeks 2 and 4 on the right side and anterior region to guide the occlusion into place.

Alternative Management Plans

No surgical intervention can be considered for a nondisplaced fracture with no evidence of any malocclusion if the patient is able and willing to be absolutely compliant with a strict liquid diet.

Common Errors in Technique

- Not making a vestibular incision at least 8 to 10 mm below the mucogingival junction can result in loss of vestibular depth and/or excessive senichiae formation along the incision.
- Not holding inward pressure at the mandibular angles when fixating a symphysis fracture can result in flaring of the gonial angles.
- Not ensuring that the occlusion is stable during reduction and fixation of a fracture results in a malocclusion.

Postoperative Period

Patients who have been treated with closed treatment are kept in MMF for 3 to 6 weeks depending on the fracture location. Condyle fractures are left in MMF for a shorter duration to reduce the risk for ankylosis of the joint. Therefore fixation is removed by 3 weeks to allow functioning of the cartilaginous disc. Wire cutters should be in the patient's possession at all times with explicit instructions for removal of the fixation wires only for emergent loss of airway secondary to choking. Postoperative instructions for patients who have undergone ORIF include a soft, non-chew diet for 6 weeks to allow for consolidation of bony segments while minimizing functional load. The use of long-term postoperative antibiotics has not been determined to show a statistically significant benefit when ORIF is performed. Postoperative antibiotics may be beneficial in consideration of patient factors such as poor wound healing in the setting of uncontrolled diabetes or tobacco use.

Complications

Posttrauma complications include loss of tooth vitality, malocclusion, exposure of hardware, non-union/malunion, and neurologic deficits such as paresthesias. The risk of inferior alveolar nerve injury was found to be greatest with fracture displacements greater than 5 mm. Patient factors for postoperative complications involve poor hygiene, medical conditions that compromise wound healing, substance abuse, and noncompliance.

Discussion

Evidence-Based Medicine Question

The practitioner, in many instances, may question the adequacy of fixation of comminuted fractures of questionable biomechanical favorability. What is the value of postoperative radiographs in such instances? Do postoperative radiographs offer changes in outcomes such as re-exploration of the fracture or change in morbidity compared with proper postoperative physical examination?

MMF without rigid fixation is still widely used for nondisplaced or minimally displaced biomechanically favorable fractures in patients with a complete complement of teeth and in intracapsular condylar fractures or severely comminuted fractures in which occlusion can be reestablished.

Postoperative radiographs, particularly CT, remain debatable as a review of the literature has shown that the sensitivity, specificity, and positive predictive value in determining complications are below expectations and add little information when supported by physical examination and history-taking. A 2015 study in *JAMA* analyzed the cost analysis of post-fracture reduction imaging as it relates to the complication rate encountered by the surgeon. The study determined that a postreduction panorex radiograph should be obtained for mandibular fracture repair until the surgeon's complication rate falls below 17.7%.

Editorial Comments

The authors have provided a comprehensive chapter that makes clear that the ideal management of mandibular fractures requires knowledge of a vast array of techniques that can be adjusted to the site, extent, type of fracture, and the patient's needs and circumstances.

Review Questions

1. A unilateral, moderately displaced subcondylar fracture will typically

manifest the following clinical exam finding

a. **Deviation of the chin point toward the ipsilateral side of the fracture due to the unopposed action of the contralateral lateral pterygoid muscle**

b. Deviation of the chin toward the contralateral side of the fracture due to unopposed action of the contralateral lateral pterygoid muscle

c. Deviation of the chin point toward the ipsilateral side of the fracture due to the action of the masseter muscle

d. Deviation of the chin point toward the contralateral side of the fracture due to the action of the masseter muscle

2. When discussing favorable versus unfavorable fracture patterns, all of the following are true, except

a. It requires an understanding of the biomechanics exerted on the fracture segments by muscle pull.

b. The elevator muscles—masseters, temporalis, and medial pterygoid —can cause displacement of fracture segment in the vertical plane.

c. Action of the lateral pterygoid and torsional forces by the mylohyoid, digastrics, and geniohyoid muscles causes horizontal displacement of the fracture segment.

d. **All of the above**

3. Surgical considerations in treatment planning mandibular fractures include all of the following, except

a. The presence of posterior occlusion along with its proper reduction allows for greater predictability in treatment outcomes when considering gonial flaring and malocclusion.

b. The desired method of fixation is highly dependent on the existing dentition and muscle forces.

c. In a dentate patient with stable teeth on either side of a fracture, closed treatment via maxillomandibular fixation is reasonable.

d. Consideration for teeth roots and avoiding ischemic necrosis caused by the violation of the oral periodontium are of utmost importance.

e. **All of the above**

4. Studies have conclusively determined that all open mandibular fractures must be surgically repaired within the first 48 hours to eliminate any risk of postoperative infections.

   a. **True**

   b. False

Fractures of the Cranio-Orbital and Midfacial Skeleton

Bernard J. Costello

Introduction

Injuries to the upper and middle facial skeleton occur regularly due to a variety of blunt and penetrating etiologies and often require operative intervention.[1–4] Understanding the patterns of injury, diagnosis, treatment, and management of complications are important for any surgeon working in the craniomaxillofacial region to understand.

Into this chapter I review the primary restoration of function and form of bony injuries to the cranio-orbital and midface region. Common injuries to the frontal sinus, orbits, and midface are reviewed. Injuries to the nose, ocular region, and dentoalveolar tooth structures are addressed elsewhere in this book.

Key Operative Learning Points

1. The primary goal of the treatment of facial injury is the restoration of form and function to the pre-injury state, including the proper projection, width, and height of the craniomaxillofacial complex.[5]

2. An accurate diagnosis of the extent of facial injuries is dependent upon a detailed history and physical examination and quality imaging.

3. Understanding the biomechanics involved in each area of concern helps the surgeon make appropriate fixation choices and accomplish reduction of the fractures with adequate stabilization.

4. A high level of skill helps achieve appropriate fixation and a clear understanding of the fixation devices, and all the accompanying

armamentaria are necessary to achieve superior results.

5. Maxillary fractures that involve occlusion require a detailed understanding of occlusion and common malocclusions.

Preoperative Period

History

1. History of present illness

   a. A detailed history of the mechanism(s) of injury clarifies the extent of injury and the potential for secondary injuries to other structures or body systems. The history of the injury may need to be obtained from friends or family.

   b. Advanced trauma life support (ATLS) protocols should guide the evaluation of the injured patient.

   c. The potential for head injury should not be ignored, particularly in those who have a loss of consciousness. Concussion should be considered in the differential diagnosis after significant injury to the head and neck region and concussion protocol initiated.

   d. A history of previous facial injury or facial dysplasia/deformity is important when understanding the extent of injury and the precise goals for reconstruction.

Physical Examination

1. A full examination of the head and neck is performed to identify any soft tissue, bone, or visceral injuries. Particular attention is given to specialized structures such as the brain, cranial nerves, globe, lacrimal system, and other important anatomic structures that may have been injured in conjunction with facial injuries.

2. A complete ophthalmologic examination is helpful when injuries are apparent in the region. At times, a skilled Ophthalmologist may help in performing additional specialized examinations of the cornea, retina, globe integrity and position, or lacrimal system.

3. A detailed neurologic examination can clarify the extent of injury to the brain and spinal cord and may help not only in the primary assessment but also during follow-up. Preoperative assessments using concussion evaluation tools such as the IMPACT assessment tool can clarify functional deficits in cognition.

4. After eliciting a historical understanding of the patient's occlusion, a detailed evaluation of the bite, excursions, maximal opening, and deviation is essential to understand maxillary fractures and their involvement with adjacent areas such as the injured or uninjured mandible.

Imaging

1. Only select injuries with little or no chance of concomitant injuries are treated by physical examination without imaging, such as the isolated nasal fracture. However, most other facial injuries are evaluated using a high-quality spiral computed tomography (CT) formatted in axial, sagittal, coronal, and three-dimensional views. Performing these scans in a manner consistent with navigation and computer-assisted surgery protocols with files saved in digital imaging and communications in medicine (DICOM) format is helpful, and additional technology may be used. CT angiography is helpful for larger caliber vessels, but it is still inadequate for imaging of the smaller vasculature in most areas of the craniomaxillofacial region.

2. Rarely, interventional radiologic techniques can be helpful for treating bleeding vessels that cannot be addressed through typical surgical exposures. Traumatic arterial dissections or bleeding arteries at the cranial base may be addressed with interventional techniques using superselective embolization or other methods.

Indications

1. Displacement of the cranio-orbital or midface bones that cause either aesthetic imbalance and/or functional impairment such as a blocked naso-lacrimal system, diplopia, ocular muscle entrapment, or malocclusion

2. Decision making regarding the timing of operative intervention is typically regarded as most effective in the early phase of healing. Delayed repair can be associated with increases in infection rates and difficulty with accurate reduction of fragments due to early remodeling.

3. There are many approaches to the cranio-orbital and midface regions, and each presentation requires a customized approach based on complexity and the need for exposure to achieve accurate reduction and fixation. There is significant variability in surgical techniques for each of these procedures.[1,2] The most common examples are described as follows.

Contraindications

1. Medical and/or traumatic comorbidities with increased risk for general anesthesia

2. Significant uncorrected bleeding disorder or nutritional deficiency that would increase risk for complication with wound healing

3. Critical injury to the brain or other structures that would be worsened with an open procedure in the region

4. Critical injury to the globe or optic nerve that would be worsened with manipulation of the contents of the orbit or surrounding region

Preoperative Preparation

1. Discontinue antiplatelet drugs or other medications that affect the ability to mount a clotting response, if possible.

2. Optimize hemodynamics.

3. Evaluation of the cervical spine to avoid worsening an existing injury and stabilization if necessary

4. Consider a staged approach if panfacial fractures are present to allow for reimaging and re-assessment.

5. Consider the use of navigation or intraoperative CT to ensure that the proper equipment is available and that positioning can accommodate the technique desired.

6. Blood products may be considered if extensive fractures requiring complex, lengthy approaches are required.

7. Patients should be counseled on postoperative care including pain management, dietary and activity restrictions, and possible need for secondary revision procedures.

Operative Period

Anesthesia

1. General: These procedures are routinely performed under general anesthesia with the patient orotracheally or nasotracheally intubated. Occasionally, a tracheostomy is needed for airway management. Often, swelling limited to the face does not impact airway dynamics significantly and is manageable without the use of a tracheosotomy. The decision to manage the occlusion is typically the key variable when considering oral versus another route of intubation.

2. Selective hypotension is helpful to avoid excessive blood loss.

Positioning

- Supine with full access to the head
- If intraoperative navigation or CT is planned, then positioning of the patient and the operating room must accommodate these techniques properly.
- A horseshoe-ring headrest can be used for more complete access to the skull.
- A shoulder roll is often helpful for slight extension of the neck if cervical spine injury has been ruled out.

Perioperative Antibiotic Prophylaxis

- Cephalexin or similar spectrum antibiotic prior to incision
- Clindamycin is used if the patient is allergic to penicillin.

Monitoring

- Consider an arterial line for long procedures and extensive reconstructions.

Instruments and Equipment to Have Available

1. Marking pen, sterile pencil, and/or cotton-tipped applicator and marking solution

2. Corneal protectors with lubrication

3. 0.5% Lidocaine with 1:200,000 epinephrine used at less than a maximum dosage

4. Cranio-orbital instrumentation with a variety of straight and curved periosteal elevators, intra-orbital instruments for retraction of the contents such as malleable retractors

5. Obwegeser retractors of various sizes

6. 10, 15, or 15c blade with long handle

7. Angled beaver blade

8. Absorbable suture, such as fast absorbing gut, polyglycolate, chromic, of various sizes

9. Bipolar and monopolar electrocautery with insulated small needle-point tip

10. Optional scalp clips for bi-coronal approaches

11. Bone wax

12. Small titanium plates and screws. Resorbable options can be considered, but they are typically reserved for growing individuals or those where revision is likely.

13. Maxillomandibular fixation (MMF) instrumentation for setting the bite such as MMF screws, arch bars, or commercially available MMF screw-based systems

14. Craniomaxillofacial fixation system that includes sizes from approximately 1.0- to 2.5-mm diameter screws with accompanying plates

Key Anatomic Landmarks

Coronal Approaches (Fig. 186.1)

- Facial nerve location within the superficial and deep layers of the superficial temporal fascia
- Supraorbital rim
- Supraorbital neurovascular bundle
- Medial canthal ligament attachments
- Zygomaticofrontal (ZF) suture

Orbital Approaches (Fig. 186.2)

- Deep fornix incision made behind the orbital septum and into adipose tissue
- Lacrimal sac and posterior lacrimal fossa medial and Horner's muscle divided medially for a transcarruncular incision
- Inferior limb of the canthal suspension system divided from the attachment superiorly near Whitnall's tubercle for additional orbital exposure
- Lacrimal duct locations for intubation with Crawford tubes

Maxillary Approach

- Mucogingival junction
- Maxillary buttresses at the zygoma and piriform rims
- Infraorbital nerve and foramen
- Parotid duct
- Piriform rims and zygomatic buttresses

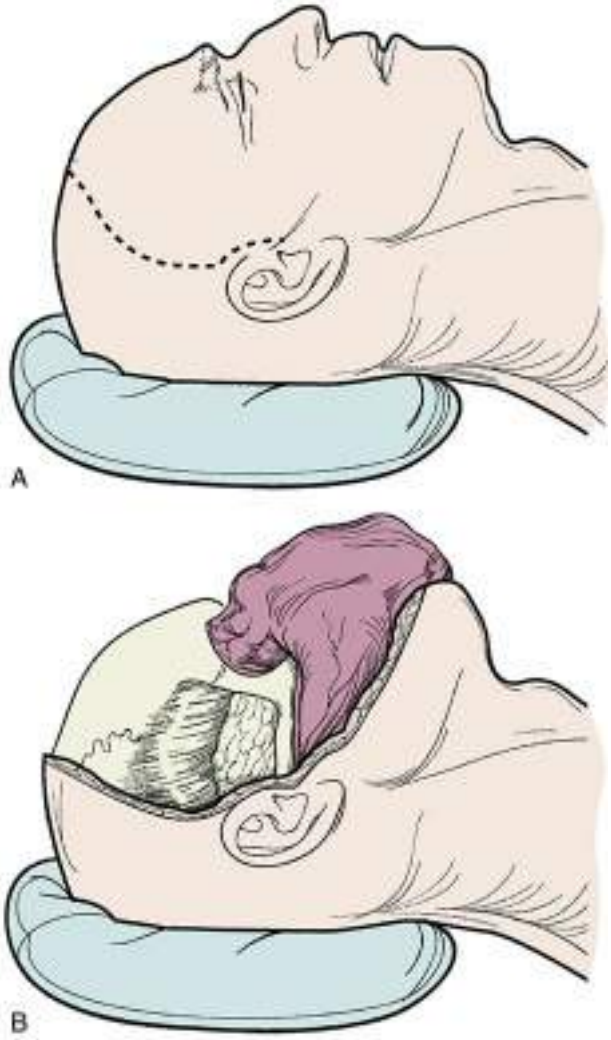

FIG. 186.1 Coronal flap incision with or without approach to the temporomandibular joint.

A, A wavy line or sine-wave incision is made with the incision placed more posterior for better aesthetics. Another option can include a posterior-auricular incision for even better aesthetics when access to the joint is less important. Either approach can be used for access to the zygomatic arch. **B,** The dissection is carried deep to the superficial layer of the superficial temporal fascia until about 1 cm above the arch within the temporal adipose tissue pad. Dissecting deep to this layer helps avoid injury to the facial nerve, particularly the frontal branch. When combined with a dissection that proceeds along the nasal bones and anterior orbital rims, 360 degrees of the orbit can be visualized when using this approach.

Prerequisite Skills

1. Detailed understanding of the anatomy of the cranio-orbital complex

2. Training in general trauma care and emergent airway management

3. Training in diagnosis and surgical repair of craniofacial conditions

4. Technical skill using internal fixation techniques such as plate and screw systems

5. Detailed understanding of normal occlusion and common pre-existing malocclusions

6. Experience with surgery in the region including cranio-orbital, peri-orbital, oral cavity, and oropharynx

7. Access and ability to work with other surgeons to address common concomitant injuries to the brain, eye, and dentition

Operative Risks

1. Early complications:
   a. Bleeding
   b. Intracranial bleeding
   c. Wound breakdown/partial dehiscence
   d. Facial nerve injury
   e. Malocclusion
   f. Vision abnormalities (diplopia, blindness, blurry vision)
2. Late complications:
   a. Periorbital scarring (entropion, ectropion)
   b. Temporal wasting with contour irregularities
   c. Enophthalmos
   d. Infection
   e. Malocclusion
   f. Dental injury

g. Malunion

Surgical Technique

The following surgical technique section includes steps common to cranio-orbital and midface fracture treatment procedures followed by particular steps that are specific to each individual procedure.

For All Procedures

- Intubation with oral ring-adair-elwyn (RAE) endotracheal, nasal straight, nasal RAE (ET) tube, or tracheostomy. I do not favor submental intubation approaches, and I avoid tracheostomy when possible.
- Place patient supine with the neck slightly extended with a shoulder roll.

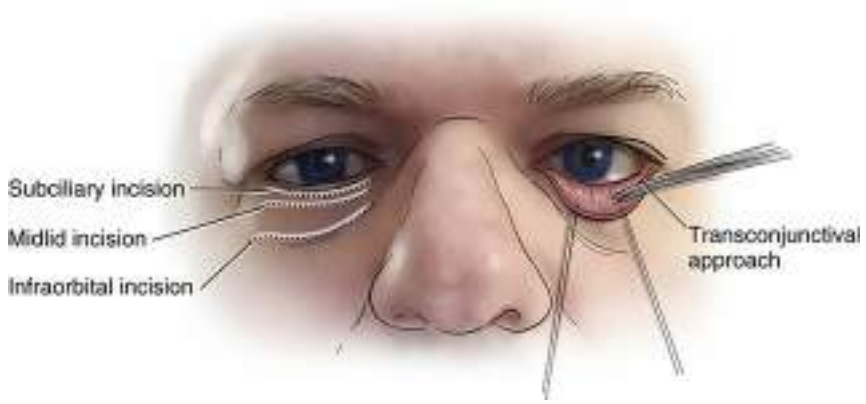

FIG. 186.2 Multiple options for eyelid incisions are shown including the transconjunctival, subcilliary, midlid, and infraorbital incision. With permission from Fonseca R, Barber HD, Powers M, et al. Fonseca's Oral and Maxillofacial Trauma, 4th ed. Philadelphia: Saunders; 2013.

- Eye protection may be helpful with corneal protectors and eye lubrication or other means.
- Prep face with betadine and brush oral cavity with chlorhexidine gluconate oral rinse.

- Incisions may be marked with a marking pen or the wooden handle of a cotton-tipped applicator dipped in gentian violet or methylene blue. Osteotomies can be marked with a sterile pencil when needed.
- Proposed incisions may be injected with lidocaine and epinephrine in a subdermal, submucosal, and subperiosteal plane, avoiding direct injection to the neurovascular bundles. Subperiosteal injection can aid in hemostasis and facilitate undermining of the mucoperiosteal flaps.
- A marked throat pack may be used to block secretions from entering the gastrointestinal (GI) tract. It should be announced during placement and removal.
- Selective hypotension may be provided from the anesthesia team to minimize blood loss. For simple fractures, an arterial line is often not needed and transfusion is rare. However, for extensive facial fractures with many approaches, these monitoring methods and blood products may be helpful.
- At times, it may be helpful to consider navigation or intraoperative CT to judge effective reduction and reconstruction. Staged procedures can also allow for additional imaging and adjustments of the three-dimensional position of segments if extensive fractures are present.
- At the finish of the procedure, an oral-gastric suction tube is passed to suction the stomach.

Cranio-Orbital Fractures (Figs. 186.3A to M)

- Marking the incision on the scalp is performed in a sine wave or saw-tooth pattern, preferably in a slightly posterior auricular location, unless access is required to the temporomandibular joint.
- A strip can be shaved to allow for the incision to be made, and the hair is washed and prepped in betadine solution. Detergents should be avoided, as they may harm the eyes.
- The incision can be made with a #10 blade or needlepoint bovie on a low setting with hemostasis controlled throughout. I prefer not to use scalp clips, but these are an option.
- Double skin hooks are used to advance the flap in the supraperiosteal

plane, just superficial to the deep layer of the superficial temporal fascia over the temporalis musculature. In the central region, the flap is advanced anteriorly just superficial to the periosteum up to the supraorbital ridge.

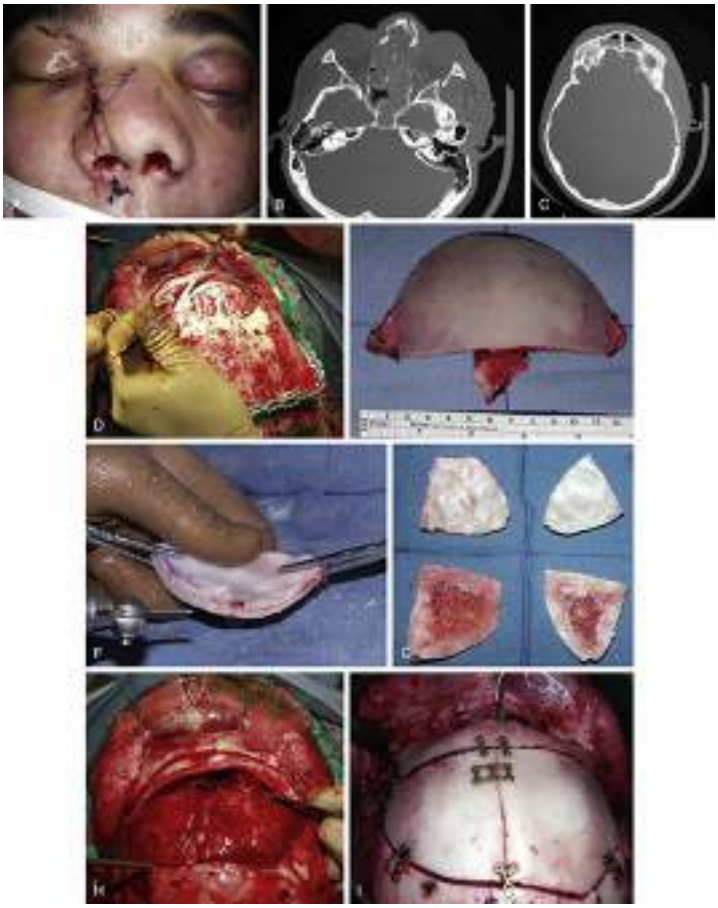
- A large pericranial flap can be advanced medial to the temporal ridges from posterior to anterior and kept moist throughout the procedure for use in the anterior cranial base as needed.
- A subperiosteal dissection is performed laterally over the edge of the lateral orbital bones, centrally over the nasal bones, and around the orbital tissues superiorly. Osteotomes can be used to mobilize the bone housing the supraorbital neurovascular bundle to gain more flap mobility.
- Medial orbital dissection is done carefully to avoid detaching the medial canthi if they are still intact. If detached from their normal insertions, then a small fragment of bone can almost always be identified.
- Medial canthal attachments can be located by using an Adson forceps with teeth externally at the canthal attachment and flipping the coronal flap inferiorly to then locate the forceps through the tissue. It can then be isolated by suturing it with a 4-0 non-resorbable braided suture. Canthal re-attachment may then occur using a trans-nasal wiring technique.
- Lateral canthal attachments can also be repositioned with a similar technique using pilot holes drilled in the approximate vector of Whitnall's tubercle.
- If the posterior table of the frontal sinus is fractured, displaced, and involves the drainage system inferiorly, then cranialization of the sinus after removal of all mucosa is performed.
- Tears in the dura at the anterior cranial base should be repaired to avoid a chronic leak of cerebrospinal fluid and potential retrograde infection. Endoscopic repairs of small leaks can be considered if an open approach is not needed.
- Anterior table fractures can simply be reduced. Rarely, internal endoscopic balloon techniques can be effective for a localized fracture that is intruded.

- I do not favor obliteration techniques, as these can lead to chronic inflammation in the sinus. Nonresorbable calcium phosphate materials should be avoided in this area.
- Craniofacial bones, including the frontal sinus, can then be reduced and plated. Appropriate three-dimensional positioning of the zygoma, superior orbital rims, and nasal bones is critical to providing the appropriate width, height, and projection of the face. The positioning of the maxilla often depends upon the position of the upper facial skeleton.
- Naso-orbital-ethmoid fractures must be completely reduced and medial cathi re-attached in an appropriate dimension to avoid telecanthus. Trans-nasal wiring secured to a contralateral plate is helpful in achieving proper dimensions.
- Access to the zygoma and nasal bones is also available via this approach. The arch is dissected out separately as needed, making the incision approximately 1 cm superior to the arch into the deep layer of the superficial fascia or adipose tissue pad.
- The bicoronal incision is closed with 2-0 resorbable braided suture using inverted knots in an interrupted fashion. The skin may be closed with staples, running 4-0 monofilament or 4-0 resorbable braided suture.

Zygoma (Figs. 186.4 and 186.5)

- Zygoma fractures are not tripod fractures but articulate at the ZF suture, infraorbital foramen/notch, zygomatic arch, zygomatic buttress, and the greater sphenoid wing. Each articulation point must be adequately reduced prior to fixation.
- Fixation can be fairly minimal, as there is not much force placed on the zygoma. While fixation points at the ZF suture, zygomatic buttress, and infraorbital rim areas are often used, less fixation can often be acceptable.
- The approaches used need to keep accurate reduction and adequate fixation in mind. Often, limited approaches give a limited view of the adequacy of reduction in three dimensions.

- Approaches may include brow, upper eyelid, coronal, maxillary vestibular, and various lower-eyelid approaches.
- Fixation devices used to secure fractures can typically be very small, and a low-profile plating system is preferred in areas that have minimal soft tissue coverage such as the ZF suture area and infraorbital rim.
- While the orbit is involved in most zygoma fractures, it does not always require reconstruction of the floor. After reduction, if the defect is small and not in a critical area where volume loss can occur, then a reconstruction of the floor may not be necessary. Critical areas where volume loss may occur include the bulge in the floor of the orbit and the medial bulge of the medial wall. Enophthalmos can occur if these fractures are not reduced.



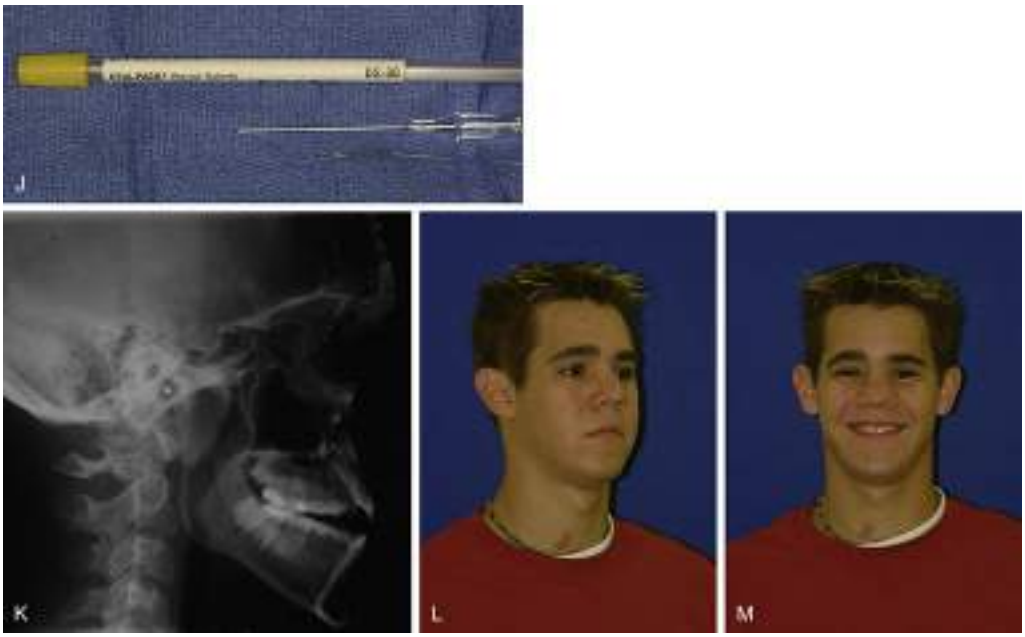


FIG. 186.3 **A–C,** A young male with telecanthus after sustaining cranial and midface injuries including a posterior cranial vault fracture, Type III naso-orbital-ethmoid fractures, orbital floor fractures, and a Le Fort II fracture. **D,** A transcranial approach was required via bicoronal incision and bifrontal craniotomy with removal of the posterior wall of the frontal sinus. All the mucosa of the frontal sinus was removed. **E–J,** Split-thickness cranial vault bone was used for reconstruction of the orbits and other areas. Transnasal wiring was used to reattach the medial canthal ligaments. **K,** The patient had a pre-existing malocclusion consisting of an open bite, which was recognized due to developmental mammelons on the incisors and a pre-injury plan for orthognathic surgery. **L–M,** Despite an elevated intracranial pressure, the patient recovered with the need for only minor nasal cartilage revision and rhinoplasty due to lacerations associated with the nose.

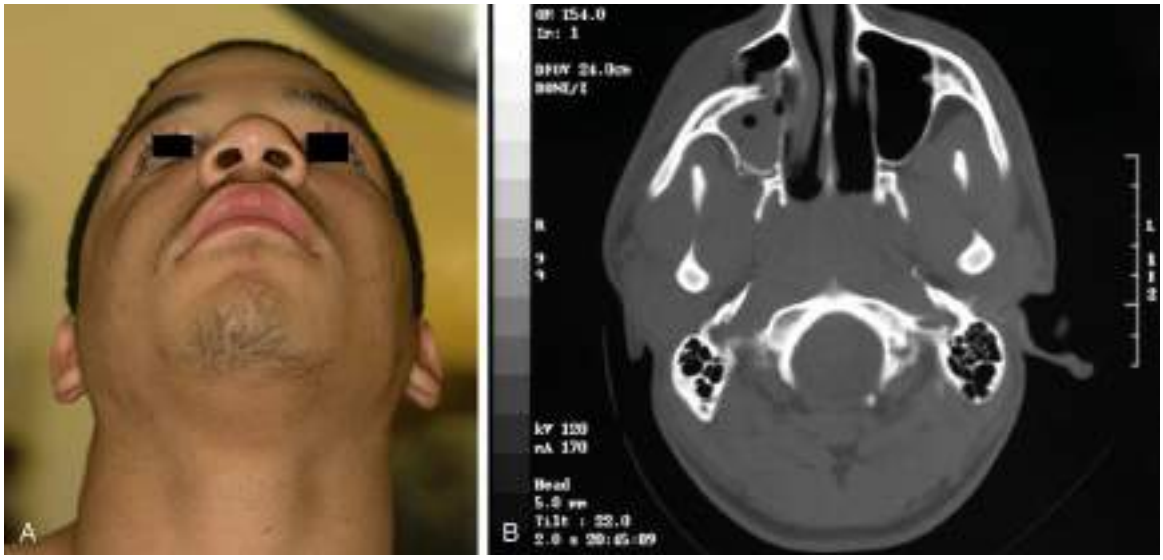

FIG. 186.4 **A,** A young male who sustained a left fist to the face resulting in a fractured zygoma with medial displacement. **B,** The computed tomography scan shows the typical displacement that requires three-dimensional repositioning via multiple incisions. Brow, intra-oral, and transconjunctival incisions are often used to position and fixate fractures such as these.

FIG. 186.5 The isolated zygomatic arch fracture is typically found in two or more fragments, requiring a repair that is more of a flat surface than an actual arch.

Orbit (Fig. 186.6)

- The orbital approach is dependent upon the location of the fractures that require reconstruction. Lower-lid approaches such as the deep fornix trans-conjunctival with or without inferior lateral cantholysis, subcilliary, or lid crease incisions can be used depending upon the need for access, existing lacerations, or preferences.[4]
- If a medial wall approach is needed, a trans-caruncular approach may be considered.
- Orbital roof fractures can be approached via a coronal incision, brow, or eyelid incision.
- Fractures of the orbital rim should be reconstructed prior to the interior wall reconstruction. Very small plates and screws are used to avoid a high profile that is palpable through the thin tissues around the eye.
- For reconstructions of the orbital wall, a subperiosteal dissection is used to get just beyond the fracture dimensions, and a substitute material is used for reconstruction. Larger defects benefit from more support with materials that retain a specific shape, such as porous polyethylene with imbedded mesh. Preformed plates are also available in a few standard sizes.
- Custom implants can be fabricated using the patient's CT scan, but this can be expensive.
- The use of navigation as a guide to placement of the reconstructive material and/or the use of intraoperative CT can be helpful in avoiding the need for return trips to the operating room for adjustment.
- When disrupted, it is important to reconstruct the inferior and medial bulges to avoid volume changes that can lead to enophthalmos. These are best reconstructed with preformed or customized reconstructive implants.
- Resorbable materials are not recommended for larger defects, as they eventually resorb and leave a defect in areas that require support.
- If a lateral cantholysis is performed, then the inferior leaflet must be repositioned back to the periosteum and upper leaflet of the suspension system, or an excessively round appearance can occur at the lateral eyelid commissure.
- Transconjunctival incisions do not require a closure with suture, but

very small resorbable monofilament suture can be considered. Some surgeons place a small drain in the floor of the orbit to avoid the formation of a hematoma.

- Skin incisions can be closed with 6-0 fast-absorbing suture.
- A Frost suture can be placed to support the eyelid by taping this lower lid suspension suture to the forehead, allowing for access in the early postoperative period to examine the eye.

Le Fort (Fig. 186.7)

- At the beginning of the twentieth century, Rene Le Fort was the first to document a tendency for the occurrence of specific patterns of midface fractures after direct facial trauma.[3] The Le Fort I fracture is a horizontal fracture of the mid-maxilla just above the teeth and alveolar bone. The Le Fort II fracture is a pyramidal shaped fracture in the central portion of the face with the base being the maxilla and the apex at the nasofrontal junction. The Le Fort III fracture is a craniofacial dysjunction in which the facial skeleton completely separates from the skull base.
- These fractures often occur due to significant force and may involve displacement of the bones posteriorly and/or superiorly, yielding an "impaction" of the maxilla. When reducing these fractures, it is important to mobilize them back to the proper projection. Maxillary disimpaction forceps can be used for this maneuver.
- The mandibular occlusion can be used as a guide. If multiple facial fractures have occurred and the maxilla is in several fragments, then the mandible is usually reconstructed to its original three-dimensional form. The occlusion is the guide that then can help position the maxilla properly.
- A vestibular incision from the first molar area to an equal point contralaterally is placed approximately 5 to 7 mm above the mucogingival junction. This allows for proper closure later and a good vascular pedicle to anterior maxillary segments.
- A subperiosteal dissection is used to expose the anterior and lateral aspects of the maxilla. Exposure to the infraorbital rims is possible. It is

often helpful to expose the anterior nasal floor and interior piriform rim to help align the segments for fixation.

- Incisions of the palate are to be avoided, as this is generally one of the main vascular supplies to the maxillary and alveolar bone. Plating is not recommended in the palatal region, as the tissue is thin in most areas causing plates and screws to become exposed and/or infected.
- Patients are typically placed into MMF with wires between the teeth and jaws, followed by open reduction and fixation of the fractures utilizing small plates and screws. Once reduced, the MMF can be removed at the end of the procedure. Palatal fractures are managed effectively with dental or palatal splints. Custom splints can be made of acrylic using dental models, but they can also be fashioned quickly from perforated thermoplastic splint material.

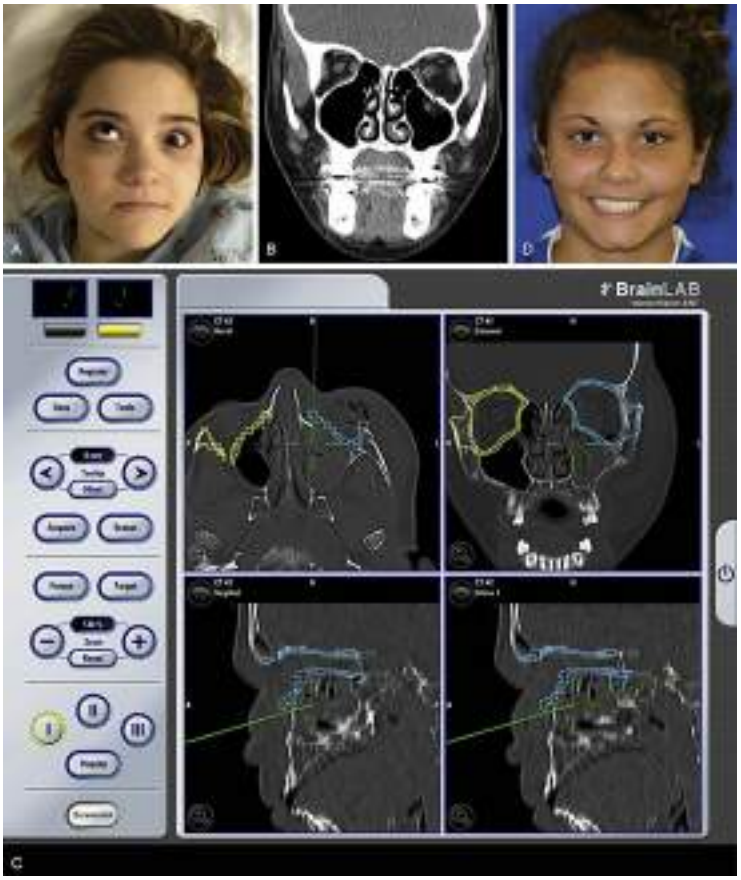

FIG. 186.6 **A,** The classic clinical appearance of an emergent trap door fracture in a young girl with entrapment. She also exhibits bradycardia and nausea

on upward gaze. **B,** A coronal computed tomography scan shows entrapment of periorbita and inferior rectus. **C,** Navigation and mirroring technology can be used to help position an orbital implant into a defect once the periorbita has been released. **D,** If done in a timely fashion, the patient's range of motion and position of the globe can be restored to the pre-injury state.

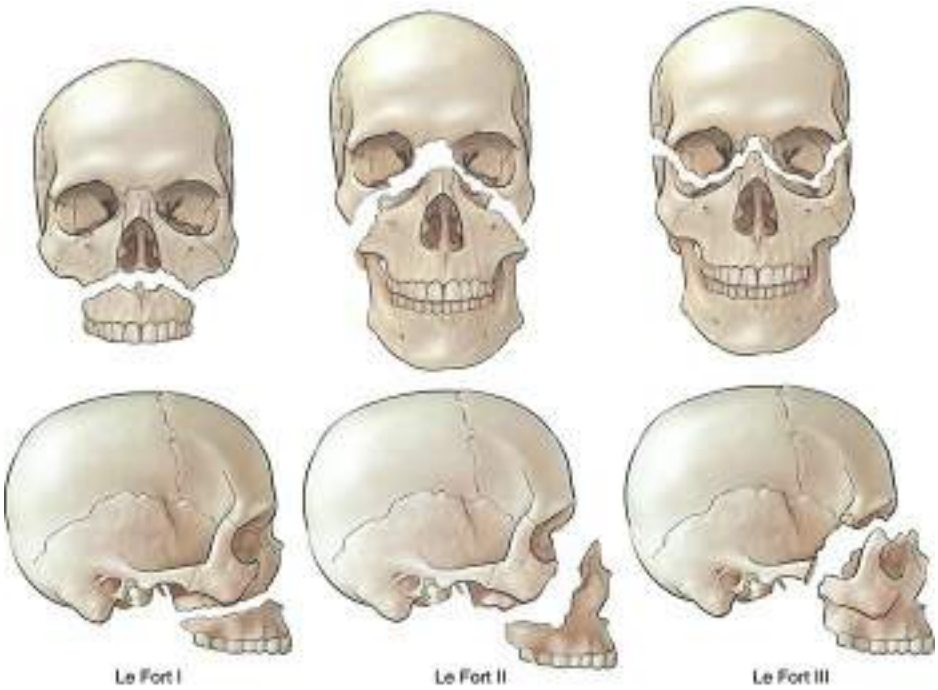

FIG. 186.7 The anterior and lateral views of the Le Fort midface fracture classification are shown highlighting the involvement of the various structures of the midface. With permission from Fonseca R, Barber HD, Powers M, et al. Fonseca's Oral and Maxillofacial Trauma, 4th ed. Philadelphia: Saunders; 2013.

- Internal fixation is the treatment of choice for mobile maxillary fractures. Wiring the teeth together with MMF alone causes the mandible to pull down the mobile maxilla under function and potentially create a non-union. As such, plating systems are often used at the four anterior buttresses of the maxilla to provide fixation. These include the piriform rims and zygomatic buttresses. Thick bone usually exists for placement of monocortical screws of medium size.
- If other upper facial fractures exist, it is important to also set the facial

width, projection, and height properly when placing the maxilla in its proper position. Many surgeons use an outside-in approach, by which the mandible and upper cranio-orbital skeleton are reconstructed prior to the maxilla when pan-facial fractures occur.

- The vestibular incision is closed with 3-0 chromic or Vicryl suture.

Common Errors in Technique

1. Failure to achieve adequate three-dimensional reconstruction of fractures prior to fixation or placement of reconstructive implants

2. Dissecting the coronal incision too superficial in the anterior area of the superficial temporal fascia layers may cause frontal nerve branch weakness.

3. Dissecting the coronal incision too deep in the anterior area of the superficial temporal fascia layers into the muscle, causing muscle wasting and a lateral aesthetic defect in the temporal region. Trismus can also occur due to scarring of the temporalis muscle.

4. Complete reconstruction of the eyelid suspension system, resulting in a rounded appearance to the eyelid

5. Incomplete repositioning of the canthi resulting in traumatic telecanthus or poorly suspended eyelids

6. Failure to achieve a stable and repeatable occlusion. This can be difficult to achieve in patients with pre-existing malocclusions.

7. Failure to integrate dento-alveolar fracture treatment with the repositioning of the maxilla and/or mandible when reestablishing the occlusion

8. Failure to refer to a dental specialist for dental injuries either during the initial reconstructive phase or soon thereafter

Postoperative Period

Postoperative Management

1. Admit for observation in many cases involving intraorbital surgery. Intensive care may be needed for patients undergoing craniotomies for exposure to cranial base fractures or extended procedures with significant blood loss or volume shifts.

2. Drains are placed to bulb suction in the scalp and can be removed when fluid collection has decreased markedly.

3. For patients who have had maxillary fractures, a smooth liquid diet is used for at least several weeks. In patients with solid fixation, soft food can be introduced within several weeks. Chewing is to be avoided until adequate bone healing occurs. In many patients with mobile fractures, this may take 6 to 8 weeks.

4. Antibiotics for 7 days postoperative (optional)

5. Facial sutures may be removed at 5 to 7 days when resorbable sutures are not used.

6. Follow up in 1 to 2 weeks

Complications

1. Postoperative nasal/oral bleeding may stop spontaneously if mild or with oxymetazoline spray for nasal bleeding. If persistent, it may require a return to the operating room for control.

2. Cerebrospinal fluid leak due to a persistent fistula or breach at the cranial base into the sinonasal region. Many small leaks can be repaired using an endoscopic approach with or without navigation. Others may require an open approach with pericranial flap placement or other techniques to block the leak. In some cases, a lumbar drain can be placed to change differential pressure for very small leaks. The outcome data on this approach are not clear, but it is occasionally employed as a conservative measure.

3. Acute intraorbital bleeding and/or intra-orbital/retrobulbar hematoma. This may cause the emergent need for decompression at the bedside and/or in the operating room with a lateral canthotomy and release of the hematoma. A drain can be placed at the time of surgery to help avoid this complication.

4. Eyelid scarring causing ectropion or entropion. This can occur with damage to the soft tissue of the eyelids. Secondary reconstruction may be needed to gain adequate coverage of the globe and cornea if this is severe.

5. Enophthalmos due to incomplete reconstruction of the floor or wall of the orbit

6. Malocclusion due to inadequate positioning of bony segments. This may require return to the operating room to reestablish a proper occlusion. Malunions discovered late may require osteotomies, orthognathic surgery, and/or orthodontic therapy to resolve imbalances in the occlusion. Malunions of the zygoma can be masked with an onlay implant or more ideally treated with a zygomatic repositioning osteotomy.

7. Nonunions of the midface are very rare but most often occur at the lower Le Fort level and involve the occlusion. They usually involve overfunction immediately after the initial repair.

8. Infections can occur and usually require antibiotics and sometimes drainage procedures. Plates and screws should be replaced during active healing or removed if the infection occurs after initial healing.

Alternative Management Plan

1. Patients with minimally displaced fractures and a stable occlusion without mobility of the maxilla can be placed on a liquid diet to avoid an operation if they are unable to tolerate it medically or wish to avoid a procedure. Ideal repositioning may not occur if this approach is used. As such, aesthetic and/or functional consequences may occur.

Discussion

Evidence-Based Medicine Question

Which eyelid incision is associated with the least complications?

Data in this area are not strong enough to make definitive statements regarding which incision may be best. Much of the data are self-reported

and have inherent bias associated with the study designs. That being said, many surgeons quote an eyelid scarring complication rate such as ectropion, lid lag, or entropion at slightly over 10%. Disruption of the orbital septum, orbicularis oculi, levators, or canthal system usually creates some lid contour irregularity. Some of these may require secondary reconstructive efforts.

Editorial Comment

The keys to achieving superior results with complex facial fractures are as follows:

1. Adequately diagnose, prepare, and then execute approaches to those fractures with proper instrumentation available.

2. Achieve a high level of proficiency with plates and screws and the techniques involved in fixation of the bones.

3. Adequately reconstruct the volume and architecture of the orbit accurately after significant fractures.

4. Understand occlusion and common malocclusions.

Review Questions

1. Early complications from frontal sinus fractures include all of the following, except

   a. Contour deformity

   b. Frontal lobe injury

   c. Cerebrospinal fluid leak

   d. **Mucopyocele**

2. Which of the following requires immediate treatment to avoid complications?

   a. Enophthalmos

   b. Ectropion

c. Entropion

d. **Trapdoor entrapment**

3. All the following are viable immobilization techniques for mobile maxillary fractures, except

a. **Maxillomandibular fixation**

b. Skeletal suspension wires

c. Internal fixation with titanium devices

d. Wire osteosynthesis

Fractures of the Orbit

Tonya Stefko

Introduction

Because the orbit is made up in part by two of the horizontal beams of facial structure and two of the vertical buttresses, orbital fractures are common, and proper repair of such fractures is critical to restoring normal facial appearance and function. Complicating evaluation and treatment are the vital and complex structures contained within the eye and optic nerve, extraocular muscles, and the lacrimal secretory and excretory systems. Understanding the classes of fractures involving the orbit is critical to their evaluation and prediction of other possible associated injuries. These categories will suggest a systematic approach to their treatment and repair.

The bony orbit is shaped similar to a pyramid with its apex directed posteromedially (Figs. 187.1 and 187.2). The medial walls are approximately parallel, and the lateral walls diverge at approximately 90 degrees. The normal volume of an adult orbit is 30 mL. The periosteum of the orbit is also known as the periorbita, and it surrounds the orbital contents in a continuous sheet except over the various foramina and fissures.

Most fractures involving the bones of the orbit occur because of blunt trauma to the face. Penetrating trauma, such as that caused by a projectile, is less common. Consideration of the probable velocity (momentum and direction) of the inciting object will often give clues to the likely location and severity of the bony involvement. For example, true blowout fractures are frequently the result of low-velocity trauma to the orbit, such as a thrown baseball, whereas a motor vehicle collision or being struck by a baseball bat in the face (high-velocity trauma) may cause a displaced zygomaticofacial complex (ZMC) or Le Fort–type

fracture.

Key Operative Learning Points

- Most diplopia will resolve without surgical intervention; this is usually not an initial sole indication for surgery.[1]
- Clues to muscle entrapment include the age of the patient, small fracture size, severe pain on attempted duction, severe limitation of upgaze, and nausea and vomiting (Figs. 187.3 to 187.5). Traction on the inferior rectus is thought to activate the oculocardiac reflex (bradycardia, hypotension, and vomiting) and could theoretically be fatal. In addition, the muscle is compressed and quickly becomes ischemic, thereby rapidly leading to irreversible scarring and permanent diplopia.[2]

Preoperative Period

Most orbital fracture repairs can be delayed for 7 to 14 days, so consideration of the status of the rest of the patient must be undertaken immediately. The usual trauma evaluation, including establishment of the airway, breathing, and circulation, is performed first. A secondary survey will then uncover less urgent issues, including facial fractures. Delayed repair allows stabilization of the patient, full evaluation of the impact of the injury, and attention to more urgent issues (e.g., decompression craniectomy). However, in some instances, fracture repair will be undertaken more urgently because of intercurrent issues, such as an intractable cerebrospinal fluid leak.

Evaluation of the severity of the fracture must include attention to the orbital contents. A basic eye examination can be performed even on a comatose patient by using a penlight and pair of toothed forceps. In most major trauma centers, an Ophthalmologist is available on call to evaluate the eye and periocular area, which is the safest way to ensure that no occult injury is overlooked. In other emergency rooms, the Otolaryngologist will need to at least document vision, and if possible, pupillary reactions, eye movements, and appearance of the eye.

FIG. 187.3 Patient 1: 16-year-old with a blowout fracture of the left orbit.

FIG. 187.4 Patient 1: attempted upgaze.

FIG. 187.5 Coronal scan of a trapdoor fracture of the left eye; note the "hanging drop" sign and small, nondisplaced fracture.

History

- Mechanism of injury
- Previous eye/orbital surgery
- Other injuries
- Other illnesses/medications (Only in the most urgent circumstances, e.g., an entrapped extraocular muscle, should surgery be undertaken with the patient on anticoagulation.)

Physical Examination

- Vital signs
- Examination of the eye by an Ophthalmologist is strongly recommended when an orbital fracture is suspected.
- Vision (in each eye separately)
- Ductions movements of eyes in all directions volitionally, or forced, by

the examiner with toothed forceps

- Enophthalmos/exophthalmos (measure with a Hertel or other exophthalmometer if possible)
- Existing lacerations, lids malposition, or scars
- Other associated soft tissue injuries

Imaging

- Fine cut orbit or maxillofacial computed tomography (CT) without contrast with coronal plane reconstruction
- Type of fracture
  - Zygomatic maxillary compound fractures (ZMC)
  - Le Fort 2/3
  - Frontal
  - Naso-orbito-ethmoidal (NOE)
  - Blowout

Force applied to the lower midface region produces variations of the classic fracture patterns described by Le Fort. Rarely do Le Fort fractures occur precisely as he described or symmetrically; however, these divisions help guide repair and provide an orderly and predictable approach. Le Fort II fractures, discussed in more detail in Chapter 122, traverse the maxillary sinus, orbital floor, medial wall, and nasal bones. Le Fort III fractures, also called craniofacial dysjunction, involve the zygomatic bones in the lateral orbital walls, the floor and medial orbital walls, and the nasal bones. Although an air-fluid level noted on CT in one maxillary sinus suggests a sinus or orbital fracture, when this sign is present in both maxillary sinuses, one must assume the presence of a Le Fort II or III fracture until careful examination has proved otherwise. All Le Fort fractures also cause some measure of malocclusion.

Application of significant force to the upper midface area can lead to telescoping nasal fractures and NOE fractures. The hallmark of these injuries is traumatic telecanthus, with the normal intercanthal distance being about 35 mm or less. Fracture lines generally travel posteriorly

through the medial orbital walls. The most urgent issues with these fractures involve possible leakage of cerebrospinal fluid with associated meningitis and trauma to the brain and the possibility of involvement of the optic canals posteriorly. Careful consideration must be given to the urgent need for decompression. Repairing these fractures requires re-establishing the normal anatomic relationships of the medial canthi. These injuries are discussed further in Chapter 122.
